Final Economic Analysis and Final Regulatory Flexibility Analysis

Supporting Document for the Final Rule
for Occupational Exposure to Respirable Crystalline Silica

Occupational Safety and Health Administration
U.S. Department of Labor

2016

CHAPTER I: INTRODUCTION

OSHA's Final Economic Analysis and Final Regulatory Flexibility Analysis (FEA) addresses issues related to the costs, benefits, technological and economic feasibility, and the economic impacts (including impacts on small entities) of the respirable crystalline silica final rule and evaluates regulatory alternatives to the rule. When OSHA identifies a significant risk to workers, section 6(b)(5) of the Occupational Safety and Health Act (OSH Act) directs OSHA to select a standard that, based on the best available evidence and to the extent feasible, ensures that "no employee will suffer material impairment of health or functional capacity, even if such employee has regular exposure to the hazard dealt with by such standard for the period of his working life." 29 U.S.C. 655(b)(5).

While drafting its final standard to fulfill its statutory directive, OSHA also acknowledges applicable executive orders pertinent to rulemaking. Executive Orders 13563 and 12866 direct agencies to assess all costs and benefits of available regulatory alternatives and, if regulation is necessary, to select regulatory approaches that maximize net benefits (including potential economic, environmental, public health and safety effects, distributive impacts, and equity). Executive Order 13563 emphasizes the importance of quantifying both costs and benefits, of reducing costs, of harmonizing rules and of promoting flexibility. Section 3(f)(1) of Executive Order 12866 requires the Office of Information and Regulatory Affairs (OIRA) in the Office of Management and Budget (OMB) to review the Agency's assessment in these areas if the rule is economically significant. OSHA has determined that this final rule governing occupational exposure to respirable crystalline silica ("silica") is an economically significant regulatory action under section 3(f)(1) of Executive Order 12866. Accordingly, the Office of Regulatory Analysis and the Office of Technological Feasibility within OSHA have prepared this FEA for the rule, and it has been reviewed by OIRA. In producing this FEA, OSHA acknowledges the requirements of OMB's Circular A-4 (OMB, 2003, Document ID 1493), a guidance document for regulatory agencies preparing economic analyses under Executive Order 12866.[1]

The purpose of this FEA is to:

- Identify the establishments and industries affected by the rule;

[1] Cost-benefit analysis is a standard economics topic. However, "technological feasibility," which is discussed in Chapter IV, and "economic feasibility," which is discussed throughout the document, are key concepts for the OSH Act, but do not have standard economic definitions, and are not required by Executive Orders 12866 or 13563 or by OMB Circular A-4.

- Determine current silica exposures, compile exposure profiles for the affected industries and construction tasks, and identify the technologically feasible methods of controlling these exposures;
- Estimate the benefits resulting from employers coming into compliance with the rule in terms of the reduction in fatal cases of lung cancer, fatal cases of non-malignant respiratory disease, fatal cases of end-stage renal disease, and cases of silicosis morbidity;
- Estimate and evaluate the costs and economic impacts that establishments in the regulated community will incur to achieve compliance with the rule;
- Evaluate the economic feasibility of the rule for affected industries;
- Evaluate the principal regulatory alternatives to the final rule that OSHA has considered; and
- Evaluate the impacts of the rule on small entities as defined by the Small Business Administration (in accordance with the Regulatory Flexibility Act, as amended in 1996).

To develop this FEA, OSHA relied considerably on the support of OSHA's contractor Eastern Research Group (ERG).

SUMMARY OF THE STANDARDS FOR RESPIRABLE CRYSTALLINE SILICA

OSHA has developed a comprehensive standard to protect employees from exposure to respirable crystalline silica in general industry and maritime and has developed a separate standard for the construction industry. The text below summarizes the requirements contained in the standards, which are explained in more detail in the preamble to the final rule, especially the sections on Summary and Explanation.

Scope and application

New 29 CFR §1910.1053 applies to all workplaces in general industry and maritime where there is occupational exposure to respirable crystalline silica. New 29 CFR §1926.1153 applies to all workplaces in construction where there is occupational exposure to respirable crystalline silica. Neither standard applies to agriculture. Both standards exempt workplaces where the employer can demonstrate, based on objective data (as defined in the standards), that exposures in their workplace will remain below an 8-hour time weighted average (TWA) of 25 micrograms per cubic meter ($\mu g/m^3$) under any foreseeable conditions.

Control Methods

Employers are required to fully and properly implement the engineering controls, work practices, and respiratory protection necessary to ensure that employees are protected from respirable crystalline silica exposures above the permissible exposure limit (PEL). The construction standard includes a table (Table 1) setting out controls for a specified list of tasks, and specifying which of those tasks require respiratory protection to complement the controls in order to maintain exposures at or below the PEL.

The two standards generally require that the employer follow OSHA's "hierarchy of controls," using engineering and work practice controls to maintain exposures to levels at or below the PEL, unless the employer can demonstrate that such controls are not feasible. Wherever feasible engineering and work practice controls are not sufficient to reduce employee exposure to the PEL, the employer must use them to reduce employee exposure to the lowest level achievable and then supplement them with respiratory protection. As an alternative to that performance standard, compliance with the construction standard's Table 1 specified methods of control for a listed task will meet a construction employer's obligation under the standard to control respirable crystalline silica, but that obligation can also be met by following the traditional hierarchy-of-controls, a performance-standard approach to ensure that employees are not exposed to levels above the PEL. In construction, exposure assessment (sampling employee exposure) is not required if an employer fully and properly implements the controls on Table 1; otherwise, exposure assessment is required as under the general industry and maritime rule.

Permissible Exposure Limit (PEL) and Action Level

For each silica standard, OSHA has established a PEL of 50 $\mu g/m^3$ as an 8-hour time weighted average (TWA) for respirable crystalline silica in the form of quartz, cristobalite, or tridymite.

In this rule, OSHA also has set an action level of 25 $\mu g/m^3$ as an 8-hour TWA. In these standards, as in previous OSHA standards, the provision for exposure assessment is only triggered once the action level is exceeded. Thus, employers may be able to considerably reduce the burden of complying with the standards by reducing employee exposures to below the action level. However, other ancillary requirements like medical surveillance for employees in general industry and maritime, and training for all employees covered by the standards, are triggered by the action level.

Exposure Assessment

With the exception of employers engaged in construction work and complying with Table 1 of the silica construction standard, each employer subject to a silica standard is required to conduct an assessment for each employee who is, or may reasonably be expected to be, exposed to levels of respirable crystalline silica at or above the action level. Each standard provides options for the assessment (performance-oriented assessments based on relevant objective data or scheduled monitoring through the employer's own air sampling of affected employees) and specifies when a reassessment of exposures must be performed, the methods of sample analysis, employee notification of assessment results, and observation of monitoring.

Regulated Areas (general industry and maritime standard)

To minimize any unnecessary employee exposures, the standard for general industry and maritime requires employers to establish a regulated area wherever an employee's exposure to airborne concentrations of respirable crystalline silica is, or can reasonably be expected to be, in excess of the PEL.

The standard requires that employers demarcate the boundaries of the regulated area (as separate from the rest of the workplace), post signs at the entrances to the regulated area, limit access to the regulated area, and provide an appropriate respirator to each employee or employee representative entering the regulated area.

This requirement does not apply to the standard for construction, which provides for restricting access to areas of significant silica exposure only through the requirement to maintain a written exposure control plan (including designation of a competent person to implement it).

Respiratory Protection

For all three affected major sectors (general industry, maritime, and construction), the standards reference OSHA's respiratory protection standard for general industry (29 CFR 1910.134), which must be complied with when employees are required to use respirators for protection against respirable crystalline silica exposure. The respiratory protection standard requires written procedures for the proper selection, use, cleaning, storage, and maintenance of respirators. The standards for respirable crystalline silica require the use of respirators in five situations: (1) during periods necessary to install or implement feasible engineering and work practice controls to meet the PEL; (2) during tasks where meeting the PEL with engineering and work practice controls is not feasible; (3) during tasks in which an employer has implemented all feasible engineering and work practice controls and these controls do not reduce exposures to the PEL; (4) for general industry and maritime, during periods when the employee/employee representative is in a regulated area; and (5) for construction, as required by Table 1 when employers are relying on Table 1 to satisfy the dust control requirements of the standard.

Housekeeping

The construction standard generally prohibits dry sweeping and the use of compressed air for cleaning clothing or surfaces where such activity could contribute to employee exposure to respirable crystalline silica.

Written Exposure Control Plan and Competent Person (construction standard)

For all three affected major sectors (general industry, maritime, and construction), the standard requires that each employer establish and implement a written exposure control plan to describe how it plans to limit employee exposure to silica. Each standard details when the plan must be evaluated, updated, and made available. The construction standard (which does not have a separate regulated areas requirement) requires that the written exposure control plan contain procedures to restrict access to work areas to minimize the number of employees exposed and their level of exposure, including exposures generated by other employers or sole proprietors.

The provision for a written exposure control plan requires that construction employers designate a competent person to make frequent and regular inspections of job sites, materials, and equipment to implement the written exposure control plan.

Medical Surveillance

The standards require employers to make medical surveillance, including specified initial and periodic medical exams (including follow-up referrals to a specialist), available at no cost to the employee, and at a reasonable time and place, for those employees in general industry and maritime who will be exposed at or above the action level for 30 or more days a year and for employees in construction who will be required to use a respirator for 30 or more days a year to limit exposure to respirable crystalline silica. All medical examinations are to be performed by a physician or other licensed health care professional (PLHCP).

Communication of Respirable Crystalline Silica Hazards to Employees

The standards include a cross-reference to OSHA's Hazard Communication Standard (HCS) (29 CFR 1910.1200) and requires that employers include respirable crystalline silica in their hazard communication program, implementation of which must include labels, safety data sheets, information and training. This is not a new requirement, as the existing hazard communication standard already requires that hazardous chemicals such as respirable crystalline silica be included in the employer's hazard communication program.

Recordkeeping

The employer is responsible for maintaining a record of air monitoring data, objective data and the basis on which that data is relevant to its work, and employee medical surveillance information. Exposure and medical records must be maintained in accordance with 29 CFR 1910.1020.

Significant Changes Between the Proposed Standards and the Final Standards

As noted above, OSHA added new limitations to the scope of the final standard to exclude activities with predictably low levels of silica exposure, i.e. below the action level (as a time-weighted average over eight hours) under any foreseeable condition. OSHA also clarified in the scope of the final rule that employers engaged in certain general industry activities identified on Table 1 of the construction standard may choose to comply with the construction standard instead of the general industry standard. A specific exemption for exposures that result from the processing of sorptive clays has been added.

For the final construction standard, OSHA expanded Table 1, from 13 construction operations to 18 common construction equipment/tasks known to generate high exposures to respirable crystalline silica, in order to address the common equipment and tasks that are overwhelmingly the common sources of exposure to respirable crystalline silica; however, neither abrasive blasting nor underground construction (tunnel boring) has been added to Table 1, and they remain subject to the traditional, performance-based methods of compliance. OSHA also transformed compliance with Table 1 from mere evidence of compliance with the PEL into a full alternative means of complying with the silica control requirements of the construction standard. Employers complying with Table 1 need not conduct exposure monitoring to determine whether their employees are exposed above the PEL.

As explained in more detail in the preamble discussion of Table 1, the final standard for construction clarifies that employers following Table 1 must protect all employees “engaged in a task identified on Table 1,” including not only the equipment operator, but also laborers and other employees who are assisting with the task. The revisions to Table 1 reduced the number of construction workers who would be required to wear respirators, which, in turn, reduced the number of workers who would receive medical surveillance since that requirement is triggered by the number of days (30 or more in the ensuing year) a worker will be wearing a respirator. In the final standard for general industry and maritime, the medical surveillance requirements are triggered by the action level rather than the PEL (provided exposure is for 30 or more days per year), which increased the number of workers who will be required to receive medical surveillance. This change accounts for a large portion of the increased costs for medical surveillance compared to the estimates in the preliminary economic analysis.

The final standards include a new requirement for a written exposure control plan and clarify that employers must protect their employees from silica exposures generated by the activities of other employers or sole proprietors. This requirement eliminated the need for a "written access control plan," which is not included in the final standards. In the construction standard, the requirement for a written exposure control plan includes a requirement for a “competent person” to implement that plan. In both the general industry and construction standards OSHA removed the proposed requirement that would have required workers to wear protective clothing in regulated areas to prevent silica contamination.

Finally, the final standards extend many compliance deadlines beyond the dates proposed in the NPRM.

OSHA revised its technological and economic analysis in response to these changes and to comments received on the NPRM. This FEA contains some costs that were not included in the PEA and updates data to use more recent data sources and, in some cases, revised methodologies. Detailed discussions of these changes are included in the relevant sections throughout this FEA.

FEA CONTENTS

Following this Introduction, the FEA contains the following chapters:

- Chapter II: Market Failure and the Need for Regulation
- Chapter III: Profile of Affected Industries
- Chapter IV: Technological Feasibility

- Chapter V: Costs of Compliance
- Chapter VI: Economic Feasibility Analysis and Regulatory Flexibility Determination
- Chapter VII: Benefits and Net Benefits
- Chapter VIII: Regulatory Alternatives
- Chapter IX: Final Regulatory Flexibility Analysis
- Chapter X: Environmental Impacts

CHAPTER II: MARKET FAILURE AND THE NEED FOR REGULATION

INTRODUCTION

Executive Order 12866 (58 FR 51735, September 30, 1993) and Executive Order 13563 (76 FR 3821, January 18, 2011) direct regulatory agencies to assess whether, from a legal or an economic view, a Federal regulation is needed to the extent it is not "required by law." Executive Order 12866 states:

> Section 1. Statement of Regulatory Philosophy and Principles.
> (a) The Regulatory Philosophy. Federal agencies should promulgate only such regulations as are required by law, are necessary to interpret the law, or are made necessary by compelling public need, such as material failures of private markets to protect or improve the health and safety of the public, the environment, or the well-being of the American people.

OSHA is revising the existing rule setting one permissible exposure limit for general industry and another, higher one for the construction and maritime industries regarding occupational exposure to respirable crystalline silica because, based on the evidence in the record, there is a compelling public need for a stricter, comprehensive standard under OSH Act legal standards. OSHA presents the legal standards governing this rule and its full findings and conclusions supporting promulgation of the revised rule in Section II of the Preamble, Pertinent Legal Authority, and throughout other sections of the Preamble (e.g., Section V, Health Effects and Quantitative Risk Assessment and Section VI, Significance of Risk).

Even a perfectly functioning market maximizes efficient allocation of goods and services at the expense of other important social values to which the market (as reflected in the collective actions of its participants) is indifferent or undervalues. In such cases, government intervention might be justified to address a compelling public need (Document ID 1493, p. 4). The history and enactment of the OSH Act indicate that Congress recognized that American markets undervalued occupational safety and health when it set forth the Act's protective purposes and authorized the Secretary of Labor to promulgate occupational safety and health standards.

Section 6(b)(5) of the OSH Act requires the Secretary of Labor, when promulgating health standards, to set the standard at the level "which most adequately assures, to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health or functional capacity . . . ." (29 U.S.C. 655(b)(5)). As discussed more fully in the Pertinent Legal Authority section of the Preamble, the Supreme Court has interpreted this language to mean that OSHA's health standards must reduce a "significant risk" of material impairment of health, subject to other regulatory constraints such as economic and technological feasibility (*Indus. Union Dep't, AFL-CIO v. Am. Petroleum Inst.*, 448 U.S. 607, 639-40 (1980) (*Benzene*)).

OSHA has determined that employees across a range of industries are exposed to levels of airborne silica that result in the development of lung cancer, silicosis, end-stage renal disease, and premature death. The Agency's final standard will reduce these occupational risks of lung cancer, silicosis, other lung diseases and end-stage renal disease. Protecting employees from a significant risk of these diseases establishes the compelling public need for the Agency's remedy: to increase worker protection from exposure to silica.

OSHA discusses, in this chapter, the possibility that this rule corrects a market failure in which private markets fail to adequately protect human health.

OSHA concludes there is a failure of private markets to protect workers from exposure to unnecessarily high levels of respirable crystalline silica. In making this statement, the Agency recognizes that many firms have responded to the risks posed by exposure to silica by implementing control programs for their workers. In fact, some existing control programs go beyond the requirements of the final rule, and information that OSHA has collected suggests that a significant percentage of all employees in workplaces where silica is present are currently receiving at least some level of protection against the risks posed by silica that is similar to the protection provided by this standard. For these firms and these workers, the economic incentives provided by private markets appear to be working effectively. Nevertheless, the effectiveness of private markets in providing the level of worker health and safety required by the OSH Act is not universal as many other employers in the same sectors fail to provide their workers with equivalent levels of protections against respirable silica. Accordingly, the general availability of adequate controls speaks to the feasibility of the standard, not to any supposed lack of need.

In this case, OSHA is addressing a situation in which there is an existing OSHA regulation that the Agency wishes to make more stringent. If markets work efficiently there would be no need for either the existing regulation or a new one. This section is devoted to showing that markets fail with respect to optimal risk for occupational exposure to silica. Other sections address whether, given that markets fail, a new regulation is needed to replace the existing regulation.

The discussion below considers why private markets, as well as information dissemination programs, workers' compensation systems, and tort liability options, each may fail to protect workers from silica exposure, resulting in the need for a more protective OSHA silica rule. That is followed by OSHA's discussion of public comments on the preliminary analysis of the need for regulation—presented in the Preliminary Economic Analysis in support of the proposed silica rule (Document ID 1720)—and the Agency's response to those comments. Finally, OSHA briefly summarizes this chapter.

PRIVATE MARKETS

Under suitable conditions, a market system is economically efficient in the following sense: resources are allocated where they are most highly valued; the appropriate mix of goods and services, embodying the desired bundle of characteristics, is produced; and further improvements in the welfare of any member of society cannot be attained without making at least one other member worse off.

Economic theory, supported by empirical data, argues that, in the job market, employers and workers bargain over the conditions of employment, including not only salary and other worker benefits, but also occupational risks to worker safety and health. Employers compete among themselves to attract workers. In order to induce workers to accept hazardous jobs, employers must offer a higher salary—termed a "wage premium for risk" or "risk premium" for short—to compensate for the additional job risk.[1] Because employers must pay higher wages for more hazardous work, they have an incentive to make the workplace safer by making safety-related investments in equipment and training or by using more costly but safer work practices. According to economic theory, the operation of the private job market will provide the optimal level of occupational risk when each employer's additional cost for job safety just equals the avoided payout in risk premiums to workers. The theory assumes that each employer is indifferent to whether it pays the higher wage or pays for a safer or more healthful workplace, but will opt for whichever costs less or improves productivity more.

For the job market to function in a way that leads to optimal levels of occupational risk, three conditions must be satisfied. First, workers and employers must have the same, perfect information—that is, they must be fully informed about their workplace options, including job hazards, or be able to costlessly acquire such information. Second, participants in the job market must directly bear all of the costs and obtain all of the

[1] The concept of compensating wage differentials for undesirable job characteristics, including occupational hazards, goes back to Adam Smith's ***The Wealth of Nations***, which was originally published in 1776.

benefits of their actions. In other words, none of the direct impacts of job market transactions can be externalized to outside parties. Third, the relevant job market must be perfectly competitive, which means it must contain such a large number of employers and such a large number of workers that no individual economic agent is able to influence the risk-adjusted wage.

