24 ABSTRACT

25 Approaches to assessing endocrine disruptors (EDs) differ across the globe, with some regulatory environments using a hazard-based approach, while others employ risk-based 26 analyses. In session four of the Society of Environmental Toxicology and Chemistry (SETAC) 27 28 North America Focused Topic Meeting: Endocrine Disruption Chemical Testing: Risk Assessment Approaches and Implications (February 4 - 6, 2014), various aspects related to the 29 hazard and/or risk assessment of EDs were explored. The presentations in the session included 30 31 an overview of the regulatory environments for assessing and managing endocrine disruptors, and scenarios whereby a hazard-based approach might be most appropriate were discussed. 32 Three case studies for ED assessment, one for an industrial chemical, one for a pharmaceutical, 33 34 and one for a pesticide, were presented. The topics of non-monotonic dose response relationships as well as potency and threshold effects were also presented in this session, since these concepts 35 are important for determining whether a risk or hazard based approach to ED regulation is most 36 appropriate. Session four concluded with an open discussion concerning the issue of hazard and 37 risk as a basis for regulating EDCs. An outcome of session four was the drafting of an outreach 38 statement that summarizes the overarching themes of this session. 39

42

43 **INTRODUCTION**

44 In session four of the Society of Environmental Toxicology and Chemistry (SETAC) North America Focused Topic Meeting: Endocrine Disruption (February 4 - 6, 2014), various 45 aspects related to the hazard and/or risk assessment of endocrine disruptor chemicals (EDCs) 46 were explored. Peter Matthiessen presented an overview on the divergent approaches to 47 48 managing EDCs in the United States and European Union. Holly Zahner and Jane Staveley 49 presented background information and current regulatory initiatives for assessing EDCs in the United States, Japan, and Canada. Three case studies of endocrine evaluations were presented 50 51 using 1) industrial chemicals, 2) a pesticide chemical, and 3) a pharmaceutical. In the industrial chemical case study, Katherine Coady discussed incorporating potency, critical effects, exposure, 52 and risk assessment in the endocrine evaluation of the chemical intermediates, nonyl and 53 54 octylphenol. The next presentation focused on a pharmaceutical example; Daniel Caldwell pointed to the value of effects-based measurements for EDCs rather than regulating on a 55 chemical specific basis. In the case study for a pesticide compound, Steve Levine presented 56 several lines of evidence that collectively indicate that glyphosate does not interact with the 57 estrogen, androgen or steroidogenesis pathways, nor does it interact with the hypothalamus-58 pituitary-gonadal or hypothalamus-pituitary-thyroidal axes. Earl Gray presented findings on the 59 occurrence of threshold, linear no threshold, and non-monotonic dose-responses from a survey of 60 the toxicology literature, and overall concluded that while there were several instances of linear 61 no threshold and non-monotonic dose responses, these occurrences did not influence the 62 outcome of a risk assessment. In the final presentation of this session, Chris Borgert emphasized 63 that the fundamental principles governing hormonal effects dictate the existence of thresholds for 64 65 hormonal activity and also define the potential for exogenous chemicals to interfere with normal

66	endocrine functioning. Session four concluded with an open discussion concerning the issue of
67	hazard and risk as a basis for regulating EDCs. An outcome of session four was the drafting of
68	an outreach statement that summarizes the overarching themes of this session.
69	
70	SESSION PRESENTATION SUMMARIES
71	Perspectives on Hazard- And Risk-Based Approaches to the Evaluation of Endocrine
72	Disrupting Chemicals by: Peter Matthiessen
73	There is a divergence between how endocrine disrupting chemicals (EDCs) are to be
74	regulated in the United States (US) as compared with the European Union (EU). Although the
75	phenomenon of endocrine disruption was first recognized as such in the 1980s, it is only now
76	that major jurisdictions such as the USA and EU are deciding how EDCs should be assessed and
77	managed. A major reason for the delay has been the need to develop and internationally
78	standardize a suite of new toxicity screens and tests that evaluate for potential adverse effects
79	through an endocrine mechanism, a huge task which has made great progress, but is still under
80	way at the Organization for Economic Cooperation and Development (OECD).
81	In the US, the Endocrine Disruptor Screening Program (EDSP) has begun deploying a

Tier 1 battery of screens on chemicals to which humans and wildlife are widely exposed, and the intention is to conduct definitive testing at Tier 2 with those chemicals which, following a weight of evidence analysis of the Tier 1 data set (or equivalent data) along with other scientifically relevant information, show potential endocrine activity. Risk assessment and management will then proceed along traditional lines. In contrast, the EU has put legislation in place which will probably lead to most EDCs being prevented from entering the market, or being removed from

NOT PEER-REVIEWED

Peer Preprints

88	it, irrespective of whether humans or wildlife are exposed to toxicologically significant doses or
89	concentrations. In other words, the EU proposes to regulate EDCs on the basis of their hazards
90	and not their predicted risks. This process has not yet begun in the EU, however, because a
91	regulatory definition of an EDC has still to be agreed upon.
92	The reasons for this divergence of approach are complex, but can be boiled down to a
93	disagreement about the implications of various unique properties of EDCs for the safety of risk
94	predictions. In summary, these properties include the following:
95	1. The ability of some EDCs to cause delayed but permanent damage to organisms after
96	only short-term exposures during critical windows of development.
97	2. The concern that some EDCs are associated with non-monotonic dose-response
98	relationships (NMDR), potentially making predictions of low-dose effects more difficult.
99	3. The alleged absence of toxic thresholds for some EDCs, which implies that there may be
100	no safe levels of exposure.
101	In the US, and in many other jurisdictions, such as Japan, it is felt that these are not
102	insuperable barriers to safe risk assessment. For example, some of the new toxicity tests are very
103	sensitive to delayed toxic effects, and would also detect NMDRs (although the latter seem to be a
104	phenomenon which rarely occurs with apical endpoints in vivo). The claimed absence of toxic
105	thresholds also seems to be rare, if it occurs at all, and modern understanding of endocrine
106	systems implies that they could not work without thresholds for agonistic action. Nevertheless,
107	genuine scientific doubts about these issues have induced the EU to proceed with more caution
108	than most other jurisdictions, with attendant implications for the continuing use, or appearance
109	on the market, of many beneficial chemicals.

NOT PEER-REVIEWED

Peer Preprints

A SETAC Pellston workshopTM was proposed which would address these scientific questions through the evaluation of some comprehensive case studies. The of the workshop would be to identify scenarios in which risk assessment of EDCs is, and is not, a safe way to proceed. The intention was for the workshop to develop a guidance document which can be used by chemical companies and regulators when evaluating chemicals. In the meantime this workshop has been held and the output is currently under review for publication by IEAM³.