The discussion below examines (1) imperfect information, (2) externalities, and (3) imperfect competition in the job market in more detail, with particular emphasis on worker exposure to silica, as appropriate.[2]

(1) Imperfect Information

As described below, imperfect information about job hazards is present at several levels that reinforce each other: employers frequently lack knowledge about workplace hazards and how to reduce them; workers are often unaware of the workplace health and safety risks to which they are exposed; and workers typically have difficulty in understanding the risk information they are able to obtain. Imperfect information at these various levels has likely impeded the efficient operation of the job market regarding workplace risk because workers--unaware of job hazards--do not seek, or receive, full compensation for the risks they bear. As a result, even if employers have full knowledge about the risk, their employees do not. If employees do not have full knowledge about the risk, employers have less incentive to invest in safer working conditions than they would in the presence of full information since wages are suppressed below what full knowledge by the workers would yield. In contrast, see Casillas-Pabellón testimony at 2452-2453 (workers who received full training about silica risks refused to work without the protections that had not been previously provided).

Lack of Employer Information

In the absence of regulation, employers may lack economic incentives to optimally identify the health risks that their workers face.[3] Furthermore, employers have an economic incentive to withhold the information they do possess about job hazards from their workers, whose response would be to demand safe working conditions or higher wages to compensate for the risk. Similarly, employers who develop cost-effective methods of reducing workplace risk have little incentive to share information with their

[2] The section on workers' compensation insurance later in this chapter identifies and discusses other related market imperfections.

[3] Other private parties may lack sufficient incentives to invest resources to collect and analyze occupational risk data due to the public-good nature of the information. See Ashford and Caldart (1996), Document ID 0538, p. 234.

competitors about such methods (unless they are patentable.) Relatedly, in the absence of regulation, employers, as well as third parties, may have fewer incentives to develop new technological solutions to protect workers on the job. For evidence of regulatory stimuli inducing innovations to improve worker health and safety, see, for example, Ashford, Ayers, and Stone (1985) Document ID 0536, as well as more recent evidence from OSHA's regulatory reviews under section 610 of the Regulatory Flexibility Act (5 U.S.C. 610).

As a result, without regulation, many employers are unlikely to make themselves aware of the magnitude of silica-related health risks in the workplace or of the availability of effective ways of ameliorating or eliminating these risks.

Lack of Worker Information about Health Hazards

Even without information from their employers, workers might reasonably be cognizant, at least at some basic qualitative level, of many occupational *safety* hazards. Many safety hazards are obvious to the eye, such as holes in floors, ice and snow covered work surfaces, and work near electrical power lines. Likewise, workers can understand that activities involving explosive materials or working at heights are inherently dangerous. Furthermore, workers can develop some, admittedly limited, knowledge of safety hazards in their workplace from their own and their coworkers' on-the-job accident and injury experience.

Occupational *health* hazards are generally less obvious and well known to employers and employees alike than occupational *safety* hazards. Whereas the relationship between a workplace accident and the resultant injury is usually both immediate and visible, the connection between exposure to an occupational health hazard and the resultant disease may not be. Even though falls and physical trauma occur in everyday life, it is easier to know when the injuries occurred on the job than to know the cause of a particular lung disease long associated with occupational exposure to a toxic substance. Some diseases have multiple potential causes and may be the result of synergistic effects, thus creating difficulties in ascertaining whether, in some specific situations, a worker's disease is job-related rather than an "ordinary disease of life" resulting from genetic, physiological, lifestyle, or non-occupational environmental factors.[4]

---

[4] It is true that, in rare circumstances, the cause of a disease is unique or nearly so. Examples of such "signature" diseases include mesothelioma and angiosarcoma, which are caused by exposure to asbestos and vinyl chloride, respectively. In some cases, silica can be uniquely identified as the dust causing a worker's pneumoconiosis, a restrictive lung disease due to inhalation of dust; in such cases, the disease is classified as silicosis. OSHA is not aware of evidence that silica can be uniquely identified, in

Compounding this causation problem is the fact that there is frequently a long latency period—sometimes 20 years or more—between exposure to the occupational health hazard and the manifestation of the resultant disease. Consequently, without specialized knowledge, the connection between work conditions and a chronic disease is more easily missed than an acute injury and more easily attributed to non-occupational exposures. Furthermore, by the time that signs and symptoms of occupational health problems arise, it is often too late for workers to make use of that information. For example, lung cancer does not surface until many years after the exposures that contributed to causing it, and preventive action can no longer be taken. Therefore, any incentive an employer has to invest in occupational disease prevention is diluted by the lengthy passage of time between exposure and disease manifestation (by which time the employees may be working elsewhere or retired) and the various uncertainties regarding causation in any specific case. Markets cannot adequately address this risk of latent occupational disease if employees and employers are unaware of the changes in risk brought about by an employer's actions. Even if employees and employers are aware of a risk, the employer may have limited economic motivation to install controls unless the employees are able to accurately assess the effects of those controls on their occupational risks. Accordingly, even if workers have general knowledge that they are at increased risk of disease from occupational exposure, it is unrealistic to expect, absent mandatory regulatory requirements, that they know the calculated risks associated with different exposure levels or the exposures they are experiencing or accumulated in the past, much less that they can use that knowledge to negotiate a significant reduction in exposures and other protections or (if more desirable) trade it for greater hazard pay. And without any way to enforce standards agreed to by an employer, employees would have no way to check that they are getting the benefit of their bargain or hold the employer to it. Another reason that imperfect information impairs a worker's decision-making ability is that workers are unlikely to know the workplace risks associated with their particular employer, or with one potential employer versus another, even if the types of work assignments are the same. More specifically, on tasks involving silica exposure, workers may not know whether adequate engineering controls are being applied or that the respirators the employer provides have adequate protection factors and have been properly fit-tested and maintained. In fact, even the assumption that the employer is using engineering controls and supplying respirators may not be warranted in the absence of regulation.

---

individual cases, as the cause of other diseases arising from worker exposure to silica, such as lung cancer, tuberculosis, and renal failure.

Both experimental studies and observed market behavior suggest that individuals have considerable difficulty rationally processing information about low-probability, high-consequence events such as occupational fatalities and long-term disabilities.[5] For example, many individuals may not be able to comprehend or rationally act on risk information when it is presented, as risk analysis often is, in mathematical terms—a 1/1,000 versus a 1/10,000 versus a 1/100,000 annual risk of death from occupational causes. See, e.g., Guth testimony (Document ID 3585, Tr. 3007-3008).

Of course, in the abstract, many of the problems that employers and workers face in obtaining and processing occupational risk can lead workers to overestimate as well as underestimate the risk. However, in the case of silica exposure, the related diseases—including silicosis and end-stage renal disease—may be sufficiently unfamiliar and unobvious that many workers may be completely unaware of the risk, and therefore will underestimate it. See, e.g., testimony of bricklayer Tommy Todd:

> I just took it as a grain of salt, the dust. I never thought it was harmful or anything. . . . If I'd known it was hurting me, you know, or killing me, shoot, I'd have done things a lot different, and I had no idea back then (Document ID 3585, Tr. pp. 3030-3035).

In addition, for markets to optimally address this risk, employees need to be aware of the changes in risk brought about by an employer's actions. Even if employees are aware of a risk, the employer may have limited economic motivation to install controls unless the employees are able to accurately assess the effects of those controls on their occupational risks. Furthermore, there is substantial evidence that most individuals are unrealistically optimistic, even in high-stakes, high-risk situations and even if they are aware of the statistical risks (Thaler and Sunstein, 2009, Document ID 1697, pp. 31-33). Although the Agency lacks specific evidence on the effect of these attitudes on assessing occupational safety and health risks, this suggests that some workers underestimate their own risk of work-related injury, disease, or fatality and, therefore, fail to demand adequate compensation for bearing those risks. Finally, the difficulty that workers have in distinguishing marginal differences in risk in alternative worksites, both within an industry and across industries, creates a disincentive for employers to incur the costs of reducing workplace risk.

(2) Externalities

---

[5] The literature documenting risk perception problems is extensive. See, in particular, the classic work of Tversky and Kahneman (1974), Document ID 1675. For a recent summary of risk perception problems and their causes, see Thaler and Sunstein (2008), Document ID 1697, pp. 17-37.

Externalities arise when an economic transaction generates direct positive or negative spillover effects on third parties not involved in the transaction. The resulting spillover effect, which leads to a divergence between private and social costs, undermines the efficient allocation of resources in the market because the market is imparting inaccurate cost and price signals to the transacting parties. Applied to the job market, when costs are externalized, they are not reflected in the decisions that employers and workers make—leading to allocative distortions in that market.

Negative externalities exist in the job market because many of the costs of occupational injury and illness are borne by parties other than individual employers or workers. The major source of these negative externalities, for chronic occupational diseases, is the occupational illness cost that workers' compensation does not cover.[6] Workers and their employers often bear only a portion of these costs. Outside of workers' compensation, workers incapacitated by an occupational injury or illness and their families often receive health care, rehabilitation, retraining, direct income maintenance, or life insurance benefits, most of which are paid for by society through Social Security and other social insurance and social welfare programs.[7] Furthermore, substantial portions of the medical care system in the United States are heavily subsidized by the government so that part of the medical cost of treating injured or ill workers is paid for by the rest of society (Nichols and Zeckhauser, 1977, Document ID 0834, pp. 44-45). To the extent that employers and workers do not bear the full costs of occupational injury and illness, they will ignore these externalized costs in their job-market negotiations. The result may be an inefficiently high level of occupational risk. It should be noted, however, that OSHA expects that the effect of these externalities on the market-determined level of occupational risk would be relatively minor in comparison to the other types of market failure described here.

(3) Imperfect Competition

[6] Workers' compensation is discussed separately later in this chapter. As described there, in many cases (particularly for smaller firms), the premiums that an individual employer pays for workers' compensation are only loosely related, or unrelated, to the occupational risks that that employer's workers bear. However, workers' compensation does not cover chronic occupational diseases in most instances. For that reason, negative externalities tend to be a more significant issue in the case of occupational exposures that result in diseases.

[7] In addition, many occupational injuries and most occupational illnesses, other than musculoskeletal disorders, are not processed through the workers' compensation system at all. In these instances, workers receive care from their own private physician rather than from their employer's physician.

In the idealized job market, the actions of large numbers of buyers and sellers of labor services establish the market-clearing, risk-compensated wage, so that individual employers and workers effectively take that wage as given. In reality, however, the job market is not one market but many markets differentiated by location, occupation, and other factors; entrants in the labor market face search frictions because of limited information on employment options; and, furthermore, in wage negotiations with their own workers, employers are typically in an advantageous position relative to all other potential employers. In these situations, discussed below, employers may have sufficient power to influence or to determine the wage their workers receive. This may undermine the conditions necessary for perfect competition and can result in inadequate compensation for workers exposed to workplace hazards. Significant unemployment levels, local or national, may also undermine the conditions necessary for adequate compensation for exposure to workplace hazards.

Beyond the classic—but relatively rare—example of a town dominated by a single company, there is significant evidence that some employers throughout the economy are not wage-takers but, rather, face upward-sloping labor supply curves and enjoy some market power in setting wages and other conditions of employment.[8] An important source of this phenomenon is the cost of a job search and the employer's relative advantage, from size and economies of scale, in acquiring job market information.[9] Another potentially noteworthy problem in the job market is that, contrary to the model of perfect competition, workers with jobs cannot costlessly quit and obtain a similar job at the same wage with another employer. Workers leaving their current job may be confronted with the expense and time requirements of a job search, the expense associated with relocating to take advantage of better employment opportunities, the loss of firm-specific human capital (i.e. firm-specific skills and knowledge that the worker possesses), the cost and difficulty of upgrading job skills, and the risk of a prolonged period of unemployment. In addition, employers derive market power from the fact that a portion of the compensation their workers receive is not transferable to other jobs. Examples include job-specific training and associated compensation, seniority rights and associated benefits, and investments in a pension plan.

---

[8] See, for example, Borjas (2000) Document ID 0565. See also Ashenfelter, Farber, and Ransom (2010) and Boal and Ransom (1997), providing supplemental evidence. The term "monopsony" power is sometimes applied to this situation, but it does not necessarily require a single employer.

[9] See Borjas (2000) Document ID 0565. As supplemental authorities, Weil (2014) presents theory and evidence both in support of this proposition and to show that, in many situations, larger firms have more monopsony power than smaller firms, while Boal and Ransom (1997, p. 97) note that the persistent wage dispersion observed in labor markets is a central feature of equilibrium search models.

Under the conditions described above, employers would not have to take the market-clearing wage as given, but could offer a lower wage than would be observed in a perfectly competitive market,[10] including less than full compensation for workplace health and safety risks. As a result, relative to the idealized competitive job market, employers would have less incentive to invest in workplace safety. Several hearing participants testified that their workplace experiences are far different from those described in the idealized competitive job market, and described the difficulty in obtaining jobs and the resulting inability to bargain for, or even request, protection from silica exposure. See, e.g., testimony of New Labor Director Ms. Casillas-Pabellon (Document ID 3583, Tr. 2449-2450); construction worker Mr. Armendariz (Document ID 3583, Tr. 2484; and construction worker Mr. Granados (Document ID 3583, Tr. 2485).

NON-MARKET AND QUASI-MARKET ALTERNATIVES TO REGULATION

The discussion in this section considers whether non-market and quasi-market alternatives to the final rule would be capable of protecting workers from the hazards of silica exposure. The alternatives under consideration are information dissemination programs, workers' compensation systems, and tort liability options.

Information Dissemination Programs

An alternative to OSHA's final silica rule would be the dissemination of information, either voluntarily or through compliance with OSHA's hazard communication standard (HCS) (29 CFR 1910.1200), about the health risks associated with workplace exposure to silica. Better informed workers could more accurately assess the occupational risks associated with different jobs, thereby facilitating, through labor market transactions, higher risk premiums for more hazardous work and inducing employers to make the workplace less hazardous. The final rule recognizes the link between the dissemination of information and workplace risks by requiring that workers engaged in jobs involving exposure to silica be provided with information and training about silica-related illnesses and ways to prevent them. There are several reasons, however, why reliance on information dissemination programs alone would not yield the level of worker protection achievable through the final silica rule, which incorporates hazard communication as part of a comprehensive approach designed to control the hazard in addition to providing for the disclosure of information about it.

[10] For a graphical demonstration that an employer with monopsony power will pay less than the competitive market wage, see Borjas (2000), Document ID 0565, pp. 187-189.

First, in the context of HCS, which requires employers to transmit information about the inherently hazardous properties of hazardous substances, that standard alone does not require that sufficient information be provided to identify risks in specific workplaces. Silica-related risks, for instance, are highly specific to individual tasks and work environments.

Second, in the case of voluntary information dissemination programs, absent a regulation, there may be significant economic incentives, for all the reasons discussed in the Private Markets section above, for the employer *not* to gather relevant exposure data or distribute occupational risk information so that the workers would not change jobs or demand higher wages to compensate for their newly identified occupational risks.

Third, even if workers were better informed about workplace risks and hazards, all of the defects in the functioning of the private job market previously discussed—the limited ability of workers to evaluate risk information, externalities, and imperfect competition—would still apply. Because of the existence of these defects, better information alone would not lead to wage premiums for risk in accordance with efficient market theory.

Thus, while improved access to information about silica-related hazards can provide for more rational decision-making in the private job market, OSHA concludes that information dissemination programs will not, by themselves, produce an adequate level of worker protection.

Workers' Compensation Systems

Another theoretical alternative to OSHA regulation could be to determine that no rule is needed because State workers' compensation programs augment the workings of the private job market to limit occupational risks to worker safety and health. After all, one of the objectives of the workers' compensation system is to shift the costs of occupational injury and disease from workers to employers in order to induce employers to improve working conditions. Two other objectives relevant to this discussion are to provide fair and prompt compensation to workers for medical costs and lost wages resulting from workplace injury and disease and, through the risk-spreading features of the workers' compensation insurance pool, to prevent individual employers from suffering a catastrophic financial loss (Ashford, 2007, Document ID 1702, p. 1712).

OSHA identifies three primary reasons, discussed below, why the workers' compensation system has fallen short of the goal of shifting to employers the costs of workplace injury and disease—including, in particular, the costs of worker exposure to silica. As a result, OSHA concludes that workers' compensation programs alone do not adequately protect workers. In addition, although not necessary to support this conclusion, OSHA takes notice of several recent studies highlighting the general decline in the adequacy and fairness of State worker's compensation programs, the significant variability among State worker compensation programs, and the compensation inadequacies that ultimately shift these costs back to the workers or to the government (www.propublica.org/article/the-demolition-of-workers-compensation and http://www.dol.gov/osha/report/20150304-inequality.pdf).

(1) <u>Failure to Provide Compensation for Most Occupational Diseases</u>

The first, and most important, reason that workers' compensation is not an adequate alternative, is that State workers' compensation programs tend not to provide benefits for most work-related diseases—including those resulting from silica exposure, such as silicosis and lung cancer. Several related factors account for this:

- Most occupational diseases have multiple causes and are indistinguishable from ordinary diseases of life. Therefore it is difficult for workers' compensation to trace the cause of these diseases to the workplace;
- Many occupational diseases have long latency periods, which tends to obscure the actual cause of disease or the place of employment where exposure occurred;
- Workers (as well as medical personnel) often do not realize that a disease is work-related and, therefore, fail to file a workers' compensation claim; and
- Most States have statutes of limitations that are 10 years or less for filing workers' compensation claims. This may preclude claims for illnesses involving long latency periods. Also, many States have a minimum exposure time period before a disease can be attributed to an occupational cause.

With the exception of musculoskeletal disorders, workers' compensation actually covers only 5 percent of occupational diseases (including silica-related occupational diseases) and 1.1 percent of occupational fatalities (Ashford, 2007, Document ID 1702, p. 1714).

(2) <u>Limitations on Payouts</u>

The second reason that employers do not fully pay the costs of work-related injuries and disease under the workers' compensation system is that, even for those claims that are accepted into the system, states have imposed significant limitations on payouts. Depending on the State, these limitations and restrictions include:

- Caps on wage replacement based on the average wage in the State rather than the injured workers' actual wage;

- Restrictions on which medical care services are compensated and the amount of that compensation;
- No compensation for non-pecuniary losses, such as pain and suffering or impairment not directly related to earning power;
- Either no, or limited, cost-of-living increases;
- Restrictions on permanent, partial, and total disability benefits, either by specifying a maximum number of weeks for which benefits can be paid or by imposing an absolute ceiling on dollar payouts;
- A low absolute ceiling on death benefits.

The last two restrictions may be the most limiting for occupational diseases with long-term health effects and possible fatal outcomes, such as those associated with worker exposure to silica.

(3) __A Divergence between Workers' Compensation Premiums and Workplace Risk__

The third reason workers' compensation does not adequately shift the costs of work-related injuries and illnesses to employers is that the risk-spreading objective of workers' compensation conflicts with, and ultimately helps to undermine, the cost-internalization objective.[11] For the 99 percent of employers who rely on workers' compensation insurance,[12] the payment of premiums represents their primary cost for occupational injuries and illnesses, such as silica-related illnesses. However, the mechanism for determining an employer's workers' compensation insurance premium typically fails to reflect the actual occupational risk present in that employer's workplace.

Approximately 85 percent of employers have their premiums set based on a "class rating," which is based on *industry* illness and injury history. Employers in this class are typically the smallest firms and represent only about 15 percent of workers (Ashford, 2007, Document ID 1702, p. 1713). Small firms are often ineligible for experience rating because of insufficient claims history or because of a high year-to-year variance in their claim rates. These firms are granted rate reductions only if the experience of the entire class improves. The remaining 14 percent of employers, larger firms representing approximately 70 percent of workers, have their premiums set on the basis of a

[11] Recall from the earlier discussion of externalities that the failure to internalize costs leads to allocative distortions and inefficiencies in the market.

[12] Only the largest firms, constituting approximately 1 percent of employers and representing approximately 15 percent of workers, are self-insured. These individual firms accomplish risk-spreading as a result of the large number of workers they cover. See Ashford (2007), Document ID 1702, p. 1712.

combination of “class rating” and “experience rating,” which adjusts the class rating to reflect a firm’s individual claims experience. A firm’s experience rating is generally based on the history of workers’ compensation payments to workers injured at that firm’s workplace, not on the quality of the firm’s overall worker protection program or safety and health record. Thus, for example, the existence of circumstances that may lead to catastrophic future losses are not included in an experience rating—only actual past losses are included.[13]

Insurance companies do have the right to refuse to provide workers’ compensation insurance to an employer—and frequently exercise that right based on their inspections and evaluations of a firm’s health and safety practices. However, almost all States have assigned risk pools that insist that any firm that cannot obtain workers’ compensation policies from any insurer must be provided workers’ compensation insurance at a State-mandated rate that reflects a combination of class and experience rating.

Workers’ compensation insurance does protect individual employers against a catastrophic financial loss due to work-related injury or illness claims. As a result of risk spreading, however, employers’ efforts to reduce the incidence of occupational injuries and illnesses are not fully reflected in reduced workers’ compensation premiums. Conversely, employers who devote fewer resources to promoting worker safety and health may not incur commensurately higher workers’ compensation costs. This creates a type of moral hazard, in that the presence of risk spreading in workers’ compensation insurance may induce employers to make fewer investments in equipment and training to reduce the risk of workplace injuries and illnesses.

In short, the premiums most individual employers pay for workers’ compensation insurance coverage do not reflect the actual cost burden those employers impose on the worker’s compensation system. Consequently, employers considering measures to lower the incidence of workplace injuries and illnesses can expect to receive a less-than-commensurate reduction in workers’ compensation premiums. Thus, for all of the reasons discussed above, the workers’ compensation system does not provide adequate incentives to employers to control occupational risks to worker safety and health.

Tort Liability Options

[13] In order to spread risks in an efficient manner, it is critical that insurers have adequate information to set individual premiums that reflect each individual employer’s risks. As the preceding discussion has made clear, by and large, they do not. In that sense, insurers can be added to employers and workers as possessing imperfect information about job hazards.

Another alternative to OSHA regulation would be for workers to use the tort system to seek redress for work-related injuries and diseases, including silica-related ones. A tort is a civil wrong (other than breach of contract), for which the courts can provide a remedy by awarding damages. The application of the tort system to occupational injury and disease would allow workers to sue their employer, or other responsible parties (e.g., “third parties” such as suppliers of hazardous material or equipment used in the workplace) to recover damages. In theory, the tort system could shift the liability for the direct costs of occupational injury and illness from the worker to the employer or to other responsible parties. In turn, the employer or third parties would be induced to improve worker safety and health.

With limited exceptions, the tort system has not been a viable alternative to occupational safety and health regulation because State statutes make workers’ compensation the “exclusive remedy” for work-related injuries and illnesses. Workers’ compensation is essentially a type of no-fault insurance. In return for employers’ willingness to provide, through workers’ compensation, timely wage-loss and medical coverage for workers’ job-related injuries and diseases, regardless of fault, workers are barred from suing their employers for damages, except in cases of intentional harm or, in some States, gross negligence (Ashford and Caldart, 1996, Document ID 0538, p. 233). Practically speaking, in most cases, workers’ compensation is the exclusive legal remedy available to workers for workplace injuries and illnesses.

Workers are thus generally barred from suing their own employers in tort for occupational injuries or disease, but may attempt to recover damages for work-related injuries and disease from third parties through the tort system. However, the process may be lengthy, adversarial, and expensive. In addition, in tort cases involving chronic occupational disease, the likelihood of prevailing in court and ultimately obtaining compensation may be small because:

- In a tort action, the burden of proof is on the plaintiff (i.e., the worker) to demonstrate by “a preponderance of the evidence” that the defendant (i.e., the responsible third party) owed a duty to the plaintiff, that the defendant breached that duty, and that the breach caused the worker’s injury or disease;
- To establish third-party liability the worker must typically show that the third party’s products or equipment or instructions were defective or negligently designed. Liability is often in dispute and difficult to prove;
- In cases of chronic disease, especially those with long latency periods, it is typically even more difficult to prove that the third-party was causally responsible. The worker must prove that not only was the disease the result of occupational exposure and not an ordinary disease of life or the result of non-

occupational exposure, but also the causal exposure was due to the defendant's product at the plaintiff's particular worksite rather than exposure to some other third party's product or exposure at some other worksite;

- For chronic diseases, the potentially lengthy latency period between worker exposure and manifestation of disease lowers the probability that the responsible third party will still be in business when tort claims are ultimately filed and have sufficient assets to cover the claims;[14] and
- Workers may be deterred from filing tort actions because of the substantial costs involved—including attorney fees, court costs, and the costs of obtaining evidence and securing witnesses—and the lengthy period before a final decision is rendered.

In sum, the use of the tort system as an alternative to regulation is severely limited because of the "exclusive remedy" provisions in workers' compensation statutes; because of the various legal and practical difficulties in seeking recovery from responsible third parties, particularly in cases of occupational disease such as silicosis and lung cancer; and because of the substantial costs associated with a tort action. The tort system, therefore, does not adequately protect workers from exposure to hazards in the workplace.

PUBLIC COMMENTS ON THE NEED FOR REGULATION

Some commenters argued that OSHA had not demonstrated a need for additional regulation because (1) various studies have shown that reported cases of silicosis are decreasing under the current OSHA silica standard and (2) improved enforcement of the existing silica standard would be superior to adding the costly new requirements in the proposed rule. These commenters include the American Foundry Society (Document ID 4229, p. 6), the Construction Industry Safety Coalition (CISC) (Document ID 4217, p. 6, fn 2), Halliburton Energy Services, Inc. (Document ID 2302, p. 10), the National Association of Home Builders (Document ID 2296, p. 14) and others (See, e.g. Document ID 2191; 4225; 2210; 2222; 4228, pp. 4-6; 2136; 2309, pp. 4-5; 2185, p. 3; 2182, p. 4; 3580, Tr. 1470; 3589, Tr. 4210 and 2024). In brief, OSHA disagrees with the conclusion reached by these commenters. OSHA has determined that significant risk to workers remains under the current OSHA silica standard, even with full enforcement, and that the final rule would significantly reduce that risk. The commenters appear to ignore OSHA's statutory duty to act to reduce the risk to the extent feasible, and disagree with OSHA's finding that the benefits of achieving the new PEL exceed the costs. A detailed discussion of the first issue—including the associated comments themselves and OSHA's full position—is presented in the preamble supporting the final rule, primarily in the risk

[14] The same qualification about the firm being in business and having sufficient assets to pay claims may also apply to liability insurers, in those cases where the firm has purchased liability insurance.

assessment, the justification for the new PEL, and the examination of the pertinent legal authority for the rule. A discussion of the second issue is presented later in this FEA in the examination of the net benefits of the rule.

One of those commenters suggested that the need for regulation may already have been satisfied by OSHA's proposal. During testimony, Bradford Hammock, counsel for CISC, suggested that OSHA could improve compliance with the existing silica rule simply by publishing a proposed rule without necessarily following that up with a final rule (Document ID 3580, Tr. 1471). While proposed rules may help to raise awareness and induce employers to comply in anticipation of a final rule, they do not give OSHA any authority to enforce the provisions of the rule. This is essentially another request for information sharing in lieu of regulation, and OSHA rejects it for the previously noted reasons.

Dr. Michael Marlow, an Affiliated Scholar at the Mercatus Center at George Mason University, offered the most comprehensive comment on OSHA's preliminary Need for Regulation chapter (Document ID 1819). Dr. Marlow noted, "While OSHA has made a reasonable general theoretical case for regulation, it fails to develop what an optimal regulation might look like" (Document ID 1819, p. 2). However, OSHA's purpose in the Need for Regulation chapter is simply to provide a general case for regulation. OSHA explains and justifies the rule in detail in the preamble and identifies and evaluates the regulatory alternatives in the Regulatory Alternatives chapter of the FEA and in the Final Regulatory Flexibility Analysis of the FEA.

Dr. Marlow did offer several criticisms of OSHA's justification for the need for regulation. For example, Dr. Marlow—as well as Mr. Danner of the National Federation of Independent Business (NFIB)—argued that OSHA's market failure evidence is too general and not specific to silica (Document ID 2210, p. 4). Dr. Marlow particularly noted that OSHA offered "little to no supporting evidence on the specifics of information problems directly associated with silica" (Document ID 1819, p. 3). OSHA disagrees. The Agency identified several characteristics of silica exposure risks that create information problems, including the inability to distinguish many diseases resulting from occupational silica exposure from ordinary diseases of life and frequently the long latency period from silica exposure to manifestation of disease. Further, concerning the inability of workers to process risk information, OSHA relied in large part on materials from the behavioral economics literature, which argues that the reported problems in risk processing are almost universal human biases. Hence, these risk processing problems would apply to employees working with silica.

Dr. Marlow also questioned the Agency's imperfect information arguments because, as OSHA acknowledges, many firms have already responded to the silica exposure risks facing their employees by voluntarily implementing control programs, some of which go beyond the requirements of the rule. Mr. Danner of NFIB offered a related criticism that OSHA failed to acknowledge that the Agency has already intervened in the market, with success (Document ID 2210, p. 4).

In OSHA's view, the fact that many employers have implemented controls to protect their workers does not contradict the Agency's market failure arguments to justify regulation. For example, the fact that some employers are aware of the occupational risks of respirable crystalline silica does not mean that all are, or that even for those who are knowledgeable there is sufficient economic incentive for them to protect their employees. The market fails even if only some employers fail to protect workers when the social benefits exceed the social costs, not just if all employers fail to protect workers. Furthermore, OSHA is statutorily obligated to provide "safe and healthful working conditions" to "*every* working man and woman in the Nation." (italics added) (29 U.S.C. 651(b)). The record includes numerous statements indicating that there are still many workers who did not understand the risks associated with working with silica until after they were exposed and permanently injured. See, e.g., hearing testimony of Mr. Ruiz, foundry worker (Document ID 3583, Tr. 2328 and 2332-2333); Mr. Mendoza, construction worker and New Labor Safety Liaison (Document ID 3583, Tr. 2465); Mr. Ward, bricklayer (Document ID 3585, Tr. 3016-3018); Mr. McNabb, former tile setter (Document ID 3585, Tr. 3023-3025 and 3054); Mr. Todd, bricklayer (Document ID 3585, Tr. 3030-3035; Mr. Barrett, terrazzo project manager (Document ID 3585, Tr. 3038 and 3055); Mr. Garcia Hernandez, construction worker and safety trainer (Document ID 3586, Tr. 3167 and 3230); J. Schultz (Document ID 3586, Tr. 3177); and Mr. Schultz, former foundry worker (Document ID 3583, Tr. 3197-3198). Kevin Turner, the Director of Safety for the East Division of Hunt Construction Group, noted that the dangers of silica are not as self-evident as other hazards:

> From my experience, … I don't even know if it's a misunderstanding, it's just lack of knowledge. …We're required to work with smaller businesses, various entities. A lot of those are literally a few folks and a pickup truck, and their knowledge of OSHA is minimal. * * * This is one of those things that typically it's just dust. Silica is not seen typically. You don't taste it. It doesn't have an odor. So in their minds, it doesn't exist; it's not an issue. It's not like falling 30 stories (Document ID 3580, Tr. 1468-1469).

Kellie Vazquez, Vice President of Holes Incorporated, also emphasized the lack of awareness of silica hazards:

> I think it is a lack of knowledge. I do think people think it is just dust. I was recently doing some safety audits … I saw two guys polishing inside of a garage dry, and they just had handkerchiefs wrapped around their face (Document ID 3580, Tr. 1470).

Some of the testimony also highlighted the efforts of some employers to avoid protection costs or shift them to workers in the absence of regulation, with the implication that they would continue to avoid providing protections absent OSHA requirements. Ms. Casillas-Pabellón, the Director of a day-laborer support group, New Labor, described employer efforts to limit worker access to information and safety equipment:

> Often, these contractors do not even give workers the correct company names, phone numbers, or they are giving workers fake names. The work is performed in neighborhoods far from where the workers live, or the workers don't speak the language, which becomes a challenge for workers to demand personal protective equipment or the right tools to perform their jobs. Workers are often left to their own devices and creativity to try to protect themselves or to perform daily job tasks (Document ID 3583, Tr. 2449-2450).

Under questioning from AFL-CIO representative Rebecca Reindel, construction worker Santos Armendariz acknowledged the pressures on employees to suppress the distribution of safety information:

> MS. REINDEL: . . . what happens when [workers who are not trained in safety] bring their safety concerns to their employers?
> MR. ARMENDARIZ: I think for the most part there is a lot of fear. People are afraid of losing their jobs … in a lot of the small companies, it’s very common that you see… a group of workers here one day and then it’s a different group the next day. And that’s because the boss doesn’t want to spend money (Document ID 3583, Tr. 2483-2484) .

Another construction worker, Jose Granados, concurred:

> in terms of your previous question about what would happen if we bring these issues [about worker exposure to silica dust] to the boss, I have done this in the past. I have brought these issues to his attention and the boss told me that I was crazy. And he told my co-workers not to listen to me because he said that I was crazy. And then he basically told me that I had to take more days off or sent me home for more days (Document ID 3583, Tr. 2485).

Finally, Dr. Marlow asserts that OSHA overstates its externality argument for regulation because the source of the externality is not silica exposure, but rather workers’ compensation and social insurance programs that shift the costs of silica exposure onto third parties. OSHA agrees that workers overexposed to silica are not the source of the externality, but the victims of it. The final rule is an attempt to help mitigate the effects of the externality using a method that is under OSHA's purview.

SUMMARY

OSHA's primary reasons for going forward with this final rule are based on the requirements of the OSH Act and are discussed in Section II of the preamble, Pertinent Legal Authority. As shown in the preamble to the final silica rule and this FEA, OSHA has determined that some workers in certain industries are exposed to silica and face a significant risk of developing silicosis, lung cancer, and end-stage renal disease. This section has shown that the private market— even when augmented by information dissemination programs, workers' compensation systems, and tort liability options—appears to still operate at a level of risk for these workers that is higher than socially optimal due to a lack of information about health risks, the presence of externalities or imperfect competition, and other factors discussed above.

CHAPTER III: PROFILE OF AFFECTED INDUSTRIES

INTRODUCTION

In this chapter, OSHA presents profile data for industries with potential silica exposure. As a first step, OSHA identifies the North American Industrial Classification System (NAICS) industries, both in general industry and maritime and in the construction sector, with potential worker exposure to silica. OSHA's final profile ranges from industries where worker exposure is documented and ongoing to industries where current occupational exposure is uncertain.[1] OSHA included preliminary profile data in the Preliminary Economic Analysis (PEA) and received public comment on those profiles. In this chapter, OSHA reviews the public comments on the preliminary profile and presents the Agency's response to those comments.

Next, OSHA provides revised summary statistics for the affected industries, including the number of affected entities and establishments, the number of workers whose exposure to silica could result in disease or death ("at-risk workers"), and the average revenue for affected entities and establishments.[2] This information is provided for each affected

[1] The following list explains how OSHA categorized the various industries potentially affected by OSHA's final rule:
Group 1: Industries identified in the technological feasibility sections as belonging to a given application group and whose silica samples encompass the bulk of the data points underlying the exposure profiles for that group.
Group 2: Industries for which some exposure samples are available for one or more activities for a given application group, but where the primary economic focus for these industries does not correspond to the primary focus of the application group. Captive foundries are the primary example. These exposure samples are included in one or more exposure profile for the application group and the extent of these activities is judged to be sufficient to add the industry to the list of affected industries and to include it in the cost and benefit estimates. The judgment about whether to include an industry in this group reflected whether industry representatives testified as to the potential for silica exposure in their industry.
Group 3: Similar to Group 2 except that the available samples and other industry information (from testimony or otherwise) were not sufficient to conclude that a significant number of establishments in the industry engage in activities corresponding to the application group. Although the sample data might be used for developing exposure profiles for the application group, the industry is not specifically added to the list of affected industries and is not included in the cost and benefit estimates. Also included in this group are industries for which OIS or IMIS silica sample data exist, but for which the data are insufficient to conclude that such exposures reflect regular, well-defined activities within these industries that have the potential for silica exposures. For industries in Group 3, a description of the industry and the existence of such data are mentioned qualitatively. Examples include NAICS 325314–Fertilizer (Mixing Only) Manufacturing; NAICS 339999-All Other Miscellaneous Manufacturing; and NAICS 423320-Brick, Stone, and Related Construction Material Merchant Wholesalers.

[2] The Census Bureau defines an establishment as a single physical location at which business is conducted or services or industrial operations are performed. The Census Bureau defines a business firm or entity as a business organization consisting of one or more domestic establishments in the same state and industry that were specified under common ownership or control. The firm and the establishment are the same for single-establishment firms. For each multi-establishment firm, establishments in the same industry

industry in total, as well as for small entities as defined by the Small Business Administration (SBA) and for small entities with fewer than 20 employees in each affected industry.

After analyzing the affected industries, OSHA presents silica exposure profiles for at-risk workers and addresses comments on silica exposure among unclassified construction workers and the effect of exposure variability on the profile of affected workplaces. These data are presented by sector and job category. Summary data are also provided for the number of workers in each affected industry who are currently exposed above the new silica PEL of 50 $\mu g/m^3$, as well as above an alternative PEL of 100 $\mu g/m^3$ for economic analysis purposes (while recognizing that the preceding PEL for construction is 250 $\mu g/m^3$). Then, OSHA examines its preliminary and final estimates to adjust for variables such as turnover rates and current baseline practices.

Finally, the Agency discusses methodological issues associated with calculating profit rates, profit, and revenue for affected employers. The factors associated with OSHA's use of survey data to support economic analysis are also discussed.

The methodological basis for the industry and at-risk worker data presented in this chapter comes from the PEA, the Eastern Research Group (ERG) analysis supporting the PEA (2007a, 2007b, 2008a, and 2008b), and ERG's analytic support in preparing this FEA. The data used in this chapter come from the rulemaking record (Docket OSHA-2010-0034), the technological feasibility analyses presented in Chapter IV of this Final Economic Analysis (FEA), and from (OSHA (2016), which updated the earlier PEA spreadsheets to reflect the most recent industry data available. To do so, ERG first matched the BLS Occupational Employment Statistics (OES) survey occupational titles with the at-risk job categories, by NAICS industry. They then calculated the percentages of production employment represented by each at-risk job title within industry (see OSHA, 2016 for details on the calculation of employment percentages and the mapping of at-risk job categorizations into OES occupations).[3] ERG's expertise for identifying the appropriate OES occupations and calculating the employment percentages enabled OSHA to estimate the number of employees in the at-risk job categories by NAICS industry (Id.).

---

within a state will be counted as one firm- the firm employment and annual payroll are summed from the associated establishments. (U.S. Census Bureau, Statistics of U.S. Businesses, Definitions. 2015, http://www.census.gov/econ/susb/definitions.html?cssp=SERP)

[3] Production employment includes workers in building and grounds maintenance; forestry, fishing, and farming; installation and maintenance; construction; production; and material handling occupations.