116 Approaches to the Evaluation of Endocrine Disrupting Compounds at Several US and

117 Foreign Government Agencies by: Holly M. Zahner and Jane Staveley

Many government agencies around the world are currently developing or implementing 118 plans to evaluate the potential environmental impacts of endocrine disrupting compounds 119 120 (EDCs), such as pesticides and pharmaceuticals. The approaches used to screen and test chemicals for their potential to interact with the endocrine system is dependent upon the legal 121 authority of the government agency, which is why a fully harmonized approach both within the 122 123 United States (US) and with other entities outside the US is not possible at this time. However, there is some overlap in the approaches used by some government agencies. The legal authority 124 and approaches to screen and test for EDCs are described and compared for four government 125 agencies (two in the US, one in Canada, and one in Japan). 126

The first and most well-known regulatory framework for screening and testing chemicals
for their potential to disrupt the endocrine system is that of the US Environmental Protection
Agency's (USEPA) Endocrine Disruptor Screening Program (EDSP; <u>http://www.epa.gov/endo/</u>).
In 1996, the Federal Food Drug and Cosmetic Act (FFDCA) and Federal Insecticide Fungicide
and Rodenticide Act (FIFRA) were amended with the Food Quality Protection Act (FQPA),

132 which mandated USEPA "to determine whether certain substances may have an effect in humans that is similar to an effect produced by a naturally occurring estrogen, or such other effects as the 133 Administrator may designate." In addition, it required all pesticides (including both the active 134 and inert ingredients) to be screened for endocrine disrupting activity. The EDSP was developed 135 in response to this statutory mandate. Amendments to the Safe Drinking Water Act (SDWA) in 136 1996 also provided USEPA with authority to provide for testing of substances in drinking water 137 sources, including EDCs (http://water.epa.gov/lawsregs/rulesregs/sdwa/index.cfm). The scope 138 of authority given to USEPA under FQPA and SDWA covers approximately 10,000 chemicals. 139 The first list of chemicals prioritized for testing under USEPA's EDSP (known as List 1) 140 consisted of 67 pesticide active and inert ingredients, and the second list (known as List 2) 141 consisted of 109 pesticide active ingredients and chemicals found in drinking water. The EDSP 142 uses a two-tier screening and testing process. Tier 1 tests are used to identify chemicals that may 143 have the potential to interact with the endocrine system, while Tier 2 tests are used to determine 144 dose-related effects information on endpoints that are useful for risk assessments and can also be 145 responsive and sensitive to endocrine modes of action. 146

There are other laws in the US that require the USEPA to evaluate the potential impacts 147 of chemicals in the environment but do not have a specific focus on EDCs, including the Toxic 148 Substances Control Act (TSCA) and the Clean Water Act (CWA). Under TSCA, USEPA has 149 the authority to regulate all chemicals in commerce, with the exception of pesticides, foods, 150 drugs and cosmetics, which are regulated under other authorities. There is currently an effort 151 152 underway to modernize this statute, which was originally passed in 1976. The CWA focuses on surface water quality from both a human and ecological perspective by regulating discharges of 153 pollutants to surface waters and setting standards for surface water quality. Consideration has 154

155 been given in recent years to developing aquatic life criteria for emerging contaminants detected in surface waters (e.g., pharmaceuticals and personal care products). USEPA published a white 156 paper discussing the challenges of, and recommendations for, developing criteria for 157 contaminants of emerging concern, such as EDCs. USEPA used ethinyl estradiol (EE2), a 158 human pharmaceutical and potent EDC, in this paper as a model compound to demonstrate a 159 potential approach to the development of criteria for an emerging contaminant (USEPA 2008). 160 Other government agencies are also developing frameworks to address the environmental 161 risk of EDCs based on their regulatory authorities, including the US Food and Drug 162 Administration (USFDA), federal agencies in Canada (Environment Canada, Health Canada, and 163 the Pest Management Regulatory Agency), and Japan's Ministry of the Environment. The 164 USFDA's Center for Drug Evaluation and Research (CDER) and Center for Veterinary Medicine 165 (CVM) assess the potential for environmental impacts from the use of EDCs (e.g., steroid 166 167 hormones) in human and veterinary pharmaceuticals under the National Environmental Policy Act (NEPA) of 1969. NEPA mandates that all federal agencies in the US must consider the 168 potential environmental impacts of their actions. One type of agency action at USFDA is the 169 approval of a new or supplemental drug application. USFDA does not have a screening program 170 similar to EDSP to determine whether a drug may potentially disrupt the endocrine system; 171 however, it is often clear from the compound class (e.g., steroid hormones), structure, proposed 172 use, and/or other available data (e.g., mammalian toxicity data) that it may be an EDC. To 173 address the potential environmental impacts of EDCs, USFDA CVM is requiring that applicants 174 submit an environmental assessment (EA) as part of the application for approval of a new animal 175 drug product when the product contains a steroid hormone(s) and is to be used in food-producing 176 animals. In the EA, risks are to be evaluated from the use of the drug by comparing predicted 177

NOT PEER-REVIEWED

Peer Preprints

178 environmental exposure concentrations to predicted effect levels. If the EA adequately

- demonstrates that significant environmental impacts are not expected from the use of the
- 180 proposed drug product, then USFDA will prepare a regulatory document known as a finding of
- 181 no significant impact (FONSI) that is needed for approval of the drug application. In addition,
- 182 USFDA CDER has recently published a Draft Guidance for Industry for comment titled

183 "Environmental Assessment: Questions and Answers Regarding Drugs with Estrogenic,

184 Androgenic, or Thyroid Activity Guidance for Industry"

185 (<u>http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/</u>

186 <u>UCM444658.pdf</u>; published on April 29, 2015). This guidance addresses specific considerations

187 for human drugs that have potential estrogenic, androgenic, or thyroid hormone pathway activity

188 (E, A, or T activity) in environmental organisms.

In Canada, there are two acts that govern the evaluation of environmental effects for 189 chemical substances: the Canadian Environmental Protection Act (CEPA) and the Pest Control 190 Products Act (PCPA). CEPA provides a definition for a "hormone disrupting substance" 191 (Section 43) and states that "the Ministers shall conduct research or studies relating to hormone 192 disrupting substances..." (Section 44.4), but neither of these acts has specific testing 193 requirements or guidance on how to address the environmental impacts of hormone disrupting 194 substances. These requirements will likely be described in the regulations when they are written. 195 However, in the meantime, some attempt is typically made by regulators to consider potential 196 hormone disrupting effects of pesticides and pharmaceuticals and the evaluation is generally 197 based upon 1) identifying structural alerts or analogs to compounds known to exert endocrine 198 effects, 2) evaluating submitted data for mammals, birds and fish for indications of potential 199 200 endocrine-related effects, and 3) modeling potential interactions with receptors of interest. This

approach is similar to that used by the USFDA. In 2012, the Office of the Auditor General of 201 Canada received a petition from Ecojustice and the Canadian Environmental Law Association 202 requesting information about federal research activities on the effects of hormone disrupting 203 compounds and, more specifically, how Environment Canada and Health Canada intend to use 204 the results of this research in risk assessment and management of hormone disrupting substances. 205 A response was prepared jointly by Environment Canada and Health Canada, which contains 206 additional information on the Canadian government's activities with EDCs, and can be viewed 207 at: http://www.oag-bvg.gc.ca/internet/English/pet 340 e 37607.html. 208 209 In Japan, the Ministry of the Environment has developed the EXTEND2010 (EXtended

Tasks on Endocrine Disruption) program to assess the environmental risk of EDCs. This

211 program promotes research, development of test methods, monitoring of environmental

concentrations, effects assessment of selected chemicals (to include testing if necessary, in a

tiered process), and risk assessment/management. The EXTEND2010 framework focuses on

identifying actions on the endocrine system and characterizing the adverse effects to organisms.