SELECTION OF NAICS INDUSTRIES FOR ANALYSIS

The technological feasibility analyses presented in Chapter IV of this FEA identify the general industry and maritime sectors and the construction activities potentially affected by the final silica standard. The following section discusses OSHA's preliminary methodology for profiling affected application groups in general industry and maritime, followed by public comments on the Agency's preliminary profile of general industry and maritime, and the Agency's final conclusions based on a review of the comments and updated data.

Hydraulic fracturing (HF), a major application group within general industry, is analyzed within a separate section, due to the lengthy and detailed comments provided by HF stakeholders in response to the PEA's treatment of that sector.

The final portion of this section addresses OSHA's preliminary profile of construction application groups, public comments on that profile, and the Agency's response to those comments.

General Industry and Maritime

Employees engaged in various activities in general industry and maritime routinely encounter crystalline silica as a molding material, as an inert mineral additive, as a refractory material, as a sandblasting abrasive, or as a natural component of the base materials with which they work. Some industries use various forms of silica for multiple purposes. As a result, employers are faced with the challenge of limiting worker exposure to silica in dozens of job categories throughout the general industry and maritime sectors.

For the PEA, job categories in general industry and maritime were selected for analysis based on data from the technical industrial hygiene literature, evidence from OSHA Special Emphasis Program (SEP) results, and, in several cases, information from ERG site visit reports. These data sources provided evidence of silica exposures in numerous sectors. While the available data were not entirely comprehensive, OSHA preliminarily concluded in the PEA that silica exposures in other sectors are quite limited.

The 25 industry application groups in the overall general industry and maritime sectors that OSHA identified in the PEA as being potentially affected by the proposed silica standard are as follows:

- Asphalt Paving Products
- Asphalt Roofing Materials
- Industries with Captive Foundries[4]
- Concrete Products
- Cut Stone
- Dental Equipment and Supplies
- Dental Laboratories
- Flat Glass[5]
- Iron Foundries[6]
- Jewelry
- Mineral Processing
- Mineral Wool[7]
- Nonferrous Sand Casting Foundries[8]

---

[4] Captive foundries is a subsector of the overall foundries industry described in Chapter IV of this FEA and includes establishments with foundry processes incidental to the primary products manufactured (e.g., heavy equipment manufacturing). Because the number of manufacturing establishments with captive foundry operations is not reported, ERG estimated the number of such establishments by industry using occupational employment information from BLS (2012) presenting, by industry, the number of employees in key foundry occupations. ERG identified those non-foundry industries reporting employment in the "pourers and casters, metal" and "foundry moldmakers and coremakers" occupational categories and then estimated overall employment in captive foundry operations by inflating the number of pourers and casters and foundry moldmakers and coremakers to account for other foundry workers. The Occupational Employment Statistics (OES) survey 6-digit NAICS-based estimates for foundries were then converted to 6-digit NAICS industries with employment in the key foundry occupations. See ERG (2008) for further discussion of the preliminary identification of industries and the development of estimates of the numbers of establishments in this subsector; see OSHA (2016) for the final identification of industries and estimates of the number of establishments.

[5] Flat glass is a subsector of the glass industry described in Chapter IV of this FEA. See also ERG (2008).

[6] Iron foundries are included within a subsector of the overall foundries industry described in Chapter IV of this FEA. See also ERG (2008).

[7] Mineral wool is a subsector of the glass industry described in Chapter IV of this FEA. See also ERG (2008).

[8] Nonferrous sand casting foundries are included within a subsector of the overall foundries industry described in Chapter IV of this FEA. See also ERG (2008).

- Non-Sand Casting Foundries[9]
- Other Ferrous Sand Casting Foundries[10]
- Other Glass Products[11]
- Paint and Coatings
- Porcelain Enameling
- Pottery
- Railroads[12]
- Ready-Mix Concrete
- Refractories
- Refractory Repair
- Shipyards
- Structural Clay

Based on a review of the record, including further analysis of OSHA's Occupational Safety and Health Information System (OIS) data, OSHA has added, for this FEA, the following application groups to the profile of affected employers.

- Engineered Stone Products
- Landscaping Contractors

---

[9] Non-sand casting foundries are found within a subsector of the overall foundries industry described in Chapter IV of this FEA. See also in ERG (2008).

[10] Other ferrous sand casting foundries are found within a subsector of the overall foundries industry described in Chapter IV of this FEA. See also ERG (2008).

[11] Other Glass Products is a subsector of the glass industry described in Chapter IV of this FEA. See also ERG (2008).

[12] While the railroad activities that can cause silica exposures are related to track work covered by OSHA's construction standard, OSHA is analyzing railroads in this section because railroads are mainly engaged in operating railroads, not in construction, and are usually grouped with other employers in "general industry" for purposes of economic analysis.

Public Comments on the Preliminary Profile of General Industry and Maritime

Several commenters stated that the PEA appeared to omit NAICS codes (i.e., industries) that would be affected by an OSHA silica standard.

Composite Manufacturing Processes

OSHA did not explicitly account for composite manufacturing processes in its preliminary profile. The American Composite Manufacturers Association questioned whether OSHA's preliminary cost and benefits estimates covered the composites industry manufacturing processes, but did not provide any additional data to assist OSHA in developing its profile of that industry (Document ID 1732, p. 1).

However, some composite manufacturers may have been included among the establishments profiled within two application groups: Cut Stone and Concrete Products. Composite manufacturing was included in NAICS 327999, All Other Miscellaneous Nonmetallic Mineral Product Manufacturing, which OSHA analyzed in the PEA for exposure, compliance costs, and other impacts facing employers and employees in the Concrete Products application group. Furthermore, composite manufacturing processes were addressed in the application group identified as Cut Stone in the PEA and all business entities in NAICS 327991, Cut Stone and Stone Product Manufacturing were included in OSHA's preliminary profile. For this final profile of the final silica rule, OSHA has again analyzed the impacts on the various composite manufacturing processes as part of the industries covered by the same two NAICS codes as in the PEA, but has updated the number of affected establishment and employees to the totals reported in the 2012 Economic Census.

Other Manufacturing

The National Association of Manufacturers (NAM) identified four NAICS codes that they believed were excluded from OSHA's preliminary profile.

> . . . we discovered that several NAM members have NAICS codes that OSHA did not include in the 24 subsectors listed, although these manufacturers know their employees work with silica-containing materials and may be exposed to silica. For example, we identified the following codes that were not included: 332215 (metal kitchen cookware, utensil, cutlery and flatware), 333249 (other industrial machinery manufacturing), 326191 (plastics plumbing fixture manufacturing), and 331529 (other non-ferrous metal foundries—except die-casting) (Document ID 3449, pp. 7-8).

OSHA notes that NAM was referencing the 2012 edition of NAICS and that of the four NAICS codes identified by NAM, two codes (331529 – other non-ferrous metal foundries—except die-casting and 332215 – metal kitchen cookware, utensil, cutlery and flatware) are in fact recognized in the PEA by their 2007 NAICS code (respectively, 332528 and 332214). For this FEA, OSHA has updated all NAICS codes to the 2012 edition.

The other two NAICS codes identified by NAM – 2012 NAICS, 333249, Other Industrial Machinery (2007 NAICS: 333220, 333292, & 333298); and 2012 NAICS 326191, Plastic Plumbing Fixtures (same code in 2007) – were not included in the PEA. For this FEA, OSHA reviewed the Agency's health sampling data from enforcement records for 1979-2014 (Document ID 3958; 4185) and found no significant respirable crystalline silica exposures associated with NAICS 326191 and 333249.[13] Therefore, OSHA concludes that no establishments in those two industries will be required to incur any costs to comply with the final standard, and OSHA is not attributing any benefits from the rule to these industries.

Electric Power Generation, Transmission and Distribution

The Edison Electric Institute (EEI) commented that the PEA did not include Electric Power Generation, Transmission and Distribution (NAICS 2211) within the profile of affected application groups (Document ID 2357, p. 39). As discussed in Chapter IV, Technological Feasibility, OSHA analyzed exposure data for the general industry tasks identified by EEI as potentially affected and the Agency determined that exposures during those tasks rarely if ever exceed the action level. Therefore, OSHA determined that NAICS 2211 will not be significantly affected by the final silica standard for general industry. For analysis of significant worker exposure in construction tasks undertaken by or for electric utilities, see the section titled Construction; Electric utilities later in this chapter.

[13] For NAICS 326191, Plastic Plumbing Fixtures, OSHA determined that there are exposure data for this NAICS code in the OIS (2011-2014) and no exposure data for this NAICS in the most recent Integrated Management Information System (IMIS) (2009-2014). Some IMIS activity on the NAICS code were identified for 1979-2002, and the establishment(s) appeared to be involved in the production of marble plumbing fixtures, such as vanities with marble counter tops, where the crystalline silica helped to create a "swirl" look of faux marble. However, based on discussions with industry experts, OSHA believes that employers in this segment of the industry have substituted away from silica.
For NAICS 333249, Other Industrial Machinery Manufacturing, OSHA determined that there are no data for this NAICS code in OIS (2011-2014); there are no data for this NAICS code in the most recent IMIS (2009-2014); and that results that are present in the "legacy" IMIS (1979-2002) and are in the more recent IMIS (2009-2014) for the legacy SIC codes associated with this NAICS code have little if any silica detected in samples or are engaged in industrial applications that are unlikely to involve significant silica exposures.

Auto Body Operations

In public testimony (Document ID 3587, Tr. 3718-3719) and in comments submitted for the record (Document ID 2358; 4019, p. 1; 4198, p. 1), the National Automobile Dealers Association (NADA) identified three NAICS industries that were omitted from OSHA's preliminary analysis but might potentially have silica exposures: NAICS 42311, 44111, and 811121. NADA stated the following in pre-hearing comments.

> Franchised automobile dealerships fall under North American Industry Classification System (NAICS) 44111 (SIC 5511) and commercial truck dealerships under NAICS 42311 (SIC 5012). The fact that neither of these NAICS codes is listed in OSHA's profile of affected industries is appropriate given that the overwhelming majority of dealership employees are rarely, if ever, exposed to airborne crystalline silica in their workplaces.
>
> At the same time, approximately 34% of automobile and truck dealerships involve auto body operations. This percentage has declined over time from approximately 60% in the mid-1980s. Dealership auto body operations are a profit center focused on motor vehicle collision and paint repair. These operations employ some 62,000 employees nationwide. The work taking place in auto body operations at franchised automobile and truck dealerships is similar to that at body shops falling within *Automotive Body, Paint, and Interior Repair, and Maintenance*, NAICS 811121 (SIC 7532). Notably, NAICS 811121 was also excluded from the proposal's profile of affected industries (Document ID 2358, p. 1).

NADA's concern was that historically the potential for airborne crystalline silica in auto body operations has been limited to two scenarios involving auto body technicians and painting prep workers: (1) sanding of vehicles and vehicle body panel surfaces and (2) the removal of paint or rust from vehicles or vehicle body panels. In those operations, small amounts of respirable crystalline silica were found in body fillers, paint system components, and abrasives (Document ID 2358, p. 4).

However, according to NADA, "[c]urrent work practices combined with the use of crystalline silica-free products and appropriate respiratory protection have served to largely eliminate any significant concerns regarding exposures to respirable crystalline silica in the auto body shop environment" (Document ID 2358, p. 2). Because significant exposures have largely been eliminated, NADA requested that OSHA exclude automobile dealerships and body shops from the scope of the rule on the grounds that silica exposures in these industries are *de minimis* (Document ID 2358, p. 3).

Because NADA has identified the continued presence, however minor, of silica in auto body shops in automobile and truck dealerships, OSHA in this final profile of affected industries has included NAICS 44111, 42311, and 811121 within the scope of the analysis to examine what costs the rule might generate for this industry.[14] In Chapter V, Costs of Compliance, in this FEA, OSHA addresses the compliance strategy, and associated costs, anticipated for the automobile industry. OSHA expects these costs to be incurred even if no auto body entity falling within these NAICS codes is ultimately determined to be within the scope of the rule.

Concrete Processing and Transportation

The National Concrete Masonry Association questioned the completeness of OSHA's preliminary profile of tasks in concrete plants:

> A number of position descriptions in a concrete block plant have exposure to respirable silica in outdoor storage and staging areas. These include those operating forklifts primarily for product transport, front-end loaders primarily for aggregate transport, and others associated with sorting/stacking and loading trucks (Document ID 2279, p. 6).

In the PEA, for the application group Concrete Products, OSHA addressed the broader group of material handlers as affected by the proposed standard; forklift operators are included within that group. In the final technological feasibility analysis, Chapter IV, fuller attention is given to baseline conditions and exposure reduction for material handlers, including forklift operators and other material transport personnel.

Closely associated with the manufacture of concrete products are the processing, transporting, and use of portland cement. The Portland Cement Association (PCA) requested that cement distribution terminals be excluded from the scope of the final rule because PCA survey data appear to indicate that "there is no probability that RCS [respirable crystalline silica] exposures can be generated above the proposed action limit among employees at cement terminals" (Document ID 3751, p. 2). In response, OSHA observes that NAICS 327310, Cement Manufacturing, and NAICS 423320, Brick, Stone, and Related Construction Material Merchant Wholesalers (within which cement terminals are classified), were not included within the preliminary profile. Due to the

[14] Because of the limited impacts expected for employers in these industries, NAICS 42311, 44111, and 811121 may not appear in all industry-wide tables throughout this FEA.

Agency's final determination that silica exposures in cement distribution terminals rarely exceed the action level (see Chapter IV of this FEA, for ready-mix concrete), NAICS 327310 and 423320 are not included in the final profile of affected industries.

Petrochemical Facilities

The American Fuel and Petrochemical Manufacturers (AFPM) questioned whether OSHA had adequately analyzed the impacts of the rule on oil refineries and petrochemical facilities employers, including AFPM members:

> Under normal production cycles, AFPM members do not work with silica related products and do not have employee exposure to RCS. During limited circumstances such as some maintenance, construction and turnaround activities, some of AFPM members' employees work in settings with the potential for exposure to RCS. Accordingly, our members have a substantial interest in this rulemaking . . . . (Document ID 2350, pp. 1-2).

Elsewhere in their comment, AFPM clarified that contracted construction operations at petrochemical facilities can create exposure to silica:

> The nature of the operations in the oil refining and petrochemical industries presents similar compliance difficulties that have not been taken into account in the NPRM. Facility turnarounds and large-scale construction projects require employers in these industries to contract construction, maintenance and repair work. Many of these activities will undoubtedly generate RCS in a variety of activities to levels that will trigger obligations under the proposed rule for both the contractor and the host employer. Yet the NPRM provides no comment and no economic or cost benefit analysis on this issue (Document ID 2350, p. 4).

In response, OSHA states that the PEA intended to include construction tasks conducted at oil and petrochemical plants within OSHA's preliminary profile if occupational exposure to silica prompted coverage under the proposed rule. However, the Agency recognizes that some construction tasks, including facility turnaround, may not have been thoroughly profiled for purposes of estimating costs and benefits for the PEA. For this FEA, OSHA has made every effort to ensure that all types of OSHA-regulated oil and petrochemical sites that are subject to the scope of the final rule are addressed in the final profile of affected workplaces and in the final analysis of costs and other impacts (including costs and impacts in construction), although it is still possible that some covered sites might not be included because of lack of information in the record.

Fertilizer Production and Distribution

The Fertilizer Institute (TFI) identified four NAICS codes that it believed were improperly excluded from OSHA's preliminary profile:

> First, although OSHA's economic analysis appears to have properly excluded [Mine Safety and Health Administration]-regulated entities from the range of NAICS codes in its economic analysis, it did not include an analysis of several fertilizer industries that may have activities that will fall within the scope of the Silica Proposal. For example, in the case of fertilizer production and distribution, TFI cannot rule out the possibility that certain companies in the Phosphate Fertilizer Manufacturing (NAICS: 325312), Nitrogenous Fertilizer Manufacturing (NAICS: 325311), Fertilizer (Mixing Only) Manufacturing (NAICS: 325314), and Farm Supplies Merchant Wholesalers (NAICS: 424910) could be affected by the Silica Proposal. Thus, unless OSHA adopts a clear threshold (*e.g.*, 5% of potentially-respirable crystalline silica) for triggering the operative provisions of a final rule, the incidental presence of naturally-occurring silica minerals in some fertilizer materials could require a much broader regulatory impact analysis. The same may be true within other industries that are anticipated to comment on the Silica Proposal (Document ID 2101, p. 11).

To investigate TFI's claim that the four NAICS industries identified in their comment (325311, 325312, 325314, and 424910) were erroneously omitted from OSHA's preliminary profile, the Agency searched inspection records for evidence of exposure samples in these industries for inclusion in the final profile. For NAICS 325314, Fertilizer (Mixing Only) Manufacturing, as noted in the Technological Feasibility section for Mineral Processing, OSHA identified silica exposure and determined that, at the time of sampling, the workers were performing tasks that were very similar to the tasks performed in Mineral Processing and therefore the NAICS code was appropriately included in the final profile of that application group.

However, for the other three NAICS codes, (325311, 325312, and 424910), OSHA determined that the available sample data and other industry information were not sufficient to conclude that a significant number of establishments in those industries engage in activities corresponding to Mineral Processing and that workers in those industries are exposed to respirable crystalline silica. Neither TFI nor any other commenter provided any sample data or other indication that workers in these NAICS codes are exposed to respirable crystalline silica in the course of their normal work. Therefore, OSHA did not include those three NAICS industries in the final profile.

Railroads

The International Brotherhood of Teamsters (IBT) identified several railroad job categories associated with maintenance-of-way track work where silica exposure can occur, including "laborers, machine operators, heavy equipment operators, on-track roadway maintenance machine operators, welders, and foremen" (Document ID 2318, p. 8). In the PEA, OSHA identified two main job categories, Ballast Dumper and Machine Operator, where significant silica exposures have been recorded. Within the Machine Operator category, OSHA's preliminary industry profile and technological feasibility analysis recognized ballast regulators, broom operators, tamper operators, and other operators.

For this FEA, OSHA evaluated the potential for silica exposure among all affected railroad job categories, including those listed above by IBT, and the Agency determined that, as in the PEA, Ballast Dumper and Machine Operator are the job categories whose workers face significant risk of silica-related disease. Therefore, in this final profile and in the technological feasibility analysis in Chapter IV, OSHA identifies the number of affected workers in the Ballast Dumper and Machine Operator job categories that were sampled for silica exposure and the distribution of these populations across exposure ranges (see Tables III-8 and III-9, below; and OSHA, 2016). OSHA recognizes that a number of workers could be nearby and thus exposed during ballast dumping activities, but they are accounted for in this analysis because they would either be considered engaged in the ballast dumping activities (categorized as ballast dumpers or operators) and protected by the required controls or the employer would ensure that they would not be exposed to silica because they would be removed to a safe area during the dust-producing portions of ballast dumping activities in accordance with the written exposure control plan required by paragraph (g) of the construction standard.

Mineral Wool

The North American Insulation Manufacturers Association questioned OSHA's source of data used in developing the Agency's preliminary profile of the Mineral Wool application group. They asserted that OSHA's PEA "included mineral wool manufacturing in its analysis of the glass industry, along with flat glass manufacturing, other pressed blown glass and glassware manufacturing, and glass container manufacturing," but complained that OSHA's exposure data were drawn from a subset of those activities:

> [N]o actual mineral wool manufacturing facility data was used for OSHA's baseline conditions and exposure profile for the larger glass industry. Rather, OSHA used only data from two National Institute for

> Occupational Safety and Health ("NIOSH") reports summarizing site visits to two large flat glass manufacturing facilities and an OSHA Special Emphasis Program ("SEP") inspection report concerning a large glass products facility. Together these provide 12 silica exposure measurements divided between two employee categories: (1) "Material Handlers" and (2) "Batch Operators and associated workers, including workers performing housekeeping/maintenance in the vicinity of such operations." OSHA used only these 12 exposure samples to develop baseline conditions and an exposure profile for the entire and diverse glass industry. Based on this sparse information, OSHA determined that exposures in these two job categories could exceed the proposed PEL and made feasibility findings for the entire glass industry.
>
> In sum, OSHA's data does not present substantial evidence for its feasibility conclusions regarding the Mineral Wool Industry. NAIMA requests that OSHA modify its PEA with an acknowledgement that none of its data came from the Mineral Wool Industry
> (Document ID 2348, pp. 18-19)(citations omitted).

In response, OSHA notes that in the PEA, Mineral Wool Manufacturing (NAICS 327993) was included in the profile as an affected industry, with an exposed worker population of 1,090 employees in 195 entities operating 321 establishments (100 percent of the entities and establishments reported by the Census Bureau). For this FEA, the 2012 Economic Census is the basic source of OSHA's estimate of affected workers, entities and establishments (see Table III-6). Chapter IV, Technological Feasibility, Section IV-11, Glass, presents details for OSHA's final exposure profile for affected workers in mineral wool manufacturing; see Table III-8 for a summary of the final exposure profile.

Determination of industries affected by the general industry and maritime standard

As described in the PEA, based on the ERG analysis (2008b), OSHA identified the six-digit NAICS codes for these subsectors to develop a list of industries potentially affected by the proposed silica standard.[15] In some cases, such as in the foundry and glass industries, affected sectors discussed in ERG (2008b) were disaggregated to facilitate the

---

[15] For the PEA, ERG (2008) discussed potential silica exposures in the engineered stone and landscape contracting industries. These industries were judged to generate negligible levels of silica exposure in the United States and, as a result, no compliance costs were estimated for these industries. Accordingly, these industries were not shown in the remainder of the scope, cost, and impact tables in the PEA.

For this FEA, OSHA identified silica exposure at levels that warranted further consideration in terms of potential impacts under the scope of the final rule. See Section IV-9, Engineered Stone, and Section IV-13, Landscape Contracting, in Chapter IV of this FEA for a full exposition of the exposure profile and analysis of control technology to reduce exposure to silica for Engineered Stone and Landscape Contracting.

cost and economic impact analysis in the PEA and in this FEA. Table III-1 presents OSHA's final set of affected application groups along with their corresponding six-digit NAICS industries.

When evaluating Table III-1 in relation to OSHA's preliminary profile of affected application groups, the following two points must be understood.

First, OSHA is aware that many industries have some silica exposure below the action level. Such industries will incur no costs as a result of the final rule. OSHA has only provided more explicit consideration of such industries when information for those industries entered the record, but the absence of discussion of exposures in an industry does not indicate that OSHA intended to exempt employers in that industry from compliance with the silica standard if it turns out that significant exposures exist. In other words, lack of record evidence showing significant exposures in the past, or affirmative evidence of exposures well below the action level, does not mean that an industry is permanently outside the scope of the rule if, in reality, their employees are, or will foreseeably be, subject to exposures at or above the action level once the rule goes into effect.

Second, OSHA's review of the rulemaking record leads the Agency to conclude that, while there may be some inevitable over- and under-inclusion of industries and over- and under-estimation of exposure levels, the costs and benefits estimated in this FEA are based on the best available evidence. The possible effects of occasional exposure in an industry on economic feasibility will be discussed in Chapter VI: Economic Feasibility Analysis and Final Regulatory Flexibility Determination.

Table III-1: General Industry and Maritime Application Groups and Industries Affected by OSHA's Final Silica Rule

Application Group	NAICS	Industry
Asphalt Paving Products	324121	Asphalt paving mixture and block manufacturing
Asphalt Roofing Materials	324122	Asphalt shingle and coating materials mfg.
Captive Foundries	331110	Iron and steel mills and ferroalloy mfg.
	331210	Iron and steel pipe and tube mfg. from purchased steel
	331221	Rolled steel shape manufacturing
	331222	Steel wire drawing
	331314	Secondary smelting and alloying of aluminum
	331420	Copper rolling, drawing, extruding, and alloying
	331492	Secondary smelting, refining, and alloying of nonferrous metal (except copper and aluminum)
	332111	Iron and steel forging
	332112	Nonferrous forging
	332117	Powder metallurgy part manufacturing
	332119	Metal crown, closure, and other metal stamping (except automotive)
	332215	Metal kitchen cookware, utensil, cutlery, and flatware (except precious) manufacturing
	332216	Saw blade and handtool manufacturing
	332439	Other metal container manufacturing
	332510	Hardware manufacturing
	332613	Spring manufacturing
	332618	Other fabricated wire product manufacturing
	332710	Machine shops
	332911	Industrial valve manufacturing
	332912	Fluid power valve and hose fitting mfg.
	332913	Plumbing fixture fitting and trim mfg.
	332919	Other metal valve and pipe fitting mfg.
	332991	Ball and roller bearing manufacturing
	332996	Fabricated pipe and pipe fitting mfg.
	332999	All other miscellaneous fabricated metal product manufacturing

Table III-1: General Industry and Maritime Application Groups and Industries Affected by OSHA's Final Silica Rule (Continued)

Application Group	NAICS	Industry
Captive Foundries (contd.)	333318	Other commercial & service industry machinery manufacturing
	333413	Industrial and Commercial Fan and Blower and Air Purification Equipment Manufacturing
	333414	Heating Equipment (except Warm Air Furnaces) Manufacturing
	333511	Industrial Mold Manufacturing
	333514	Special Die and Tool, Die Set, Jig, and Fixture Manufacturing
	333515	Cutting Tool and Machine Tool Accessory Manufacturing
	333517	Machine Tool Manufacturing
	333519	Rolling Mill and Other Metalworking Machinery Manufacturing
	333612	Speed changer, industrial high-speed drive, and gear manufacturing
	333613	Mechanical power transmission equipment manufacturing
	333911	Pump and pumping equipment manufacturing
	333912	Air & gas compressor manufacturing
	333991	Power-driven handtool manufacturing
	333992	Welding & soldering equipment manufacturing
	333993	Packaging machinery manufacturing
	333994	Industrial process furnace and oven mfg.
	333995	Fluid power cylinder and actuator mfg.
	333996	Fluid power pump and motor manufacturing
	333997	Scale and balance manufacturing
	333999	All other miscellaneous general purpose machinery manufacturing
	334519	Other measuring and controlling device manufacturing
	336111	Automobile manufacturing
	336112	Light truck and utility vehicle manufacturing
	336120	Heavy duty truck manufacturing
	336211	Motor vehicle body manufacturing
	336212	Truck trailer manufacturing
	336213	Motor home manufacturing
	336310	Motor vehicle gasoline engine and engine parts manufacturing

Hydraulic Fracturing

OSHA received a disproportionate amount of comments on the profile characteristics for, and economic effects of the standard on, hydraulic fracturing in the oil and gas extraction industry. The review of the preliminary industry profile of hydraulic fracturing presented below is lengthier than the profile discussion for any other affected application group for two reasons: (1) the preliminary profile for hydraulic fracturing involved uniquely complex challenges for modeling the production activities on an oil and gas well drilling site, and (2) because of those production modeling complexities, detailed stakeholder commentary required OSHA, in turn, to reevaluate a number of the model's methodological assumptions and adjust the profile where necessary.

In this section, OSHA presents a brief description of the hydraulic fracturing application group and its activities. OSHA then identifies the NAICS industries with potential worker exposure to silica during hydraulic fracturing. Next, OSHA (1) reviews the preliminary summary statistics for the affected entities and establishments, and the average revenue for affected entities and establishments (2) discusses public comments concerning OSHA's preliminary profile, and (3) addresses the issues on the industrial profile of hydraulic fracturing raised by commenters.

The information in this profile is provided for each affected NAICS industry in total, as well as for small entities as defined by SBA. Finally, in this profile of hydraulic fracturing, OSHA provides other production estimates that will be useful for subsequent cost estimates. The following paragraphs summarize production and process information on the industry; see the PEA and Chapter IV, Technological Feasibility, of this FEA for a fuller discussion of these topics.

Hydraulic fracturing is a process used to extract natural gas and oil deposits from shale and other tight geologic formations. The process begins once well drilling is complete. Workers in the oil and gas industry pump fracturing fluid, composed of base fluid (usually water); a proppant (usually sand); and chemical additives, into the new well bore under extremely high pressures (e.g., 7,000 psi to 9,000 psi) (Esswein, 2012, Document ID 1578). The high pressure fractures the shale or rock formation, allowing the natural gas trapped in the formation to flow into the well. Silica sand that is used as a proppant contains a high percentage of crystalline silica, typically ranging from 60 percent to 100 percent depending on the source (Halliburton MSDS, 2008, Document ID 1529; Carmeuse MSDS, 2009, Document ID 1525). Therefore, when silica sand is used as a proppant in hydraulic fracturing, high concentrations of respirable silica dust can become airborne as workers deliver, convey, and mix the sand with fracturing fluid. [16]

Hydraulic fracturing crews work as a team that travels from well site to well site. Individual workers are specialized and have defined roles. Those whose jobs keep them in the central area near the sand-handling equipment can experience high levels of respirable silica exposure. Ancillary workers who have work locations on the perimeter can experience elevated silica exposures, although they are not in the immediate vicinity of the dust emissions. Workers whose jobs either do not require entry into the central work area or only require entry intermittently experience variable exposure depending on the amount of time they spend near dusty activities.

Hydraulic Fracturing -- Affected Industries by NAICS

Oilfield activities are classified primarily into five NAICS codes, but only one encompasses hydraulic fracturing:

- NAICS 211111 (Crude Petroleum and Natural Gas Extraction)
- NAICS 211112 (Natural Gas Liquid Extraction)
- NAICS 213111 (Drilling Oil and Gas Wells)
- NAICS 213112 (Support Services for Oil and Gas Operations)
- NAICS 333132 (Oil and Gas Field Machinery and Equipment Manufacturing)

U.S. Census (Census Bureau, 2015b) identifies NAICS 213112 (Support Services for Oil and Gas Operations), as the industry that includes the establishments involved in hydraulic fracturing. This NAICS code also captures a range of other oilfield service activities (other oil and gas field services; oil and gas exploration services; oil and gas well surveying; cementing oil and gas wells; and running, cutting, and pulling casings,

[16] Hydraulic fracturing crews frequently spend several days performing active hydraulic fracturing at a site where a well has several zones, with additional days for equipment setup and removal on the days before and after hydraulic fracturing. The stay can be longer when multiple wells are located at the same site. Once the job is complete, the crew moves onto another site, where the process is repeated. The hydraulic fracturing process is a relatively brief phase of well installation, which can take three or four months, including site preparation, drilling, installing pipelines, and the initial stages of environmental reclamation (Rader, 2102, Document ID 1535). Over this period, a number of different specialized work crews will occupy the site, often for overlapping periods. During hydraulic fracturing several dozen workers can be on the site, but most work occurs outside the central sand-handling zone, which is only occupied by fracturing sand workers. The number of fracturing sand workers typically ranges from a half-dozen to two dozen, depending on the size of the project and whether multiple hydraulic fracturing crews are involved. A crew of ten to twelve workers is typical (STEPS, 2012, Document ID 1537).

The worksite around the wellhead is known as the well pad. The size of the well pad will vary, depending on the location, but it is typically between 1.5 and 5.7 acres. A well pad may contain one well, but it has become common to drill multiple wells from a single well pad (NYSDEC, 2011, Document ID 1595).

tubes, or rods) designed to support oilfield exploration or to supplement the production from oil and gas wells. In 2012, hydraulic fracturing represented 21.6 percent of the economic activity in NAICS 213112 (Census Bureau, 2015b). Table III-2 presents the seven- and eight-digit NAICS service divisions within NAICS 213112 where significant shipment values were reported.

Discussions held by ERG with industry personnel and a review of the available literature confirm the Census data: hydraulic fracturing is performed almost entirely by oilfield service contractors that are classified in NAICS 213112. These contractors are employed by oil and gas firms. Some industry contacts also mentioned that a few oil and gas producers own and deploy their own fracturing crews, but noted that the share of fracturing activity performed by oil and gas firms is negligible. Therefore, in the analysis in both the PEA and this FEA, OSHA has ignored the portion of hydraulic fracturing that might be performed by oil and gas production companies and focused on NAICS 213112. OSHA requested comment on the size and scope of hydraulic fracturing performed by oil and gas production companies; public comments are presented below.

The character of the hydraulic fracturing application group is blurred by the additional services the companies engaged in hydraulic fracturing might provide. At the large firms, extensive engineering and well management services are often provided. Firms also manufacture some well equipment and otherwise reflect the diversity of activities in the oilfield. In an online business publication produced by Dun & Bradstreet, some of the largest entities are classified in multiple NAICS codes (Dun & Bradstreet, 2013, Document ID 1569).[17] These NAICS designations might be accurate, as the various companies engage in a range of oilfield activities.

Even among the smallest firms, companies performing hydraulic fracturing might also offer various well services (e.g., acidizing, where acid pumped into the formation helps to improve flow) that might help keep low-pressure wells producing. Most of these other activities offered by the smallest firms, however, are within the coverage of NAICS 213112.

[17] As information provided to both Dun & Bradstreet and Census is self-reported by the employer and is not subject to audit, some of the listings or data might be erroneous and subject to revision at each publication cycle.

Table III-2: Product Line Breakdown for Support Services for Oil and Gas Operations (NAICS 213112)

Product code	Industry	Value of shipments for the product code (1,000)	Percentage of Industry Value (%)[a]
213112	**Support activities for oil & gas operations**	**$80,766,512**	**100%**
21311235	Other oil & gas field services	$41,383,751	51.2%
21311233	**Hydraulic fracturing of oil & gas wells**	**17,465,941**	**21.6%**
213112W	Support activities for oil & gas operations, not specified by kind	9,515,774	11.8%
21311231	Cementing oil & gas wells	3,397,211	4.2%
21311232	Oil & gas well surveying & well logging	3,114,888	3.9%
21311234	Running, cutting, & pulling casings, tubes, or rods	2,987,921	3.7%
21311211	Oil & gas field exploration services	2,901,026	3.6%

[a] Total does not equal the sum of components as result of rounding.

Characteristics of Affected Entities and Establishments

Number of Entities

Based on discussions with industry contacts, a review of the literature by ERG, and an examination of websites advertising hydraulic fracturing services, OSHA estimated in the PEA that approximately 200 entities (firms) were engaged in hydraulic fracturing. Three large companies accounted for approximately 30 percent of the hydraulic fracturing market (measured in dollar volume of fracturing activity), whereas a second tier of approximately 10 firms served a substantial share of the remaining market, had sufficient equipment to handle the largest hydraulic fracturing jobs, but did not provide the same range of technical services as the largest three firms. A third tier consisted of approximately 40 to 50 firms that also had capability for large hydraulic fracturing jobs but were not as widely active across oil and gas regions in the United States.

In the preliminary analysis, the final, fourth tier consisted of small, possibly single-crew, hydraulic fracturing companies that only had sufficient capacity to handle minor, low-

[18] U.S. Census Bureau, 2012 Economic Census, Table EC1221I2: Mining: Industry Series: Product or Service Statistics for the U.S. Census.

pressure refracturing jobs on conventional oil and gas wells.[19] All of the major oil and gas producing regions host a number of these very small hydraulic fracturing firms, and although no reliable figures were identified, OSHA, based on ERG's interviews with industry representatives, estimated that there were approximately 150 of them. Employment within these small companies can be as low as 20 or fewer workers, as very small hydraulic fracturing jobs might be accomplished with as few as 5 or 6 workers. With additional administrative and technical support personnel, it is estimated that the smallest firm size would require at least 10 employees. One industry contact noted that it is possible that some operations are run by sole proprietors who then assemble a temporary hydraulic fracturing crew for individual jobs (ERG, 2013b). The frequency of this arrangement was not known and was likely very limited because of the difficulty of assembling a sufficiently experienced crew for individual jobs.

Number of Establishments

To estimate the number of establishments in the hydraulic fracturing application group, ERG examined the company websites of some of the largest firms in that group in order to gauge the approximate number of establishments each firm operated. While the small firms are almost certainly operating in one or two locations, ERG noted that the largest firms operate up to 30 locations in the United States. From these data and discussions with experts on hydraulic fracturing, ERG estimated the number of establishments per entity across various size classes in order to derive the aggregate number of affected establishments. Using these judgments, ERG estimated that the 200 entities in hydraulic fracturing operate 444 establishments and 530 fleets (the operational unit for hydraulic fracturing entities). OSHA relied on these estimates in the PEA, and the estimates supporting this calculation were shown in Table A-4 in the PEA and are reproduced below in Table III-3.[20]

[19] Refracturing is an operation to restimulate a well after an initial period of production. It is performed to restore well productivity to near original or even higher rates of production and to extend the productive life of a well (Schlumberger, 2013).

[20] The discussion in the previous section referred to three large hydraulic fracturing companies accounting for 30 percent of the market (in terms of dollar volume). As shown in Table III-3, four hydraulic fracturing companies (entities) have an estimated employment of 500 or more workers per entity.

Table III-3: Estimated Number of Hydraulic Fracturing Establishments and Fleets in OSHA's PEA

Employee Size Category	Estimated Number of Entities in Hydraulic Fracturing	Estimated No. of Establishments per Entity	Total Establishments	Total Fleets
10-19	100	1	100	100
20-99	50	1.2	60	60
100-499	46	4	184	184
500+	4	25	100	186
Total	**200**		**444**	**530**

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on ERG, 2013b.

In its comments, the American Petroleum Institute and the Independent Petroleum Association of America (API/IPAA or "the Associations") presented data on typical fleet size and numbers of affected employees.

> OSHA's estimate that there are 530 hydraulic fracturing fleets with 15.6 million [hydraulic horsepower] HHP operating in the United States (derived from a 2012 analysis by PacWest Consulting Partners) may be a reasonable estimate for 2012, but it is not the most current or accurate estimate. As noted in PacWest's more recent May 2013 analysis of aggregate pumping capacity, domestic hydraulic fracturing capacity was projected to increase by 700,000 HHP from the 2012 estimate utilized by OSHA and ERG, "bringing total US capacity to 16.3 million HHP," by the end of 2013. Our recent discussion with another well-regarded source of industry financial information, Richard Spears, generally corroborates this estimate regarding the increase in industry capacity by the end of calendar year 2013.
>
> PacWest, however, did not estimate the number of fleets it associated with the increase aggregate pumping capacity. Applying the 4.29% increase in HHP that PacWest reported between 2012 and 2013 to its earlier estimate that 530 fleets operated in 2012, the best available evidence strongly suggests that there are now approximately 553 hydraulic fracturing fleets operating in the United States. Importantly, the 23-fleet increase between 2012 and 2013 is further ratified by dividing the total reported HHP increase of 700,000 by OSHA's estimate of "30,000 horsepower for a typical fleet."

> While we appreciate the difficulty in affixing an estimate to a changing demographic, we believe that OSHA must rely on the most recent data available from the sources on which it bases its analysis. As such, the Associations request that OSHA update its employment/fleet profile, and all calculations derived therefrom, based on this "best available evidence" (Document ID 2301, pp. 18-19)(citations omitted).