215 "Chemicals that can be subjected to tests for endocrine disrupting effects" are selected based on

results from national monitoring programs and a reliability evaluation of existing data obtained

from the literature. Similar to EPA's EDSP, the EXTEND2010 framework

(http://www.env.go.jp/en/chemi/ed.html) has two tiers for assessing the effects of EDCs. Tier 1 consists of *in vitro* assays (reporter gene assays) and short-term *in vivo* assays using established test methods (e.g., fish short-term reproduction test, OECD guideline 229). Tier 1 considers all existing knowledge from the literature and test results to determine whether the compound may affect the endocrine system and whether additional analysis is required under Tier 2. Under Tier

NOT PEER-REVIEWED

Peer Preprints

224

following OECD guidelines 230 and 231. Finally, an ecological risk assessment is conducted 225 based on all of the available information in the literature and obtained from test results. 226 227 Octylphenol and Nonylphenol as Case Studies for Determining the Relevance of the 228 Endocrine Mode of Action in Environmental Assessments by: Katherine Coady 229 Nonylphenol (NP) and 4-tert-octylphenol (OP) are chemical intermediates that are used 230 in the manufacture of nonionic surfactants, phenolic resins, lacquers, antioxidants, and 231 lubricating oil additives (Van Miller and Staples, 2005; Soares et al., 2008.) Most NP (65%) and 232 a smaller fraction of OP are used to make the nonionic surfactants, nonvlphenol ethoxylate 233 (NPE) and octylphenol ethoxylate (OPE), respectively (Van Miller and Staples, 2005; Talmage, 234 1994; Soares et al., 2008). NPEs and OPEs are used in a wide range of products as emulsifiers, 235 stabilizers, wetting agents, dispersants, and detergents (Talmage, 1994; Staples et al., 2004; 236 Soares et al., 2008). NP and OP reach the aquatic environment primarily as degradation 237 intermediates of NPE and OPE through wastewater treatment processes (Klecka et al, 2007, 238 Melcer et al, 2007). NP and OP are slower to degrade and more toxic than their ethoxylates, and 239 both NP and OP show a weak binding affinity for the nuclear estrogen receptor (Talmage, 1994; 240 Servos, 1999; Environment Canada and Health Canada, 2001; Staples et al., 2004; Coady et al., 241 2010; Van Miller and Staples, 2005; Recchia et al., 2004; Olsen et al., 2005; Preuss et al., 2006; 242 243 Van den Belt et al., 2004; USEPA, 2009). The estrogenic activity of NP and OP varies and is 244 generally in the range of 1,000 - 1,000,000 fold less potent than the endogenous estrogen, 17β-

characterize the endocrine disrupting effects of the compound of interest, including tests

estradiol (E2) (Coady et al., 2010; Van Miller and Staples, 2005; Wenzel et al., 2001).

246 While NP and OP have weak estrogenic activity, the adverse apical effects observed in fish exposed to NP and OP are not clearly endocrine mediated. In mixture studies with other 247 estrogenically active compounds and NP and OP, the phenomenon of decreased fish 248 reproduction due to OP exposure alone was clearly not solely attributed to estrogen-like activity 249 (Brian et al., 2007). This mixture study concluded that OP "... exerts its effects on reproduction 250 via more than one mechanism. The response pattern could be explained by a general toxic 251 response..." (Brian et al., 2007). Furthermore, investigations using gene array technologies to 252 specifically compare NP and E2 gene transcription profiles have established that NP has 253 additional modes of action that are independent of the estrogen receptor (Larkin et al., 2002; 254 Ruggeri et al., 2008; Watanabe et al., 2004). Molecular evidence in both mammalian and fish 255 models have demonstrated that OP and NP influence a greater suite of genes than estrogens. For 256 example, 425 genes were differentially expressed in liver tissue from zebrafish exposed to 10^{-7} M 257 NP, while 153 genes were differentially expressed in liver tissue from zebrafish exposed to 10⁻ 258 ^{7}M E2. Of the 30 most differentiated genes affected by NP compared to controls, only 1/3 of 259 these genes were also altered among E2-exposed fish, and then not all in the same direction of 260 change (Ruggeri et al., 2008). In mice, NP activated more genes than E2 in liver tissue, and the 261 activated genes in the livers of NP-exposed mice were distinct from estrogen-responsive genes 262 (Watanabe et al., 2004). These molecular studies of gene activation illustrate that NP and OP 263 have multiple modes of action, of which weak estrogenic activity is one. 264

In chronic fish studies, NP and OP affect reproductive endpoints, such as sex ratio and spawning activity, at similar concentrations that affect growth and survival. Effects on growth and survival, as pointed out by the OECD guidance document on the assessment of chemicals for endocrine disruption, do not necessarily lead to a conclusion of endocrine disruption in fish

(OECD, 2011). Thus, the endocrine activities of NP and OP via binding to the estrogen receptor 269 are not clearly the Critical effect¹ responsible for observed adverse effects in fish. In fact, the 270 European Commission risk assessment on NP states: "Concentrations of nonvlphenol at which 271 oestrogenic effects are observed appear to be higher than those producing other effects" 272 (European Commission, 2002). As an example, NOEC values in fish for OP based on 273 reproduction range from 12 to 1,000 μ g/L, while NOEC values based on growth range from 12 274 to 900 µg/L, and NOEC values based on survival range from 10 to 300 µg/L. Also, the most 275 sensitive apical endpoints among fish toxicity studies with both NP and OP are based on 276 277 decreased growth and survival (particularly in early life stage fishes), and not on endpoints that would be conceivably linked to the weak estrogenic activity of NP (Van Miller and Staples, 278 2005). Collectively, the NOEC levels for OP and NP for reproduction, growth and survival 279 endpoints in fish all occur at very similar levels (Staples et al., 2004; Van Miller and Staples, 280 2005), indicating that the known weak estrogenic activity of NP and OP is not the sole, nor 281 necessarily, the most sensitive, mode of action associated with observed adverse effects. 282 This signature of adverse effects on survival, growth, and reproduction occurring at 283 similar concentrations is not the case when examining the toxic effects on fish exposed to potent 284

estrogens. Estrogens affect sexual development and reproduction at concentrations that are far
lower than the concentrations that cause acute lethality via narcosis, or baseline toxicity. For
example, the 96-hr LC50 for zebrafish exposed to the synthetic estrogen, ethinylestradiol (EE2)
was determined to be 1700 µg/L, and the NOEC for fertilization success (a reproductive

endpoint) was 0.0003 μ g/L EE2 in a lifecycle study with the zebrafish (Wenzel et al., 2001).

¹ Defined by EPA-IRIS as the first adverse effect, or its known precursor, that occurs to the most sensitive species as the dose rate of an agent increases.

The ratio of these two endpoints is 5.73×10^6 for EE2. In the same study design, the 96-hour LC50 for zebrafish exposed to OP was determined to be $370 \mu g/L$, while the NOEC based on fertilization success was $12 \mu g/L$ OP (Wenzel et al., 2001). The ratio of these two endpoints for OP is 31, and similar acute to chronic ratios can be calculated for NP. The relatively small acute to chronic ratios for NP and OP are far different than the ratio of over a million that was evident for EE2. These smaller acute to chronic ratios for NP and OP are more indicative of a narcosis mode of action rather than a very specific and potent estrogen receptor binding mode of action.

Concentrations of NP and OP detected in the environment are below levels of concern for 297 environmental organisms. As part of the Water Framework Directive, surface water 298 concentrations of OP, NP, and numerous compounds have been measured in various European 299 waterways between 2007 and 2009 (DG Environment, 2009a; DG Environment, 2009b). From 300 this investigation, the median and upper 90th percentile concentrations for OP in surface 301 freshwaters in Europe was reported to be 0.05 and 0.25 µg/L, respectively, and the median and 302 maximum concentrations of NP in European surface waters were reported to be 0.03 and 0.460 303 µg/L, respectively (DG Environment, 2009a; DG Environment, 2009b). In North America, a 304 comprehensive review of the exposure data for NP and OP in surface waters revealed that the 305 average and upper 90th percentile concentrations for NP were 1.71 and 2.5 µg/L, respectively 306 (Klecka et al., 2007). OP concentrations were considerably lower in North America, with 307 average concentrations of 0.46 µg/L, and the complete range of reported concentrations of OP 308 spanning from 0.0003 to 1.10 µg/L (Klecka et al., 2007). In this review, it was noted that the 309 highest concentrations of OP and NP detected in surface waters were associated with effluent 310 dominated streams (Klecka et al., 2007). These NP and OP concentrations in both the U.S. and 311

- 312 European waters are generally well below NOEC and LOEC values from short term,
- reproductive, and life cycle studies with NP and OP in aquatic organisms.

While both NP and OP do show weak estrogenic activity both *in vitro* and *in vivo*, it is 314 evident that they do not possess similar potency nor exert toxicity in the same pattern as natural 315 and synthetic estrogens. A close examination of both molecular data and data from chronic, 316 multigenerational studies with fish indicate that there are multiple modes of action of NP and OP 317 co-occurring within the same dose range. Regardless of the mode of action by which toxic 318 effects occur, concentrations of NP and OP in the environment are, by in large, too low to 319 adversely affect fish populations. These case studies with NP and OP illustrate the need to 320 incorporate the concepts of potency, critical effect, exposure, and risk in decision-making 321 regarding determinations of endocrine disruption and assessments of human health and 322 environmental impacts. 323

324

325 Magnifying Perceived Risk: A Case Study of Hazard and Risk Assessment of a

326 Pharmaceutical Compound, 17α -Ethinylestradiol (EE2) by: Daniel J. Caldwell²

Inaccurate or snapshot field measurements used as 'environmentally-relevant' test concentrations in laboratory studies, biomarker detection (*i.e.*, vitellogenin in male fish) incorrectly reported as an effect, and field experiments using confined exposure (*i.e.*, lake) being inappropriately extrapolated to surface water (river) risk assessment have contributed to the misconception that EE2 exposure is of great consequence to wildlife and humans.

PeerJ Preprints | https://doi.org/10.7287/peerj.preprints.2580v1 | CC0 Open Access | rec: 4 Nov 2016, publ:

² This talk was scheduled for the Society of Environmental Toxicology and Chemistry (SETAC) North America Focused Topic Meeting: Endocrine Disruption Chemical Testing: Risk Assessment Approaches and Implications, however was not able to be presented at that time. It is included here for completeness.

332 Hazard assessments using *in vitro* studies typically depict EE2 as a potent EDC. Using *in* vivo data, safe exposure levels for EE2 for aquatic species and humans were developed and a 333 sufficient Margin of Safety demonstrated for aquatic species exposed in surface waters (Caldwell 334 et al. 2012), and for humans potentially exposed via drinking water (Caldwell et al. 2010). 335 However, continued attention is directed to this compound, including imposition of specific 336 monitoring requirements in Europe. Monitoring or regulating individual substances ignores other 337 estrogenic substances and will not eliminate responses in wildlife. A better approach is to 338 establish a level of estrogenic activity that is without population impact and monitor waters for 339 that endpoint. In this way, we identify 'hot spots' and can correct them, as the ultimate intent of 340 the EU Water Framework Directive is to bring river basins to "good" ecological status. 341

There is evidence that EDCs with similar modes of action (MoA) can act together in an 342 additive manner to produce effects. While some note that knowledge of MoA is necessary to be 343 able to predict mixture toxicity, others indicate the more appropriate way is to base the prediction 344 on common adverse outcomes (EFSA 2013; Report of the Endocrine Disrupters Expert Advisory 345 Group 2013). There is a general agreement that the estimation of an experimental threshold in 346 the case of mixed exposures is even more challenging and that information in relation to the 347 MoAs (e.g. common or different MoAs of the ingredients of a mixture) is important for scientific 348 349 understanding and for performing the appropriate risk assessment. In addition, there is not an adequate amount of scientific research to disregard other possibilities for combination effects of 350 mixed exposures (e.g. synergistic, antagonistic action). For example, toxicokinetic and 351 352 toxicodynamic interactions between chemicals may cause deviations on the shape of the dose response curves of individual chemicals (e.g., inhibition of metabolism if substances are sharing 353 the same metabolic pathway). Assessment of combination effects of chemicals in general, not 354

355	just EDCs, is already the subject of an initiative in the EU (Commission Communication to the
356	Council on the Combination Effects of Chemicals, 2012).

Proposals to implement compound specific environmental quality standards, such as 0.035 ng/L for EE2, will cost European countries billions of Euros to treat wastewater to remove estrogens. For a UK town of around 250,000 people, such a system would cost \in 8 million to install and \in 800,000 a year to operate - for the 1,400 facilities that would need upgrading in England and Wales alone, this would amount to more than \in 30 billion in total (Owen and Jobling, 2012). These costs will be borne by the public through higher water prices.

EE2, the estrogen ingredient in oral contraceptives, was estimated to be 1% of total estrogen load excreted in the Dutch population in a paper that reviewed the literature regarding various sources of estrogens in surface, source and drinking water and estimates that the risk of exposure to synthetic estrogens in drinking water on human health is negligible (Wise et al., 2011).

368 Monitoring data suggest that exposures of fish to EDC in surface water are largely due to chemicals other than EE2 and that observed effects are likely due to the total estrogenic load, of 369 which EE2 is a minor contributor. A comprehensive assessment of EE2 exposure in Europe and 370 371 the United States, based on prescribed amounts of EE2, further supports this statement (Hannah et al. 2009). This study by Hannah et al. used measured concentrations (MECs) taken from the 372 literature and predicted environmental concentrations (PECs) using the GREAT-ER and PhATE 373 models to develop expected exposure concentrations for surface waters of the US and EU. Key 374 findings were: 375

376	• 80% of all EE2 measurements globally show environmental concentrations below the
377	detection limit of 0.1-1 ng/L and are consistent with modeled PECs.
378	• The highest MECs were not consistent with PECs, attributed to poor sample clean up or
379	to inappropriate analytical methods.
380	The authors conclude that the 90th-percentile low-flow PECs of EE2 in surface water,
381	conservative estimates of long-term exposure that should be used for risk assessment, are
382	approximately 0.2 and 0.3 ng/L for the US and EU, respectively.
383	Thus, unless total estrogenic activity of surface water is addressed holistically we may
505	
384	miss important contributors to the total estrogenic exposure by focusing on individual EDCs
385	rather than the mixture.
386	Estrogen-active substances are the ideal test-case for this approach for several
386 387	Estrogen-active substances are the ideal test-case for this approach for several reasons. First, they act by a common mechanism of action that has been shown to demonstrate