As indicated in the PEA, the Census data are not sufficiently precise to isolate the hydraulic fracturing component from the larger NAICS (213112) covering oilfield services. Nevertheless, OSHA did not base the estimated size distribution of the hydraulic fracturing application group on Census or other published data. OSHA notes that API/IPAA's number of fleets does not vary significantly from the estimate that OSHA used in the PEA: the available data on the number of fracturing fleets, as estimated by PacWest, placed the number at 530 fleets while API/IPAA offered an estimate of 553 fleets. OSHA judges these totals to be roughly consistent with the establishment estimates below given that larger establishments will likely operate more than one hydraulic fracturing fleet.

OSHA is not accepting API/IPAA's higher estimate for the number of fleets because there is no record evidence to support API/IPAA's hypothesis that employers increased their fleet size in response to a single-year snapshot of increased pumping capacity. API/IPAA's estimate is extrapolated entirely from a 4.29 percent increase in aggregate pumping capacity that the commenters argued reflected an upturn in the hydraulic fracturing industry several years ago, occurring after the timeframe of OSHA's estimate, that theoretically could have caused employers to increase their number of fleets. But although API/IPAA shared feedback from its member organizations about actual increases in crew size, it did not provide any such evidence that an increase in fleets actually followed the increase in aggregate pumping capacity, or that the aggregate pumping capacity has remained at that level. In fact, even if the hydraulic fracturing employers had increased their fleets during a brief upturn in the industry, by the same logic the employers would also decrease the number of fleets during a downturn in the industry. While the industry did experience growth in recent years, there is no evidence that the growth continued. OSHA therefore concludes that the estimates of establishments and fleets based on objective third-party data, the source of which is not disputed by the commenter, provides better evidence of production activity in the industry than API/IPAA's manipulation of that data based on extrapolations and assumptions based on a short period of past growth. (However, see Chapter VI of this FEA for a discussion of the uncertainties concerning the future of the hydraulic fracturing industry.)

Table III-4 presents the estimated number of hydraulic fracturing firms and establishments; all entities in the table will be affected by the final standard.[21] Table III-4 is identical to Table III-3, as there are no changes from OSHA's preliminary estimates.

Table III-4: Final Estimate of the Number of Hydraulic Fracturing Establishments Affected by the Final Rule

Employee Size Category (Entity)	Estimated Number of Entities Specializing in Hydraulic Fracturing	Estimated No. of Establishments per Entity	Total Establish-ments	Total Fleets
10-19	100	1	100	100
20-99	50	1.2	60	60
100-499	46	4	184	184
500+	4	25	100	186
Total	**200**		**444**	**530**

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA, 2016.

Number of Employees

API/IPAA also addressed OSHA's estimates of the numbers of employees involved in hydraulic fracturing:

> The Associations further believe that OSHA and ERG underestimated the average number of workers in the "large crews" required for deeper, more complex, higher pressure fractures with horizontal components, and that this difference in the size of large crews should also change OSHA's estimates regarding the size of a "typical" or average crew. OSHA estimated that large crews employ between 15 and 20 workers and assigned a midpoint estimate of 17.5, but never explained the basis for this estimate. Elsewhere, OSHA provided its understanding of the functional

[21] As discussed above, API/IPAA commented that an estimate of 150 small entities was unaccountably changed into an estimate of only 100 small entities. In the table below, however, the 150 'small' entities were always intended to include the entities in both the 10-to-19 and the 20-to-99 size categories. Among the establishments in the 20-to-99 category, ERG judged that these firms were clustered at the lower end of that category. The term 'small' was that used by ERG's industry consultants and was not based on the Small Business Administration's definition or any other precise definition. Neither ERG nor other sources could provide detailed information on the size distribution of hydraulic fracturing firms.

distribution of a “typical hydraulic fracturing crew,” consisting of 16 workers:

Estimated Number of Workers	**Primary Function**
5	Sand Mover Operators
1	Conveyor Belt Tender
2	Blender Tenders
1	Hydration Unit Operator
2	Water/Chemical Hands
3	Pump Operator Technicians
1	Supervisor
1	Ground Guide (Sand Coordinator)
16	

Members of the Associations have stated that crew size and functional distribution are variable depending on region, well size, depth, pressure needs, complexity, and company policies. While they viewed the distribution above as a reasonable portrayal of a hydraulic fracturing crew generally, they did not view it as an accurate portrayal of a “large crew.” In particular, members of the Associations stated that large fracturing jobs frequently require more than five sand movers – sometimes as many as eight or more, with one sand mover operator per sand mover. A large fleet and the crew that is a part of that fleet will thus have more than the five sand mover operators shown in the table above; we would estimate six to be an appropriate average. Similarly, OSHA’s profile incorrectly assumes only one hydration unit operator in the crew. On a large crew, however, there are commonly three to four hydration unit operators. Members of the Associations further reported that “large crews” would likely have up to five pump operator technicians, and, if two blenders were in use, could have twice as many blender tenders [as] well. Additionally, large crews would also likely include repair and maintenance personnel and other technicians and support personnel. As such, the Associations believe it is more accurate to estimate that a large hydraulic fracturing fleet typically contains between 20 and 25 workers, and, in some cases, even more. We will assume 24 as the average crew size for a large crew, and we request that OSHA utilize a similar figure for its estimate of “large crew” size.
* * *

In the Table below, we estimate total industry employment of 29,368 hydraulic fracturing workers in the crews working with these fleets.

Fleet Size	Avg. # Workers Per Crew	# Primary Crews Per Fleet	# Rotation/Relief Crews Per Fleet	# Fleets	Total # of Workers
Small	8	1	0	104	832
Medium	16	2	1	255	12,240
Large	24	2	1 1/2	194	16,296
					29,368

(Document ID 2301, pp. 18-22)(citations omitted)

OSHA finds this analysis convincing and is increasing the number of crews per fleet in response to the higher estimates of employees presented by the Associations. In the PEA, OSHA estimated hydraulic fracturing-specific employment based on an estimated average crew size of 16 workers, allowing for two crews per fleet on average. This calculation was intended to take into account both single crew (daytime-only crews) and around-the-clock hydraulic fracturing operations in which three crews (day, night and relief crews) would be assigned to a single fleet of equipment, resulting in a total of 16,960 workers across 530 fleets. For this final profile, OSHA finds that the average number of crews per fleet is likely to be larger than two because the small crews and firms represent a smaller share of all activities than was estimated in the PEA. OSHA has therefore increased the fleet size in its final estimate to an average of three crews per fleet. Table III-17 presents the breakdown of employment by job function in OSHA's final profile of hydraulic fracturing.

As noted earlier, however, the Associations criticized OSHA's estimate of 16,960 workers, arguing that the largest crews were larger than OSHA's preliminary estimates, and OSHA has accepted the Associations' estimates on fleet sizes. For this final profile, OSHA concluded that the average number of crews per fleet is likely to be larger than two because the small crews and firms represent a smaller share of all activities than was estimated in the PEA. Allowing for three crews per fleet, the total hydraulic fracturing industry employment is estimated to be 25,440 workers. The difference between OSHA's final employment estimate (25,440) and the Associations' employment estimate (29,368) is explained by the estimates of industry fleets (OSHA, 530 fleets; the Associations, 553 fleets).

Hydraulic fracturing - Small Entity definition

When OSHA was preparing the PEA, the SBA definition of a small entity for NAICS 213112, Support Activities for Oil and Gas Operations, was a firm that earns receipts no greater than $7 million per year. Examining the 10-19 employee size category, OSHA noted in the PEA that an entity averaging $25,000 per hydraulic fracturing job would only earn the industry-wide Census Bureau per-firm estimate of $2.1 million per year if it performed 84 small hydraulic fracturing jobs per year,[22] or substantially less than the upper limit of the SBA small entity definition. If these small hydraulic fracturing jobs typically only require one day to complete, then such a firm would have a utilization rate for its hydraulic fracturing equipment of 23 percent of the days of the year. A firm with a less conservatively low utilization rate, namely a rate three times as high (69 percent), would generate $6.3 million per year, or nearly the small business revenue limit (ERG, 2013b). Because firms with revenue of that amount would still meet the SBA's definition of a small entity, OSHA preliminarily concluded that all 100 entities with 10-19 employees would qualify as small entities under the SBA criteria.

For firms in the 20-99 employee size category, however, OSHA preliminarily concluded that only a fraction were appropriately categorized as small businesses.[23] OSHA noted in the PEA that the average reported revenues were calculated at $5.9 million. Nevertheless, OSHA's conclusion in the PEA was that this revenue amount was too low. Most of the firms in this size category are likely to compete for new well completion work, which is considerably more lucrative than the small refracturing jobs. Most new wells require fracturing of multiple stages (sections of the well), with one to three stages often being performed per day.[24] A typical single stage of a new well fracturing job is estimated to generate roughly $100,000. One hydraulic fracturing company reported that its annual average revenue per stage for 2011was $136,335 (FTSI, 2011, Document ID 1583).

As a result, OSHA noted in the PEA that the average revenue figures in the Census data appeared to be substantially too low. A firm in the 20-99 employee size category, if performing new well fracturing, would have performed only 52 stages before reaching the average revenue level and 70 stages of work before reaching the small business size limit. While it is possible that a few firms would fall below the SBA size limit, OSHA

---

[22] $2.1 million per year/$25,000 per job = 84 jobs.

[23] OSHA could not estimate a precise percentage of firms in this category that are small as defined by SBA, but believes that the percentage is low for the reasons discussed below.

[24] A stage in hydraulic fracturing refers to the completion of the fracturing process for a given geologic zone and section of drill pipe. Shallow wells might require only one stage while most deep wells and horizontal wells require fracturing of more than ten zones and thus more than ten stages.

judged in the PEA that the large majority of firms in this size category would exceed the small business revenue limit of $7 million per year.

API/IPAA provided extensive comments on OSHA's preliminary analysis of impacts on hydraulic fracturing, including questioning OSHA's calculation of the number of small entities in that industry. The Associations "largely [found] OSHA's assumptions for the economic profile to be rational and supportable" (Document ID 2301, pp. 15). However, they stated:

> . . . we have concerns that OSHA and ERG may have underestimated the number of smaller entities in the hydraulic fracturing industry, and therefore also underestimated the proportion of the hydraulic fracturing industry that is made up of small entities. While both ERG and OSHA note that certain "very small frac jobs might be accomplished with as few as 5 or 6 workers," and that "small fracking crews commonly range from 6 to 10 workers," OSHA assumed that there were no hydraulic fracturing companies with less than 10 workers.
>
> In addition to concluding that there are no hydraulic fracturing entities with less than 10 employees, OSHA and ERG appear to have changed their initial estimate that there are 150 "very small fracking firms" that can "handle only minor, low-pressure refracturing jobs on conventional oil and gas wells." These 150 very small firms that can handle only minor jobs on conventional wells presumably must have between 10 and 19 employees because the next larger size class (firms with 20 to 99 employees), "compete for new well completion work, which is considerably more lucrative than the small refracturing jobs."
>
> But, without any explanation, OSHA in Table A-4 of Appendix A contradicted the Agency's earlier estimate that there are 150 of these very small firms with between 10 and 19 employees that constitute SBA "small entities," and showed instead in the first row of the table that there are only 100 such firms. This is confusing. * * * Instead of using the 150-entity estimate that was proffered and discussed by both ERG and OSHA, every subsequent analysis conducted by ERG and OSHA was based on an industry profile that only contains 100 entities with between 10 and 19 employees.
>
> . . . The Associations fully appreciate the difficulty of compiling a profile of the hydraulic fracturing industry in the absence of Census data delineated with a discrete NAICS code, and we generally believe that ERG and OSHA made fair assumptions and estimates. However, in this instance, we are concerned that small entities may be undercounted and underrepresented in the industry profile. As such, the Associations request that, at a minimum, OSHA amend its analysis to reflect its initial estimate

> (recommended by ERG based on its research), that the hydraulic fracturing industry includes 150 entities with between 10 and 19 employees (Document ID 2301, pp. 15-16)(citations omitted).

The Agency's PEA estimate was that 150 entities (100 with fewer than 20 employees and 50 with 20-99 employees) were limited to small jobs. In the 2014 SBA Table of Small Business Size Standards, SBA redefined a small entity for NAICS 213112, as a firm that earns receipts no greater than $38.5 million per year.[25] Now that the SBA has raised that cutoff for being considered a small entity in this industry to $38.5 million in receipts, all of those 150 entities are small business entities as defined by SBA. The revenue estimates for hydraulic fracturing businesses, including small entities, are presented in more detail in the Revenue and Profit section later in this chapter.

OSHA therefore concludes that, for purposes of the regulatory flexibility screening analysis, all 150 entities in the 10-99 employee size category (see Table III-4) are capable of performing hydraulic fracturing work and yet are small enough to remain below the SBA small business cutoff of $38.5 million in annual receipts.

To support the small business analysis, OSHA examined the activities of entities with fewer than 100 employees. OSHA concluded that there were no significant number of hydraulic fracturing entities with fewer than 10 employees, and therefore focuses in this FEA on the next higher employee size categories of firms, those with 10 to 19 employees and 20 to 99 employees. Moreover, OSHA concludes that only a negligible number of firms in the next larger size category (100-499) would also be small entities.

Construction

The construction sector is an integral part of the nation's economy, accounting for approximately 4.5 percent of total private sector employment.[26] Establishments in this industry are involved in a wide variety of activities, including land development and subdivision, homebuilding, construction of nonresidential buildings and other structures, heavy construction work (including roadways and bridges), and myriad special trades such as plumbing, roofing, electrical, excavation, and demolition work.

---

[25] The 2014 revision to the SBA size standard for NAICS 213112 was retained for the 2016 SBA table of size standards. See U.S. Small Business Administration, Table of Small Business Size Standards Matched to North American Industry Classification System Codes, 2016. **https://www.sba.gov/sites/default/files/files/Size_Standards_Table.pdf**.

[26] 2012 County Business Patterns (NAICS), http://censtats.census.gov/cgi-bin/cbpnaic/cbpsect.pl. 5,260,942 paid employees, NAICS 23, Construction; 115,938,468 paid employees, all sectors.

Construction activities were selected for analysis based on historical data of recorded samples of construction worker exposures from the OSHA IMIS and the National Institute for Occupational Safety and Health (NIOSH). In addition, OSHA reviewed the industrial hygiene literature across the full range of construction activities and focused on dusty operations where silica sand was most likely to be fractured or abraded by work operations. These physical processes have been found to cause the silica exposures that pose the greatest risk of silicosis for workers (See Table III-8: Distribution of Silica Exposures by Application Group and Job Category or Activity – Final Profile, and Chapter IV, Technological Feasibility, for details on exposures in construction operations).

In the PEA, the 12 construction activities, by job category, that OSHA identified as being potentially affected by the proposed silica standard as follows:

- Abrasive blasters
- Drywall finishers
- Heavy equipment operators
- Hole drillers using hand-held drills
- Jackhammer and impact drillers
- Masonry cutters using portable saws
- Masonry cutters using stationary saws
- Millers using portable or mobile machines
- Rock and concrete drillers
- Rock-crushing machine operators and tenders
- Tuckpointers and grinders
- Underground construction workers.

Based on the ERG Technological Feasibility Study for Construction (ERG, 2008a), the PEA recognized that these construction activities occur in the following construction industries, accompanied by their four-digit NAICS codes:

- 2361 Residential Building Construction
- 2362 Nonresidential Building Construction
- 2371 Utility System Construction

- 2372 Land Subdivision
- 2373 Highway, Street, and Bridge Construction
- 2379 Other Heavy and Civil Engineering Construction
- 2381 Foundation, Structure, and Building Exterior Contractors
- 2382 Building Equipment Contractors
- 2383 Building Finishing Contractors
- 2389 Other Specialty Trade Contractors

In addition, the PEA noted that some public employees in state and local governments are exposed to elevated levels of respirable crystalline silica. These employees were included in the construction sector because their exposures are the result of construction activities. As discussed earlier in this chapter, OSHA requested comment on which other industries, if any, perform construction work outside the construction sector that involves worker exposure to respirable crystalline silica, and the amount of such work performed. The public comments related to these questions, and OSHA's response to those comments, appear below.[27]

Public Comments on the Preliminary Profile of Construction

Four-digit versus six-digit NAICS codes

In the PEA, OSHA used four-digit NAICS codes, rather than six-digit NAICS codes, in its economic analysis of the construction sector. OSHA had selected the broader four-digit codes both because of limitations in the BLS's Occupational Employment Statistics Survey and IRS data on profitability. The National Association of Home Builders (NAHB) noted that more recent versions of both data sets contain "somewhat more detail," and NAHB objected to OSHA's method of mapping affected construction contractors to four-digit NAICS:

> For example, the mapping produces no costs for electrical or plumbing and [heating, ventilation, and air conditioning] HVAC contractors—two large subcategories of the specialty trades that each has hundreds of thousands of employees…
>
> Electrical and plumbing/HVAC contractors [6-digit NAICS codes] account for roughly 93 percent of all employment in the 4-digit NAICS

[27] For a detailed discussion of changes to the scope of the analysis of affected construction application groups, see Chapter IV-5 of this FEA.

code for Building Equipment Contractors (according to the BLS Quarterly Census of Employment and Wages for 2012). Assuming away all assessment costs for 93 percent of employees (which is inconsistent with the general language of the proposed rule) but including them in the base revenue and profits is one of the ways the PEA produces unrealistically low estimates of costs as a share of revenue and profits for Building Equipment Contractors (Document ID 2296, p. 17).

OSHA acknowledges NAHB's point about relying on four-digit NAICS information and in this final profile has applied occupational data at the six-digit NAICS level now that such information is available. However, it is not the case that OSHA uses the revenue and profit base of the entire industry while using costs only in affected establishments. In each industry OSHA uses the costs and revenues per establishment as compared to costs to the establishment. As in the PEA, OSHA analyzes cost impacts per establishment-wide revenue and profit, a micro analysis that presents greater precision than NAHB's implied alternative that involved estimation of revenue and profit shares associated with the percentage of affected occupational categories within entire NAICS codes but overlooks the firm-specific technological distinctions recognized by OSHA's analysis of construction activities. OSHA also notes that its change to the scope of the final construction standard is intended to exclude workers who are only occasionally exposed to silica at low levels, making it even more likely that NAHB's approach would over-estimate the costs of the rule.[28]

OSHA's Treatment of Specialty Trades

Landscapers

NAHB identified several job categories that would be affected by the OSHA silica rule. Among these affected job categories is Landscapers, a group preliminarily judged in the PEA to "generate negligible levels" of respirable crystalline silica (see PEA III-4, fn 11):

> Home builders, as well as remodelers, typically subcontract the majority of their construction work. On average, 25 specialty trade subcontractors are used to build a single-family detached house. A major reason for subcontracting is due to the increasing complexity, features, and amenities supplied with new homes that require specialized expertise that trade [contractors] have. Below are some of the job categories, mostly performed by Specialty Trade Contractors, for which workers are potentially exposed to respirable crystalline silica in the residential construction industry (*i.e.,* home building):

[28] See the discussion below on OSHA's final profile of low-silica exposed construction trades.

. . .