Second, there are multiple categories of estrogen-active substances, naturally produced estrogens, naturally produced phytoestrogens, synthetic estrogens (<i>e.g.</i> , EE2), and industrial chemicals (<i>e.g.</i> , phthalates, Bishenol-A, octylphenol, nonylphenol) that have demonstrated estrogenic activity. Comparing the relative differences in occurrence and concentration with the relative differences in estrogenic effect among these categories facilitates a science-based understanding

396	We reviewed measured concentrations of selected phthalates, bisphenol-A, octylphenol,
397	nonylphenol, estradiol (E2), estrone (E1), estriol (E3), ethinyl estradiol (EE2), atrazine, and
398	genistein in North America and Europe and compared them to aquatic predicted no effect
399	concentrations (PNECs) (Caldwell et al 2009). Robust PNECs for the estrogens were derived by
400	Caldwell et al. 2012. DEHP, BBP, and DBP PNECs were drawn from the Southern California
401	Coastal Water Research Project Technical Report (Anderson et al., 2012), derived using the
402	Ecosar chronic value / 100 or fish chronic NOEC / 100. PNECs for NP, OP, and BPA were
403	bridged to E2 using VTG induction data presented in Brain et al. 2005, divided by 100. Genistein
404	was bridged to E2 using the E-screen value of Falconer et al. 2006, divided by 100. A
405	cumulative risk quotient (RQ) was calculated from the exposure concentrations and derived
406	PNECs, with and without EE2 in the mixture. The RQ including EE2 was 124; without EE2 iT
407	was 121.

Feminization in fish populations has been observed in a number of field surveys, but a 408 detrimental impact on those populations has not been established nor been attributed to EE2 409 specifically. Based on the above RQ, it is unlikely that EE2 is a prominent contributor of the 410 observed effects. Further, municipal wastewater effluents contain a variety of estrogenic 411 compounds (including a significant component of female human origin) and EE2 is unlikely to 412 play the prominent role in any estrogenic effects. The Dutch Ministry of the Environment 413 concluded in 2010 that "in comparison with ethinyl estradiol, estradiol (and its transformation 414 product estrone) is by far the greatest contributor to estrogenic activity in the aquatic 415 environment." 416

417 Exposure to a mixture of EDCs has been predicted to result in additive effects, but this has not been studied using environmentally relevant mixtures of EDCs. Yu et al. 2015 418 systematically investigated the estrogenic effects of 11 EDCs of high environmental concern 419 using the yeast estrogen screen (YES) method. The contribution of individual chemicals to the 420 total endocrine activity of environmentally relevant mixtures was evaluated using the ratio 421 previously determined (Caldwell et al 2009). On an individual basis, bisphenol-A, estrone, 422 estriol, ethinyl estradiol (EE2) and genistein showed estrogenic activity when compared with 423 estradiol, whereas bis(2-ethylhexyl) phthalate, octylphenol, nonylphenol, benzyl butyl phthalate, 424 and dibutyl pthalate showed anti-estrogenic activity. The full mixture of all these chemicals at an 425 environmentally relevant ratio also showed week anti-estrogenic activity. Further, EE2 did not 426 have a prominent contribution to the estrogenic activity of the mixture. The authors conclude 427 that a holistic evaluation of the estrogenic activity is necessary to evaluate the risk of a mixture 428 of endocrine active chemicals (EACs). This approach is also advocated in the EU by Kase and 429 colleagues (Kase et al. 2014), who recently introduced a project proposal for effect-based 430 monitoring approaches for steroidal estrogens under the EU Water Framework Directive. 431

EE2 is a minor contributor to the total estrogenic activity of surface water, yet is the topic of much media coverage, which gives the public an inaccurate and incomplete risk profile. Media emphasis on 'the pill' has misguided regulatory attention to focus on one component of an endocrine active mixture. Unless estrogenic activity of surface water is addressed holistically important contributors to the total estrogenic exposure may be missed by focusing on individual EDCs. Rather than focusing on the detection of low levels of EE2, the effects of which are known at true environmentally-relevant concentrations, efforts should go toward developing a

439	reliable estrogenicity assay to holistically determine the overall exposure that may result from
440	the mixture of EDC's that may be present. The Kase proposal has merit in this regard.
441	

442 Regulatory Safety Studies and Tier 1 Endocrine Screening Assays Provide a Weight of

443 Evidence that Glyphosate is Not an Endocrine Disruptor; Steven L. Levine

Glyphosate (N-(phosphonomethyl)glycine, CAS number 1071-83-6) is a foliar non-444 selective herbicide belonging to the phosphono amino acid class of pesticides. Glyphosate is a 445 specific inhibitor of one of the enzymes of the shikimate pathway, 5-enolpyruvyl-shikimate 3-446 phosphate synthase (EPSPS), which is essential for the biosynthesis of aromatic amino acids and 447 other aromatic compounds in algae and higher plants, bacteria and fungi. Since the shikimate 448 449 pathway is found only in plants, bacteria and fungi, and not in animals, glyphosate generally exhibits low toxicity to higher organisms, including mammals, birds, fish, aquatic invertebrates 450 and terrestrial invertebrates (Giesy et al. 2000). 451

In June 2007, EPA published in the Federal Register a notice announcing the draft list of 452 initial pesticide active ingredients and pesticide inerts to be considered for screening under the 453 454 Endocrine Disruptor Screening Program (EDSP). Chemicals were selected based on exposure by three or four human exposure pathways that included food and drinking water consumption, 455 456 residential use exposure, and occupational exposure [70 FR 56449]. Throughout the selection 457 process, EPA clearly stated that "this list should not be construed as a list of known or likely endocrine disruptors. Nothing in the approach for generating the initial list provides a basis to 458 infer that by simply being on the list these chemical are suspected to interfere with the endocrine 459 460 systems of human or other species, and it would be inappropriate to do so".

The Office of Management and Budget in its "Terms of Clearance" for List 1 compounds 461 stated that, "EPA should promote and encourage test order recipients to submit OSRI in lieu of 462 performing all or some of the Tier I assays, and EPA should accept OSRI as sufficient to satisfy 463 the test orders to the greatest extent possible" (OMB, 2009). Other Scientifically Relevant 464 Information (OSRI) is defined by EPA as "information that informs the determination as to 465 whether the substance may have a similar effect produced by to a substance that interacts with 466 estrogen, androgen and thyroid systems." In other words, information that informs the 467 determination refers to data of a suitable nature and quality that provides the same essential 468 469 predictive information even if different methods and procedures may have been used for obtaining the data. 470

The Tier 1 EDSP screening battery tests whether there is the potential for endocrine 471 modulation through a specific endocrine mechanism(s) and not to assess if there is an adverse 472 473 effect through a non-endocrine mode of action. Tier 2 EDSP testing determines whether a substance may cause endocrine-mediated effects through or involving estrogen, androgen, or 474 thyroid hormone systems, the potential consequences to the organism of the activities observed 475 in Tier 1, and establishing the relationship between dose and potential adverse effects for a 476 quatitative risk assessment. Therefore, results from Tier 1 and Tier 2 endocrine screening and 477 testing must be evaluated with a weight of evidence that includes a careful assessment of 478 potential overt toxicity. Consequently, dose setting for endocrine screening takes on great 479 significance to ensure that the interpretation of results are not confounded by overt toxicity and a 480 481 conclusion of hazard based on an endocrine mechanism is wrongly concluded (Marty et al. 2003). The analog for overt toxicity in *in vitro* assays are impacts to proteins in solution or 482 cytotoxicity to a cell line. Presently, the EDSP test guidelines permits $\leq 20\%$ cytotoxicity before 483

a test concentration is eliminated from the analysis but no correction for cytotoxicity is
considered. There are diagnostic tools for non-cell line *in vitro* assays to detect confounding
effects that impact the stability of the assay environment such as denaturing or altering
conformation receptors. Therefore, safeguards need to be in place to ensure that the assay is
being conducted under proper biochemical conditions and there is proper data interpretation
(Laws et al. 2007).