- Landscapers – cutting pavers, stone, rock, concrete, and installation for patios and moving soil during landscaping activities. (Document ID 2296, p. 33)[29]

---

[29] For this comment response, OSHA focused on landscapers because this occupation is one that would represent a unique addition for the final profile. NAHB's complete list of job categories is as follows, but each of the other silica-related activities are already encompassed in the final profile

- Brick and Block Masons – cutting and installing brick and block, as well as mixing mortar, and possibly disturbing ―in-place mortar (*i.e.*, tuck pointing).
- Stone Masons / Exterior Façade Applicators – cutting and installing/fixing stones to structure.
- Concrete Mixing – mixing water, cement, sand, and gravel.
- Concrete Installers – handling, depositing, and placing concrete.
- Concrete Finishing – moving concrete horizontally into final position and finishing, such as screeding, bullfloating, jointing, floating, troweling, patterned-stamping the surface, and sawing control or expansion joints.
- Tile and Marbles Installers – cutting performed onsite and installation of tile and marble for floors, countertops, and walls, and also mixing grout.
- Stucco Installers – mixing stucco material and applying to the structure.
- Counter Installers – cutting performed onsite and installing granite and quartz countertops.
- Siding Installers – sawing, cutting, and installing cementitious siding (*i.e.*, fiber-cement siding).
- Demolition Crew – jack hammering, cutting, and grinding materials such as concrete, bricks, blocks, drywall, and plaster.
- Laborers / clean-up crew – dry sweeping that is likely to be performed in basements or garages after saw cutting.
- Electricians – drilling holes through concrete, block, and siding to run conduit.
- HVAC Installers – drilling holes through concrete (*i.e.*, basement walls), block, and siding to run conduit.
- Plumbers – drilling holes through concrete or block for water and drain lines.
- Roofers – cutting and installing concrete and clay tiles on roofs.
- Landscapers – cutting pavers, stone, rock, concrete, and installation for patios and moving soil during landscaping activities.
- Drywall Installers – installing (*i.e.*, hanging) drywall (also known as plasterboard, wallboard, gypsum board, sheetrock, or gyprock) and cement board, which is used in lieu of drywall in some rooms in a home, such as a bathroom.
- Drywall Finishers – finishing (*i.e.*, taping, texturing, and sanding) of drywall and cement board.
- Carpenters – drilling into concrete to attach framing.
- Heavy Equipment Operators – equipment operators (*i.e.*, backhoe, bulldozer, grader, skid steer loader/Bobcat) moving soil during land development and landscaping activities.
- Rock/well drilling – boring or drilling in the ground to access groundwater in underground aquifers.
- Iron Workers – erecting and installing pre-cast concrete beams, columns and panels.
- Deck builders – mixing concrete for post footings.
- Construction Managers – supervising the construction project's progress, which may include: obtaining construction work permits; ordering materials; overseeing trade contractors; troubleshooting emergencies; and scheduling walk-throughs/inspections of a jobsite (Document ID 2296, pp. 33-34).

In a profile supporting the PEA, ERG (2008) discussed potential silica exposures in the landscape contracting industry. This industry was judged to generate negligible levels of silica exposure in the United States and, as a result, no compliance costs were estimated for landscaping contractor employers and the industry was not included in the PEA.

After reviewing the record, including testimony and post-hearing comments from NAHB (Document ID 3587; 3750) on remodeling activities associated with residential sites and evidence pointing to the likelihood that exposures can reach significant levels, OSHA has elected to include landscaping contractors in this final industry profile, the final technological feasibility analysis (see Chapter IV, Section IV-13 of this FEA), and the final analysis of costs and economic impacts. Accordingly, OSHA includes NAICS 561730, Landscaping Services in this final profile of affected industries and elsewhere throughout this final economic analysis.[30]

With respect to the other job categories identified in NAHB's comment, OSHA's final exposure profile and technological feasibility analysis in Chapter IV evaluate the significance of exposure for all construction trades potentially affected during residential remodeling and other construction activities.

Exhibit III-A below presents the final set of construction activities analyzed for technological feasibility and the associated Table 1 tasks in the NPRM and the final rule. For the technological feasibility analysis of all construction tasks not addressed by Table 1, see Chapter IV-5, Technological Feasibility for the Construction Industry.

Exhibit III-A: Construction Activities Analyzed for Technological Feasibility in Relation to Table 1 of the Final Silica Rule.

Final Table 1 Equipment / Task	NPRM Table 1 Equipment/Task	FEA Construction Activity (Technological Feasibility chapter sections)

[30] OSHA judged that Landscaping Services qualified as a general industry application group (and not a construction application group) due to the typical work performed—remodeling and renovation.

(i) Stationary masonry saws	Using Stationary Masonry saws	5.7 Masonry Cutters Using Stationary Saws
(ii) Handheld power saws (any blade diameter)	Using Hand-Held Masonry Saws	5.6 Masonry and Concrete Cutters Using Portable Saws
(iii) Handheld power saws for cutting fiber-cement board (with blade diameter of 8 inches or less)	Using Hand-Held Masonry Saws	5.6 Masonry and Concrete Cutters Using Portable Saws
(iv) Walk-behind saws	Using Portable Walk-Behind or Drivable Masonry Saws	5.6 Masonry and Concrete Cutters Using Portable Saws
(ix) Vehicle-mounted drilling rigs for rock and concrete	Operating Vehicle-Mounted Drilling Rigs for Rock **and** Operating Vehicle-Mounted Drilling Rigs for Concrete	5.9 Rock and Concrete Drillers
(v) Drivable or ride-on concrete saws	Using Portable Walk-Behind or Drivable Masonry Saws	5.6 Masonry and Concrete Cutters Using Portable Saws
(vi) Rig-mounted core saws or drills	Using Hand-Held Masonry Saws	5.6 Masonry and Concrete Cutters Using Portable Saws
(vii) Handheld and stand-mounted drills (including impact and rotary hammer drills)	Using Rotary Hammers or Drills (except overhead)	5.4 Hole Drillers Using Handheld or Stand-Mounted Drills
(viii) Dowel drilling rigs for concrete	Using Hand-Held Masonry Saws	5.9 Rock and Concrete Drillers
(x) Jackhammers and handheld powered chipping tools	Using Jackhammers and Other impact Drillers	5.5 Jackhammers and Other Powered Handheld Chipping Tools
(xi) Handheld grinders for mortar removal (e.g., tuckpointing)	Tuckpointing	5.11 Tuckpointers and Grinders
(xii) Handheld grinders for uses other than mortar removal	Using Hand-Operated Grinders	5.11 Tuckpointers and Grinders
(xiii) Walk-behind milling machines and floor grinders	Milling	5.8 Millers Using Portable or Mobile Machines
(xiv) Small driveable milling machine (less than half-lane)	Milling	5.8 Millers Using Portable or Mobile Machines

Exhibit III-A: Construction Activities Analyzed for Technological Feasibility in Relation to Table 1 of the Final Silica Rule, continued

Final Table 1 Equipment / Task	NPRM Table 1 Equipment/Task	FEA Construction Activity (Technological Feasibility chapter sections)
(xv) Milling machines (half-lane and larger with cuts of four inches in depth or less)	Milling	5.8 Millers Using Portable or Mobile Machines
(xvi) Crushing machines	Rock Crushing	5.10 Mobile Crushing Machine Operators and Tenders
(xvii) Heavy equipment and utility vehicles used to abrade or fracture silica-containing materials (e.g., hoe-ramming, rock ripping) or used during the demolition of concrete or masonry structures	Use of Heavy Equipment during Earthmoving	5.3 Heavy Equipment Operators and Ground Crew Laborers
(xviii) Heavy equipment and utility vehicles for tasks such as grading and excavating but not including: demolition of concrete or masonry structures or abrading or fracturing silica-containing materials	Use of Heavy Equipment during Earthmoving	5.3 Heavy Equipment Operators and Ground Crew Laborers

Electricians, carpenters, plumbers, and other low-silica exposed trades

Commenting on OSHA's preliminary profile for construction, the Construction Industry Safety Coalition (CISC), comprised of 25 construction trade associations, made similar points as the NAHB critique of OSHA's estimate of the scope of construction tasks affected by the proposed rule as being under-inclusive:

> OSHA has inexplicably omitted from the Agency's analysis of the economic costs and impacts of the Proposed Standard at least 1.2 million additional workers in the construction industry who also routinely perform dusty tasks on silica-containing materials. These workers – members of large construction trades such as plumbers and plumber helpers, roofers, electricians and electrician helpers, and including specialty trades such as plasterers and stucco masons and helpers and tile and marble setters – perform tasks identical or similar to those performed by occupations included by OSHA in the Agency's cost analysis such as bricklayers, concrete finishers and construction laborers. Together the additional occupations increase OSHA's base estimate of the affected construction workforce by more than one-third.
>
> Not only do workers in these additional occupations engage in some of the single tasks used by OSHA to identify other at-risk occupations (e.g., drilling holes in concrete or masonry to affix anchors as performed by carpenters), they are known to perform multiple silica-generating tasks during the course of their work day. For example, an electrician may both drill pass-through holes in masonry or other silica-containing construction materials using a hand-held drill and also open silica-containing wall, ceiling, and floor surfaces to install, repair or replace wiring, equipment, or fixtures (Document ID 4217, p. 73).

In post-hearing comments, CISC acknowledged that the 19 occupations OSHA identified in the PEA addressed the majority of the drilling, cutting, breaking, abrading and other construction work with silica-containing materials that result in potential silica exposures, but CISC also stated that "many other construction occupations also perform such tasks and generate sometimes significant silica exposures" (Document ID 4217, p. 74). They claimed that OSHA's approach made two types of omissions:

- OSHA has failed to include other occupations that include large numbers of construction workers who routinely engage in drilling, cutting, breaking and abrading of masonry and other silica-laden materials, albeit often for fractions of worker time smaller than many (but not all) of OSHA's selected occupations.

- OSHA's profile for carpenters, one of the largest construction occupations addressed in the Agency's analysis, includes only hole-drilling into masonry materials for the purpose of affixing anchors, while failing to include other silica-exposure-generating tasks commonly performed by carpenters such as sawing through masonry; demolition or removal of silica-containing walls, ceilings or floors; drilling through brick, block or plaster for the purpose of passing something through the hole rather than affixing an anchor; grinding or otherwise abrading surfaces such as stone countertops or plaster and lath walls; and more. These additional tasks may individually amount to small fractions of a carpenter's work day, but most carpenters will perform one or more of such tasks at least weekly, if not daily. Taken together, these additional at-risk tasks contribute to an increased exposure profile in which the typical carpenter is spending several times more than the 1% of his work year that OSHA estimates performing dusty tasks.

> The additional construction occupations that we include in cost analysis account for 1.26 million additional workers beyond OSHA's occupations, and the additional carpenter time that we also include results in three times as many affected carpenter FTEs as OSHA estimates among the 860,000 carpenters and helpers (Document ID 4217, Appendix B, p. 10).

To address the first type of omission alleged by CISC (failing to include other occupations that include large numbers of construction workers engaged in silica tasks for short periods of time), OSHA compared exposure data for "classified" and "unclassified" sources of silica exposure from the Agency's OIS inspection files (2011-April 2014). Classified sources were defined as exposure samples that could be grouped by NAICS into an application group or industry and could be identified as part of a job category associated with that application group or industry (for examples, an abrasive blasting operator in the Cut Stone application group, categorized in NAICS 327991 - Cut Stone and Stone Product Manufacturing); whereas unclassified sources were defined as samples that could not be classified by NAICS into an application group, or by job description into a job category associated with an application group (for example, a carpenter employed in NAICS 238310 - Drywall and Insulation Contractors, where the job description may have been excluded from the inspection report). Significantly, data are unclassified because of lack of data, not because these unclassified sources of silica exposure represent new application groups that have not been covered. Because of the complexity of American industry, it is almost inevitable that there will occasionally be silica exposures as a result of rare instances where a person does silica related work without being classified in a relevant occupation in government statistical data sources.

As shown in Table III-10 later in this chapter, OSHA determined that for 56 OIS construction data samples where classification was not possible, 41 samples, or 73 percent, were below the 50 μg/m^3 PEL, compared with 55 of 107 samples, or 51 percent, for exposure data where classification was possible.[31] From this review of recent OSHA inspection data, OSHA concluded that for the majority of exposures where the encounter with silica is so incidental or scattered as to lack classification in the inspection records, risk levels for those atypical encounters would fall below the level of significance.[32] Because the use of silica in the industries that are unclassified is very rare, the viability of these industries will not be threatened by this rule.

For the second type of omission alleged by CISC, carpenters, OSHA notes that the PEA included Carpenters as an occupational category in the application group, Hole drillers using hand-held drills. For this FEA, OSHA has assigned the Carpenters job category to two tasks, Hole Drillers Using Hand-Held Drills and Masonry Cutters using Portable Saws (see OSHA, 2016). Based on OIS exposure data (see Chapter IV), OSHA has concluded that, other than those two job categories, carpenters are not significantly exposed to silica during sawing or demolition activities and therefore carpenters are not included in the final profile for those activities.

In order to address questions concerning the worker categories newly identified by CISC, OSHA has expanded the preliminary profile of construction trades to include new trade categories, while determining that other silica-related activities identified by CISC were captured in the PEA. Specifically, OSHA has added plumbers, electricians, sheet metal workers, and their helpers to the hole drilling task (which already included carpenters and carpenter helpers); terrazzo workers and finishers to the milling task; and roofers and their helpers to the stationary masonry saw task in response to CISC comments. OSHA did not include any additional tasks that commenters claimed for these workers because the Agency's technological feasibility analysis indicates that these tasks do not generate hazardous levels of respirable crystalline silica and commenters provided no exposure data or other evidence to support the need to include them in this analysis.

The Agency also notes that it has modified the scope of the construction standard so that the final rule excludes exposure "where employee exposure will remain below 25 micrograms per cubic meter of air (25 μg/m^3) as an 8 hour time-weighted average (TWA) under any foreseeable conditions" (paragraph (a) of the standard for construction). As

[31] Also shown in Table III-10 is a distribution of exposures for unclassified general industry OIS samples. Of 169 unclassified general industry samples, (excluding abrasive blasting) 119samples (70 percent) were below 25μg/m^3 and 21 samples (12 percent) were between 25μg/m^3 and 50 μg/m^3.

[32] For a complete discussion of OSHA's use of OIS data for the final silica exposure profile, see Chapter IV-01, Technological Feasibility – Introduction,

discussed in the summary and explanation of that scope provision, OSHA's analysis of the rulemaking record indicates that a substantial number of employees in the construction sector perform tasks involving occasional, brief exposures to respirable crystalline silica that are incidental to their primary work. Where employees perform tasks that involve exposure to respirable crystalline silica for a very short period of time, OSHA finds that exposures for many tasks are below 25 $\mu g/m^3$ as an 8-hour TWA. Therefore, OSHA expects that a significant proportion of employers of employees in these groups will be excluded from the standard.

The Associated Builders and Contractors (ABC) raised objections, similar to those of NAHB and CISC, to what they viewed as an incomplete preliminary profile.

> One of the main problems with OSHA's economic analysis is it omitted 1.5 million workers who perform tasks that could expose them to respirable crystalline silica. For example, OSHA has omitted plumbers, roofers and electricians—all of whom perform tasks similar to those of carpenters and [plasters] who were included in the cost estimate. OSHA's analysis left out a significant portion of the workforce, by adding in these occupations it increases OSHA's estimate of the affected construction workforce by about 50 percent (Document ID 2289, p. 5).

Several other groups provided examples of other construction tasks that they believed would be impacted by the rule and should therefore be included in industry profiles. ABC identified specific construction tasks – cement mixing, overhead drilling, handling of paving stones and compaction of interlocking pavers – that it believed were improperly excluded from OSHA's preliminary profile of affected application groups (Document ID 2289, p. 3).

With respect to ABC's concerns about excluded construction tasks, OSHA notes that in the final technological feasibility analysis (see Chapter IV), cement mixing was included within the application group Concrete Products; overhead drilling was included within the application group Hole Drillers using Handheld Drills; and in the application group Landscape Contracting, interlocking paving was included but handling of paving stones was excluded based on comments by the Interlocking Concrete Paving Institute (Document ID 2246, p. 8-10).

The National Electrical Contractors Association (NECA) also submitted a list of tasks potentially affected by the proposed rule (Document ID 2295, p. 3):

- Overhead anchor drilling and installation
- Floor, sidewalk and asphalt cutting

•Installation and demolition of concrete-encased electrical duct-banks
•Mixing, pouring and finishing of concrete pads for equipment and transformer
•Light pole base installation
•Underground excavations in all types of soil where rock and dust are encountered
•Anchoring of equipment on poured-in-place concrete walls and block masonry walls
•Exposure to conveyors and equipment in production and manufacturing plants that uses and as raw materials for the finished product when maintenance and servicing is being performed
•Sand blasting equipment for renovations
•Cutting drywall and wall board for the installation of boxes and fixtures
•Core drilling of concrete floors and walls for conduit penetrations
•Working adjacent to areas where concrete and wall finishers are sanding and grouting
•Working in surface and underground mines where raw material is extracted from the earth
•Working in underground tunnels
•Earthmoving equipment operations

NECA further stated (id.): "This list does not include all electrical construction activities that may also result in exposures greater than OSHA proposed PEL limits. All of these tasks are usually performed on an intermittent basis. Employee exposure is minimal and with the right training, employees are qualified to protect themselves and those around them."

The Building and Construction Trades Department, AFL-CIO (BCTD) also identified several categories of exposed construction workers (Document ID 4223, pp. 39-40):

- Terrazzo workers and finishers (47-2053)
- Plumbers and plumber helpers (47-2152 and 47-3015)
- Roofers (47-2180)
- Painters and helpers (47-2141).

It is important to note that while OSHA did not explicitly identify "painters and helpers" by name, it did consider workers performing abrasive blasting. OSHA included an additional 15,446 full-time equivalent (FTE) construction workers performing abrasive blasting in its total FTEs for all industry sectors. The FTEs performing abrasive blasting were distributed between the categories Building and Finishing Contractors (11,043 FTEs) and Other Specialty Trade Contractors (4,403 FTEs).

- Sheet Metal Workers (47-2210)

> As the testimony demonstrates, when the workers in these classifications are engaged in silica-generating tasks, their potential exposures may be intense, and they therefore must be covered by the provisions of the proposed standard. However, because only a limited number of such workers are engaged in silica-generating tasks and their exposures are brief or intermittent, the addition of these workers to OSHA's cost assessment should not have a significant impact on OSHA's cost estimate.

OSHA has expanded the profile of affected workers to include the job categories identified by BCTD that OSHA determined potentially involve substantial silica exposure. See Tables III-8 and III-9 below, OSHA, 2016, Chapter IV, Technological Feasibility, and Chapter V, Costs of Compliance, for the presentation of OSHA's final profile of affected construction workers and the categorization of construction occupations within Table 1 tasks.

By the same token, OSHA has not expanded the profile where it concludes that the types of workers identified by CISC, ABC, NECA, as well as NAHB, as improperly excluded from the scope of the analysis are not for the most part significantly exposed to silica. As will be discussed in greater detail below under Silica Exposure Profile Of At-Risk Workers and in Chapter IV, Technological Feasibility, OSHA reviewed exposure data from the Agency's inspection database and other sources (e.g., NIOSH and ERG site visits) and determined that for silica exposure samples where neither the NAICS code nor the job category could be classified within the preliminary profile, 73 percent of the readings (41 samples of 56 total) were below the new PEL of 50 μg/m^3. In order to address the remaining 27 percent of workers, OSHA has expanded the preliminary profile of construction trades to include new trade categories, while reviewing the PEA and determining that other silica-related activities identified by commenters were already captured in the PEA. Specifically, as previously noted, OSHA has added, in response to CISC comments, the following occupations potentially affected by the final rule: plumbers, electricians, sheet metal workers, and their helpers; terrazzo workers and finishers; and roofers and their helpers. See OSHA (2016).