Prior to receiving Tier 1 test orders, the endocrine-modulating potential of glyphosate 490 was rigorously evaluated in a variety of studies, including in vitro assays and standard in vivo 491 toxicology studies capable of detecting adverse endocrine effects. Glyphosate in vitro assays 492 demonstrate a lack of estrogenic, anti-estrogenic, androgenic and anti-androgenic activity and 493 show no impact on steroidogenesis (Kojima et al. 2003; Petit et al. 1997; Hecker et al. 2011; 494 Forgacs et al, 2012). Consistent with these *in vitro* findings, glyphosate was negative in the Tier 495 496 1 estrogen receptor (ER) and androgen receptor (AR) binding assays, the estrogen receptor transactivational activation assay, aromatase assay and the H295R steroidogenesis assay. Based 497 on what is known about the structure of compounds that bind the ER and AR, it was predicted 498 with a high level of certainty that glyphosate would not be a ligand for the ER and AR nor alter 499 steroidogenesis (Schmieder et al. 2003a, b; Schmieder et al. 2004, Blair et al., 2000; Nishihara et 500 al., 2000; Kojima et al, 2004; Fang et at al., 2003; Devillers et al., 2009; Hecker et al, 2011). 501

502 Glyphosate has low oral absorption and is rapidly eliminated essentially unmetabolized 503 (Williams et al 2000). Therefore, the potential for systemic exposures to endocrine tissues is 504 extremely low for glyphosate. Results from the Tier 1 Hershberger and Uterotrophic assays with 505 glyphosate demonstrated no impact on estrogenic, androgenic, or anti-androgenic endpoints at 506 the limit dose of 1000 mg/kg/day. Consistent with the results of the multigenerational studies

507 (BVL 2013; William et al. 2000), there was no evidence of any estrogenic, anti-estrogenic androgenic, anti-androgenic effects on pubertal development or thyroid function up to the limit 508 dose of 1000 mg/kg/day. In accord with the results of the Tier 1 in vitro assays, there were also 509 no definitive findings in the glyphosate subchronic, chronic, developmental and reproductive 510 toxicity studies conducted for global registrations that would indicate an endocrine-modulating 511 effect (Williams et al. 2000, Williams et al. 2012; Giesy et al. 2000; WHO/FAO 2004). These 512 repeat dose in vivo toxicology studies had extended exposure periods encompassing various 513 stages of endocrine development and did not detect endocrinopathies with histopathological 514 assessment and endocrine organ weight data (Carney et al., 1997; Stevens et al., 1997, 1998; 515 Harvey and Johnson, 2002). 516

Over the past four decades, in-depth reviews on the safety of glyphosate have been 517 conducted by regulatory agencies and scientific institutions worldwide and concluded that there 518 519 is no indication glyphosate has endocrine activity. The U.S. EPA (1998) reviewed the subchronic and chronic mammalian studies for glyphosate and concluded that there was no evidence to 520 suggest that glyphosate produces endocrine-modulating effects. In a comprehensive review of 521 the standard mammalian toxicology studies, Williams et al., (2000) also concluded that 522 glyphosate does not have the potential to produce adverse effects on endocrine systems in 523 humans or other mammals and the Institute of Environment and Health (IEH, 2005) lists 524 glyphosate as a substance with no evidence of potential endocrine-disrupting effects. In a recent 525 review of the standard mammalian and wildlife toxicology studies by ECETOC (2009), it was 526 also concluded that glyphosate is not an endocrine disruptor. 527

In addition to the *in vivo* mammalian assays, the Tier 1 EDSP battery includes two assays
with wildlife species. Results from the amphibian metamorphosis assay demonstrated that

NOT PEER-REVIEWED

PeerJ Preprints

530	glyphosate did not impact thyroid structure or interfere with the function of the amphibian
531	hypothalamic-pituitary-thyroid (HPT) axis up to the highest concentration tested of 90 mg/L.
532	This result is consistent with the findings from the two pubertal assays and from a
533	multigenerational study that evaluated thyroid structure and function (U.S. EPA, 1993). Results
534	from the fish short-term reproduction assay showed no evidence of estrogenic, androgenic or
535	hypothalamic-pituitary-gonadal (HPG) axis effects up to the highest concentration tested of 30
536	mg/L. This result is consistent with results from the other Tier 1 assays and from a fish full life-
537	cycle study which has a NOEC at the highest tested concentration of 26 mg/L based upon no
538	adverse impacts on survival, growth and reproduction (U.S. EPA, 1993).
539	Recently, EPA completed their review of the Tier 1 EDSP screening battery for
540	glyphosate (U.S. EPA, 2015). EPA concluded for glyphosate, based on weight of evidence
541	considerations using OSRI that included guideline-compliant studies, that there was no
542	convincing evidence of potential interaction with the estrogen, androgen or thyroid pathways and
543	that Tier 2 EDSP testing is not recommended.
544	
545	Nonmonotonic dose response curves (NMDRCs) are common after Estrogen or Androgen
546	signaling pathway disruption. Fact or Falderal? by: Leon Earl Gray Jr
547	The shape of the dose response curve in the low dose region has been debated since the
548	late 1940s. The debate originally focused on linear no threshold (LNT) vs threshold responses in
549	the low dose range for cancer and noncancer related effects. Recently, claims have arisen that
550	endocrine disrupters (EDs), which act via high affinity, low capacity nuclear receptors,

551	commonly induce effects displaying NMDRCs at low doses which would be missed in standard
552	screening and multigenerational toxicity studies.
553	This presentation discussed LNT, threshold and NMDRCs responses from case studies of
554	chemicals that disrupt reproductive development and function via the androgen (A) and estrogen
555	(E) signaling pathways and includes in vitro and in vivo multigenerational data. The literature
556	was selected to address several specific questions including:
557	• What is the shape of the dose response curve over a broad range of doses?
558	• What is the sensitivity of <i>in vivo</i> endpoints to low doses of chemicals that disrupt A and E
559	signaling pathways?
560	• If NMDRC responses were detected, were these adverse effects and did they occur in the
561	low dose region of the dose response curve?
562	• What is the potential impact of LNT or NMDRC responses on chemical screening and
563	testing for E and A disruption?
564	The objective of the literature review was to critically evaluate the reproductive and
565	developmental toxicity data from well executed studies in this field to address concerns that
566	current screening and multigenerational reproductive test guidelines are missing adverse low
567	dose effects of EDs because they routinely induce nonmonotonic adverse effects at low dose.
568	The literature was searched on a chemical-by-chemical basis and included chemicals that
569	disrupted key events in the E and A signaling pathways.
570	Endocrine disrupting chemicals acting via the following adverse outcome pathways were
571	reviewed to determine the shape of the dose response in the "Low" Dose Range.
572	Androgen signaling pathway:

NOT PEER-REVIEWED

PeerJ Preprints

573	• AR antagonists
574	Steroid hormone synthesis inhibitors
575	• Pesticides that disrupt the androgen signalling pathway via multiple mechanisms
576	of toxicity
577	Androgen agonists
578	• Selective androgen receptor agonists (SARMs)
579	• AhR agonist – 2,3,7,8 TCDD
580	Estrogen signaling pathway:
581	• Estrogens
582	• Selective estrogen receptor agonists (SERMs)
583	Aromatase inhibitors
584	Some studies considered for review were found using Pub Med, or Google search engines
585	while others were selected from extensive literature reviews published in peer-reviewed
586	publications and regulatory agencies guidance or risk assessment documents.
587	The characteristics for studies included in the review for threshold, linear no threshold, or
588	non-monotonic dose responses were:
589	• Measured multiple endpoints related to disruption of the estrogen or androgen
590	signaling pathways
591	• Preferred-Reproductive, one or multigenerational studies
592	• Preferred – oral administration – diet or gavage

594	• Included a broad range of dosage levels from "low" to "high"
595	 Definitions of "Low Dose" used in the review
596	 ng/kg for chemicals like EE2 and E2, µg/kg for pesticides and
597	toxic substances, or
598	 A dose below the reported NOEL
599	• Preferred – 6 or more doseage levels, but no less than 4 dose levels (three treated
600	groups and a control group)
601	• Primarily rodent studies also includes some porcine and human studies
602	• Published literature and Regulatory Agency and NTP documents (and large
603	supplemental files)
604	• Thousands of papers considered, selected more than 200 in vivo studies
605	\circ >70 of which had 6 or more dose levles
606	\circ >40 for the Androgen signaling pathway
607	\circ >30 for the Estrogen signaling pathway
608	My current conclusions based upon the review of this literature are: 1) EDCs appear to
609	induce some LNT effects in vivo. 2) NMDRCs are biologically plausible and occur frequently in
610	vitro, but these often occur at high concentrations of estrogens or androgens that are not relevant
611	<i>in vivo</i> . 3) It appears that NMRDCs are more common in short- versus long-term exposures,
612	with upstream, mechanistic events versus downstream phenotypic effects. 4) The shape of the
613	dose response curve for an EDC can be affected by several factors, including (but not limited to
614	life stage, route of exposure, target tissue, species differences in E and A pathways or ADME,
615	gut microbiome, and/or concurrent exposure to other chemicals or nonchemical stressors. 5) A
616	few adverse effects of EDs are non-monotonic, but often other effects displaying monotonic

responses occur at lower dosage levels. 6) A number of robust multigenerational studies of
estrogens and antiandrogens have been executed and NMDRCs were uncommon at low dosage
levels. 7) Multigenerational test guidelines can be enhanced on a case-by-case basis to improve
the sensitivity to low dose effects of some EDCs. 8) Additional data need to be examined from
robust, multigenerational studies using a broad range of dosage levels for other pathways.

622

Modernizing Problem Formulation for Risk Assessment: Potency and Mass Action Govern Endocrine Activity; Christopher J. Borgert

In risk assessment, the questions addressed are typically articulated in the problem 625 formulation phase, which includes hazard identification (HI). However, HI procedures were 626 formulated to address questions involving overtly observable adverse effects, e.g., acute toxicity, 627 628 cancer and reproduction, in an era when mechanistic understanding was scant. As a result, HI 629 processes do not address the types of mechanistic data that arise in identifying potential endocrine activity, and unlike basic sciences, have not been modernized to keep pace with 630 631 advancements in biological and pharmacological understanding. The thesis proffered here is that if risk assessments for endocrine active substances are to claim a basis in modern science, the 632 problem formulation phase must be modernized so that HI is based on potency thresholds rather 633 than a presumption of effects based on the mere identification of potential endocrine activity. 634 The need for recognizing potency thresholds in the identification of endocrine hazards is 635 firmly grounded in fundamental principles of endocrine pharmacology, which have been 636 established over decades of experimental and clinical research. Vital signaling functions of the 637 endocrine system require it to continuously discriminate the biological information conveyed by 638

639 potent endogenous hormones from a more concentrated background of structurally similar, endogenous molecules with low hormonal potential. This obligatory ability to discriminate 640 important hormonal signals from background noise is achieved through differential potency and 641 laws of mass action which together determine receptor occupancy and activation state in target 642 cells. Discrimination based on potency can be theoretically-derived and corroborated by 643 experimentally and clinically observable potency thresholds, without which normal physiological 644 functions would be impossible (Borgert et al. 2013; 2012). Although it has been argued that 645 because the endocrine system is basally activated by endogenous hormones, very small amounts 646 647 of low-potency chemicals could alter its function, simple receptor occupancy calculations reveal that in contrast, trillions of molecules would be required to change receptor occupancy by any 648 measurable degree (Borgert et al., 2013). The requirement for a sufficient change in receptor 649 650 occupancy and cellular activation state, both of which depend on potency and mass action, forms the theoretical basis for potency thresholds derived directly from established principles of 651 endocrine pharmacology. 652

Potency thresholds for the induction of endocrine-mediated effects can be estimated 653 empirically from an understanding of the differential potency of endogenous hormones (or their 654 pharmaceutical agonists and antagonists) versus endogenous products of metabolism or essential 655 nutrients that may interact with the hormone's receptor but which lack hormonal function 656 (Borgert et al. 2013). An example of such differential potency is seen with pharmaceutical 657 658 estrogens, which exhibit potencies within one to two orders of magnitude of the primary 659 endogenous estrogen, $17-\beta$ -estradiol, versus both aromatizable and non-aromatizable androgens, which exhibit potencies five to six orders of magnitude less than that of the endogenous estrogen 660 661 (ICCVAM, 2011; Chen et al. 2005; Borgert et al. 2013). While the effects of many androgens

662 on estrogen-sensitive tissues could occur via conversion to estradiol by aromatase, this conversion does not occur to any appreciable extent for non-aromatizable androgens. Although 663 androgens are also uterotrophic, albeit at high doses, the effect is blocked by cyproterone but not 664 by ICI-182,780, and thus appears to be an anabolic effect mediated by uterine androgen rather 665 than by estrogen receptors (Beri et al., 1998; Schmidt et al. 1979; 1976). A second example 666 includes essential fatty acids, which exhibit low-potency estrogenic and anti-estrogenic activity 667 in vitro, but which fail to elicit clinically identifiable estrogenic activity even at high doses 668 (reviewed in Borgert et al. 2013). Several phytoestrogens exhibit potencies intermediate 669 between the endogenous or pharmaceutical estrogens and androgens (ICCVAM, 2011; Ranhotra 670 & Teng, 2005; Kim et al., 2005). The high-dose estrogenic activity of phytoestrogens in sheep 671 (Adams, 1995) versus their lack of apparent clinical effect in women (Cline et al., 2001) suggests 672 673 that these natural compounds could be used to define a potency threshold for estrogenic hazard, similar to their use as a benchmark for activity-exposure profiling in prioritizing chemicals for 674 endocrine screening (Becker et al., 2015). Based on this example, the potency threshold for 675 defining an estrogenic hazard could be set conservatively at four orders of magnitude below the 676 potency of the endogenous hormone 17-β-estradiol. 677

Requirements for using the maximum tolerated dose concept based on body weight
reductions and other measures of overt toxicity have been a primary deterrent to modernizing the
HI step of risk assessment for cancer and general toxicity endpoints, but can be remedied by use
of toxicokinetics in dose setting (Saghir et al., 2012) and articulating hypothesized modes of
action in problem formulation (Borgert et al. 2015). For potentially endocrine-active substances,
arguments favoring a no-threshold assumption based on fluctuating and heightened hormonal
sensitivity during some life stages should be addressed in order to justify modernizing HI to

685 comport with well established principles of endocrine pharmacology that rely on thresholds of potency. While it is clear that sensitivities to hormones vary during different life stages, it is also 686 clear that the mechanisms enabling discrimination of molecular potency fluctuate accordingly, 687 thus preserving the ability of the endocrine system to distinguish the biological signals produced 688 by potent ligands such as hormones and pharmaceuticals from spurious molecular interactions 689 with low-potency substances such as normal products of metabolism and nutrients (reviewed in 690 Borgert et al., 2013). Hence, while it is important to consider exposures to sensitive life stages 691 when assessing risks, identifying endocrine hazards depends on the differential potencies of 692 693 hormones versus molecules that interact with insufficient potency to convey or interrupt endocrine signals regardless of life stage sensitivity. 694

In summary, the fundamental principles governing hormonal effects – affinity, efficacy, 695 potency, and mass action - dictate the existence of thresholds for hormonal activity and also 696 697 define the potential that exogenous chemicals might have to interfere with normal endocrine functioning. These properties are well established and used clinically in endocrine 698 pharmacology, but have not yet been incorporated into HI for risk assessment. Unless the HI step 699 is modernized to incorporate these well-established principles and phenomena, false hazards will 700 be proposed, followed by the needless expenditure of animals, effort and resources to calculate 701 and manage theoretical risks that could never manifest as adversity. Without the modernization 702 step proposed here, hazard identification based on endocrine screening methods would 703 704 conceivably identify substances as potential estrogens that, in fact, present as little estrogenic 705 hazard (*i.e.*, none) as non-aromatizable androgens and essential fatty acids. The derivation of hormone-specific potency thresholds for defining potential endocrine hazards is a theoretically 706 707 sound and empirically supportable method for averting such problems.

708 CONCLUSION

709 Discussion at the Focused Topic Meeting made it clear that an overwhelming majority of attendees believed that risk assessment and management of EDCs can be conducted in a safe and 710 scientifically sound manner, although it was pointed out that one non-EU jurisdiction (Brazil) is 711 also proposing to regulate EDCs by their hazard alone. The rationale for this policy was 712 primarily based on political necessity due to resource limitations. There was strong support for 713 the proposed SETAC Pellston Workshop TM, (proposed by Matthiessen in this publication), as a 714 rational way forward to further enhance discussion on EDCs and potentially develop guidance 715 for environmental hazard and risk assessment approaches of endocrine active substance. This 716 workshop was held in early February 2016 and publications that emanated from this workshop 717 are currently in review for publication by IEAM³. Furthermore, the following outreach 718 statement on EDCs was drafted as an outcome to Session four of the SETAC North America 719 720 Focused Topic Meeting: Endocrine Disruption.

721

722 SETAC FOCUSED TOPIC MEETING ON ENDOCRINE DISRUPTING CHEMICALS: 723 OUTREACH STATEMENT

724

More than 200 participants representing industry, government, and academia from ten countries attended a SETAC North America Focused Topic Meeting (FTM) on February 4-6, 2014 dealing with the issue of "*Endocrine Disruption: Chemical Testing, Risk Assessment Approaches and Implications.*" The primary focus of the FTM was to address the dichotomy of approaches evolving for the management of endocrine disrupting chemicals (EDCs). EDCs are defined as exogenous chemicals or mixtures that can alter the function(s) of the endocrine system

and consequently cause adverse health effects in an intact organism, its progeny, or (sub)
populations (see also SETAC Tip:

733 http://www.setac.org/resource/resmgr/Publications and Resources/Endo-TIP.pdf).

It is possible that as many as 50,000 chemicals could require assessment for their 734 endocrine disruption potential. Results from those assessments will influence decisions 735 concerning new chemical approvals and the handling of existing chemicals in commerce. In the 736 US, Canada and Japan, the approach is risk-based, incorporating both the inherent hazards and 737 exposure potential when determining risks posed by suspected EDCs. In contrast, in Europe, a 738 hazard-based approach is being discussed because there is concern among some toxicologists 739 and endocrinologists that traditional risk assessment may not always be appropriate when 740 considering unresolved issues including low-dose or non-threshold effects and portions of the 741 life cycle sensitive to exposure. In the hazard-based approach, the primary focus is the intrinsic 742 743 endocrine hazard of a chemical and not the effect concentration or environmental concentrations of the chemical in question. 744

Some attendees supported the hazard-based approach because it is precautionary in 745 nature. They were not convinced that traditional risk assessment covers the uncertainties 746 connected to potential no-threshold, low dose, or sensitive periods of exposure and response to 747 endocrine disruptors. However, the majority of attendees at the FTM supported the concept that 748 EDC assessments should consider environmentally-relevant exposures. It was also recognized 749 that interactions of chemicals with endocrine receptors or alterations in endocrine response do 750 not always result in irreversible adverse outcomes, and that linkages between endocrine mediated 751 752 responses and adverse outcomes such as malformations, growth, reproduction and development

must be established. This was considered important despite the fact that these assessments aremore costly and time consuming to conduct.

The FTM presented an opportunity to publically recognize some of the controversies 755 surrounding the developing science around EDCs and to further the debate concerning hazard-756 and risk-based approaches. At this time there is no agreement on the manner by which EDCs 757 should be regulated although most participants were convinced that efforts to advance our 758 understanding of the potential impacts of EDCs need to be based on a systematic review of all 759 available information and that agreed upon criteria be developed to evaluate these data. In the 760 end, the FTM recommended the need for meaningful dialog between the proponents of risk and 761 762 hazard based approaches to evaluate EDCs as this will be critical in assisting both the public and regulators on an issue that may impact both humans and wildlife. 763

As a follow up to the discussions held at the FTM and a preceding meeting in Brussels in 2012, a SETAC Pellston workshop was proposed to develop scientific case studies of both environmental hazard and risk assessment approaches applied to EDCs. The idea was to use realworld data to evaluate different assessment method which, conducted rigorously by global experts on EDS, would give rised to authorative guidance to regulators. This workshop has been held in the meantime.³

³Note from the Guest Editor: The SETAC Pellston WorkshopTM 'Environmental Hazard and Risk Assessment Approaches for Endocrine-Active Substances (EHRA)' was held from 31st January to 5th February 2016 in Pensacola, Florida, USA. The primary aim of the workshop was to provide objective advice, based on current scientific understanding, to regulators and policy makers, whether in industry, government or academia; the aim being to make considered, informed decisions on whether to select an ecotoxicological hazard- or a risk-based approach for regulating a given endocrine-disrupting substance (EDS) under review. The workshop additionally considered recent developments in the identification of EDS. Case studies were undertaken on six endocrine active substances (EAS – not necessarily proven EDS), that are representative of a range of perturbations of endocrine system and considered to be data-rich in relevant information at multiple biological levels of organisation for one or more ecologically-relevant taxa. The workshop was successful in developing consensus. Scientific papers are currently in review for publication by IEAM.