Concrete segmental retaining wall installation

The National Concrete Masonry Association (NCMA) identified the installation of concrete segmental retaining wall (SRW) systems as an activity that would bring NCMA contractors under the scope of the proposed standard (Document ID 2279, p. 10). In the final technological feasibility analysis, drilling and cutting of SRW systems are broadly grouped within tasks involving brick, concrete, stone, and related landscaping materials;

these general industry tasks are addressed in Chapter IV, section IV-13, Landscape Contracting. Where installation of SRW systems constitutes construction, sections IV-29, Masonry Cutters Using Portable Saws, IV-30, Masonry Cutters Using Stationary Saws, and IV-32, Rock and Concrete Drillers address the feasible controls for protecting employees of NCMA contractors and other construction employers from exposure to silica. Tables III-8 and III-9 in this chapter present the distribution of exposures for the job categories in these application groups and the exposure distribution for affected NAICS divisions, while Chapters V and VI present, respectively, OSHA's final estimate of compliance costs and economic impacts for the affected NAICS divisions within general industry and construction.

Construction laborers

The Laborers Health and Safety Fund of North America cautioned OSHA to not overlook the risks from exposure to silica facing laborers on construction projects:

> Laborers often work in and near silica hazards created by other trades (e.g., operators, blasters, cement masons). Laborers also operate dust-creating equipment (e.g., jackhammers, chipping guns, handheld grinders and drywall sanders). Whether it is due to helping other trades, operating heavy equipment, mortar mixing or housekeeping, laborers have a unique and often overlooked exposure profile. Their hazard exposure can be driven as much by their bystander experience as their task or tool use. This can lead to laborers being omitted from respiratory protection planning. Therefore, we strongly support requiring the use of controls for all dust-generating tools and providing protection to everyone in the defined work area. We believe these proactive measures will go a long way toward protecting workers whose exposure profiles are difficult to characterize but nonetheless very real (Document ID 2253, pp. 1-2).

Chapter IV, Technological Feasibility, of this FEA addresses exposure to silica among laborers as a distinct group, and Chapter V, Costs of Compliance, of this FEA specifically estimates the number of construction laborers directly involved in silica-generating tasks and estimates compliance costs for those workers as a distinct group. For construction laborers not directly engaged in silica-generating tasks, OSHA anticipates that after the final rule is issued, silica exposure among these laborers will be minimized through the use of engineering and administrative controls, including written exposure control plans, to such an extent that few if any additional controls will be needed to reduce exposures indirectly impacting laborers. Nonetheless, to the extent construction laborers are covered by the final standard through ancillary requirements alone, OSHA addresses costs for those requirements in Chapter V, Costs of Compliance.

Public employees

The American Federation of State, County and Municipal Employees (AFSCME) submitted comments addressing silica exposure among public employees in construction and in general industry:

> AFSCME represents approximately 275,000 members employed in public works, maintenance and highway departments. These workers perform many tasks that expose them to silica, including highway maintenance and repair, masonry work, sidewalk and concrete repair or removal, sandblasting and other abrasive blasting, excavation and earth removal, and bridge repair and maintenance. Other members are exposed to silica while engaged in maintenance and repair activities in school and university settings. Because these public employees perform various tasks in diverse settings, both the silica general industry and construction standards apply.
>
> AFSCME's concern for public employee exposure to silica is substantiated in published literature. We submitted with our testimony, *Highway Repair: A New Silicosis Threat,* (Valiante et al. American Journal of Public Health; May 2004, Vol 94, no.5) [footnote omitted]. In that study, researchers found that large populations of highway workers are at risk of developing silicosis. Their conclusions stated the need for engineering controls, medical screenings and protective health standards to protect workers from occupational disease related to silica exposure.
>
> Although our public works and highway workers are the most likely to be exposed to silica, employees in other job classifications also risk exposure. For example, we represent workers employed in dental facilities in public health and university settings. These workers face potential exposure while making certain dental molds (Document ID 4203, pp. 1-2).

OSHA recognizes that this rule will have an indirect effect on public employees through adoption of the rule by states that have state plans applicable to state employees (Section 18 of the OSH Act requires authorized state plans to cover public employees "to the extent permitted by law," 29 U.S.C. 667(c)(6)); there are twenty-six such states, ranging in size from Vermont to California, plus Puerto Rico and the US Virgin Islands. Although the rule itself is not directly applicable to public employees, and OSHA cannot enforce it in the public sector, the Agency generally considers costs and benefits in this sector for this reason. With respect to AFSCME's last point, OSHA notes that in the PEA, dental technicians in dental laboratories were included within the profile of affected job categories. For this final economic analysis, OSHA evaluated silica exposure among dental technicians and all other public employees identified by AFSCME and the Agency has revised the final profile, presented below and in Chapter IV, Technological

Feasibility, to recognize distinctly the exposures facing that category of workers. To present a broad overview of affected public employees, OSHA estimates that approximately 44,000 full-time-equivalent public employees in State Plan States (and thus protected by this standard) are engaged in at-risk construction tasks. Of these, roughly 83 percent will be employed in the application group Tuckpointers and Grinders, while smaller groups of at-risk public employees will be found in all other affected construction application groups with the exception of Underground Construction Workers and Abrasive Blasters. Further details on the final profile of affected public employees can be found in OSHA, 2016.

Sole proprietors ("self-employed" workers)

A final category of worker raised in comments was "self-employed" workers, which OSHA typically refers to as sole proprietors. The PEA did not mention or include self-employed persons in the exposure profile or cost calculations because they are not "employers" subject to OSH Act. However, comments raised the issue that, particularly because of the unique approach presented by Table 1, the activities of sole proprietors could impact the exposures of others, so appropriate costs need to be taken to the extent that OSHA expects affected employers to act to control those exposures. Below, OSHA reviews and responds to the comments, while the actual self-employment data and estimated effect on employer costs are presented in Chapter V of this FEA.

CISC, in its pre-hearing comments, cited a report it commissioned and claimed that there would be costs applied to 2.5 million self-employed persons who perform construction work consistent with Table 1 specifications (Document ID 2319, p. 84). In its post-hearing comments, CISC predicted that many self-employed persons would comply with the requirements in Table 1 for a number of reasons:

- Concerned, self-interested self-employed workers will recognize the Table 1 specifications as the safe way to perform their work;
- Construction general contractors will demand that anyone working on their site, whether self-employed or not, do the job safely and in conformity with regulatory requirements;
- Regulated construction trade contractors will demand a level playing field relative to their self-employed competitors; and
- Regulated construction workers working with or near self-employed workers will demand that they not suffer increased silica exposures from inappropriate practices by self-employed workers.

> We think it reasonable to expect that all self-employed construction workers will eventually come to perform silica-generating tasks consistent with the Table 1 specifications in the Proposed Standard. We believe the costs for self-employed workers to change their practices in this manner should be counted as a cost of the Proposed Standard -- absent the Proposed Standard, they would not perform their work in this way and would not incur the costs of doing so.
>
> We do not believe, though, that self-employed workers will be induced to meet the ancillary requirements of the Proposed Standard. We assume that they will choose not to incur costs to comply with administrative requirements (Document ID 4217, p. 80).

BCTD disagreed with CISC's assertion as follows:

> In the best of all worlds, OSHA standards would apply to all types of workers so everyone in the country could be assured a safe and healthy workplace. The reality is that self-employed workers are not covered by the Occupational Safety and Health Act, which applies only to "employee[s] of . . . employer[s]." 29 U.S.C. § 652(6). OSHA cannot enforce its standards on self-employed workers and these individuals have no legal obligation to comply with OSHA requirements.
>
> During the hearing, industry representatives suggested that self –employed workers would choose to comply with the standard's provisions. Although that would certainly be beneficial, not only to the health of the self - employed worker but to others working in the same vicinity, OSHA is neither responsible for nor has to account for the voluntary actions of those not covered by the Act. By the same token, to the extent that industry representatives suggested that general contractors might require their self-employed subcontractors to comply with the standard, such voluntary actions would similarly fall outside the ambit of OSHA's authority (Document ID 4223, pp. 54-55).

OSHA concurs with BCTD's view that applicable costs will not be incurred by the self-employed persons themselves in response to any requirement in this standard, as they are not required to comply with OSHA's standard. However, OSHA concurs with CISC's assessment that employers covered by the rule will incur costs for engineering controls to protect against exposures generated by sole proprietors acting as subcontractors in certain multi-employer settings. The reason is that other employers are required by the new standard to ensure that their employees on the worksite are protected against silica exposures above the PEL even if those exposures are generated by a party not subject to the OSH Act. In such circumstances, and where the exposure cannot be prevented by other means such as re-scheduling or distancing the self-employed worker from affected workers, the Agency has concluded that the engineering control costs would be borne by another employer (possibly the host employer or controlling employer)—either by providing the controls to the sole proprietor or by reimbursing the self-employed contractor for the costs of the controls.

OSHA further agrees with CISC that engineering control costs would be the only costs associated with self-employed workers for the host employer; OSHA is not factoring these employees into its profile for compliance with the ancillary or respirator provisions because a self-employed person's compliance with those provisions would not contribute to the protection of other employees protected by the standard.

NAHB introduced a related argument concerning host employers having to incur ancillary costs, specifically exposure monitoring costs, for sole proprietors, which they called "non-employers":

> Although these [non-employers] are technically outside the scope of the silica rule, general contractors may have trouble distinguishing among small subcontractors depending on whether or not they have payrolls, resulting in hundreds of thousands of extra assessments beyond those considered in the PEA (Document ID 2296, p. 19).

OSHA does not accept the premise of this argument. The possibility that a general contractors may mistakenly (or even knowingly) treat a sole proprietor as an employer covered by the rule's requirements for controlling exposures should not transform the associated costs into direct costs of the standard and do not provide any grounds for including "non-employers" in an industry profile of the employers impacted by the new rule. The Agency therefore has not adjusted its industry profiles or added ancillary costs in response to the NAHB comment. NAHB's comment is noted again in the section in Chapter V of this FEA concerning exposure monitoring costs in construction.

Electric utilities

The Edison Electric Institute (EEI) questioned whether OSHA's preliminary profile had recognized the electric utility industry:

> EEI is concerned that, in spite of the potential impact of the rule upon the industry, OSHA's Preliminary Economic Analysis (PEA) did not include Electric Power Generation, Transmission & Distribution (NAICS 2211). OSHA should assess the health risk respirable crystalline silica poses to the industry, which, to our knowledge, has no history of silicosis disease. Further, the agency should determine whether the proposed rule is economically and technically feasible to the electric utility industry. The

> proposed rule contains no discussion on these matters (Document ID 2357, p. 39)(footnote deleted).

Another employer association in the electric utility industry, the National Rural Electric Cooperative Association, presented a request that appears contradictory to EEI's request in relation to OSHA's final profile:

> Rural electric cooperatives and electric utilities in general, are not included in those listed by the agency as affected industries. This makes sense due to the very limited exposure of our workers to RCS. Therefore NRECA recommends that the utility industry not be listed as an affected industry. In support of this recommendation, Federated Rural Electric Insurance Exchange, the provider of workers' compensation insurance to over half of the 900 member cooperatives of NRECA, reports ZERO cases of silicosis in over 25 years (Document ID 2365, p. 13).

For this final profile of electric utilities, OSHA determined that significant exposures to silica in electric utilities occur during the following Table 1 construction tasks: Jackhammers and handheld powered chipping tools; Heavy equipment and utility vehicles (all uses); and Drills and Drilling rigs (all forms). Tables III-8 and III-9 below present OSHA's final exposure profile for NAICS 2211, Electric Utilities. The costs, benefits, and other impacts facing the electric utility industry are presented later in this FEA.

CHARACTERISTICS OF AFFECTED INDUSTRIES

In the sections that follow, OSHA presents its final profile of affected industries; included within the profile is the Agency's response to additional concerns raised by commenters. The profile includes revenue and profit information, which is explained in the section that follows on Revenue and Profit.

Table III-5 provides an overview of the industries and estimated number of workers affected by the final rule. Included in Table III-5 are summary statistics for each of the affected industries, subtotals for construction and for general industry and maritime, and totals for all affected industries combined.

The first five columns in Table III-5 identify the NAICS code for each industry in which workers are routinely exposed to respirable crystalline silica and the name or title of the industry, followed by the total number of entities, establishments, and employees for that industry.[33] Note that, while the industries are characterized by such exposure, not every entity, establishment, and employee in these affected industries engage in activities involving silica exposure. Hence, figures for total entities, establishments, and employees are given for each affected industry, but, in separate columns, so too are the subset of figures for affected entities, establishments, and employees (totals and full-time-employment (FTE) equivalents).

Thus, columns six through eight in Table III-5 show, for each affected industry, the number of entities and establishments in which workers are actually exposed to silica and the total number of workers exposed to silica; while column nine shows the FTE estimates (for construction only).[34] The number of affected establishments was set equal to the total number of establishments in an industry (based on Census data) unless the number of affected establishments would exceed the number of affected employees in the industry. In that case, the number of affected establishments in the industry was set equal to the number of affected employees, and the number of affected entities in the industry was reduced so as to maintain the same ratio of entities to establishments in the industry.[35]

Finally, the last three columns (ten through twelve) present data on total revenues in the affected industry (not just affected entities), revenues per entity, and revenues per establishment. Because OSHA did not have data to distinguish revenues for affected entities and establishments in any industry, average revenue per entity and average revenue per affected entity (as well as average revenue per establishment and average revenue per affected establishment) within any industry are estimated to be equal in value.

Public comments relating to this Table, as it was presented in the PEA (PEA Table III-2), are discussed after Table III-5.

---

[33] The source of these industry data is the U.S. Census Bureau, Statistics of U.S. Businesses, 2012.

[34] Estimates of the numbers of affected employees in general industry and maritime are based on an assessment for each sector of the job categories of workers who perform tasks where silica exposures can occur. OSHA matched occupational titles from the 2012 BLS OES survey with these at-risk job categories and then used OES occupational employment statistics to generate industry-specific estimates of the numbers of affected employees. To ensure data compatibility, OES occupational employment statistics were benchmarked to the 2012 County Business Pattern employment totals for each industry.

[35] For the PEA, OSHA determined that removing this assumption would have a negligible impact on total costs and would reduce the cost and economic impact on the average affected establishment or entity. OSHA requested comment on this methodological test and received none. Therefore, OSHA has applied this methodology in this FEA and again has determined that removing this assumption would have a negligible impact on total costs and would reduce the cost and economic impact on the average affected establishment or entity.

[a] US Census Bureau, Statistics of US Businesses, 2012.

[b] OSHA estimates of "affected" categories represent associated entities and establishments with employees potentially exposed to silica. Affected entities and establishments constrained to be less than or equal to the number of affected employees (see discussion above in the text introducing this table). Full-time-equivalent estimate does not apply to general industry and maritime. Estimates of the numbers of affected employees in general industry and maritime are based on an assessment for each sector of the job categories of workers who perform tasks where silica exposures can occur. OSHA matched occupational titles from the 2012 BLS OES survey with these at-risk job categories and then used OES occupational employment statistics to generate industry-specific estimates of the numbers of affected employees. To ensure data compatibility, OES occupational employment statistics were benchmarked to the 2012 County Business Pattern employment totals for each industry.

[c] State-plan states only. State and local governments are included under the construction sector because the silica risks for public employees are the result of construction-related activities.

[d] For NAICS 482110, Rail Transportation, data on entities, establishments and revenues were not available from the US Census Bureau. OSHA's final profile of rail transportation is drawn from supplementary government and industry sources; see Chapter VI, Economic Feasibility Analysis and Regulatory Flexibility Determination.

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA, 2016.

The National Concrete Masonry Association (NCMA) objected to OSHA's preliminary estimate of the size of the NAICS code within which their members are classified:

> The National Concrete Masonry Association represents the manufacturers of Concrete Block and Brick as well as the manufacturers of related products such as Segmental Retaining Wall Units and Manufactured Stone. While it is unclear which producers are classified into which concrete products categories, we will assume that all of our members fall into NAICS Code 327331. NCMA estimates that its members constitute about 1/3 of the producing entities under this code and represent about 2/3 of the production capacity. While we do not have definitive data to contradict the 599 entities and 951 establishments referenced in Table III-2, we would believe that these numbers may be more reflective of the industry prior to the recent recession and they are inflated by about 20-30% (Document ID 2279, pp. 2-3).

In response, OSHA notes that (1) as shown in Table III-5, the estimated number of affected firms and establishments for NAICS 327331, Concrete Block and Brick Manufacturing, will total 511 and 817, respectively, or approximately 15 percent lower than the preliminary estimates, and (2) NAICS 327331 may include concrete block and brick manufacturers who are not members of NCMA. NCMA's comment did not foreclose that possibility. Therefore, OSHA's final estimate of affected concrete block and brick producers may be closer to NCMA's industry profile and should meet the concrete masonry association's objections.

As shown in Table III-5, only slightly more than 66 percent of the entities and establishments, and about 21 percent of the workers in affected industries, actually engage in activities involving silica exposure.[36] However, a total of approximately 652,600 entities (586,800 in construction; 65,900 in general industry and maritime), 675,800 establishments (600,700 in construction; 75,100 in general industry and maritime), and 2.3 million workers (2.0 million in construction; 0.3 million in general industry and maritime) are shown to be affected by the final silica rule.

OSHA notes that a fraction of the workforce exposed to silica is likely exposed to other substances currently regulated by OSHA and therefore may benefit from existing controls. OSHA has not attempted to quantify the extent to which silica exposures, and

[36] These percentages vary significantly depending on the industry sector and, within an industry sector, depending on the NAICS industry. For example, about 35 percent of the workers in construction, but only 6 percent of workers in general industry, actually engage in activities involving silica exposure. As an example within construction, about 59 percent of workers in highway, street, and bridge construction, but only 11 percent of workers in land subdivision, actually engage in activities involving silica exposure.

exposure control, overlap with other OSHA-regulated substances, but estimates that any effect (for example, a reduction in compliance costs in relation to an OSHA silica standard) would be minor.

OSHA requested comment on the overlap of other health and safety regulations with silica protection. Dr. Ruth Ruttenberg, an economic consultant to the AFL-CIO, identified four areas where overlap of the silica standard with existing regulations would reduce silica compliance costs: respirators, exposure assessment, portability of records, and ventilation technology (Document ID 2257, Attachment 4, p. 5). Similarly, the International Union of Operating Engineers (IUOE) stated that measures for practicing good industrial hygiene and implementing measures to control exposure to dust, noise, and diesel fuel will also help to protect workers from silica exposure (Document ID 2262, p. 2). OSHA agrees in principle with these statements on the potential overlap of silica controls with the controls required under other standards but did not attempt to calculate cost savings. In Chapter V, Costs of Compliance, the Agency addresses in greater detail the concerns raised by Dr. Ruttenberg and IUOE.

Full-Time-Equivalent Workers

For construction, an industry profile must recognize a distinction between an estimate of the total number of workers involved in a production activity and a measure that translates that level of worker involvement into actual workday exposures. This distinction is necessary because, unlike in general industry, affected construction workers may spend large amounts of time working on tasks with no risk of exposure to respirable crystalline silica. The ninth column in Table III-9, with data only for construction, shows for each affected NAICS construction industry the number of full-time-equivalent (FTE) affected workers that corresponds to the total number of affected construction workers in the previous column.[37] As shown in Table III-5, the 2.0 million affected workers in construction converts to approximately 387,700 FTE affected workers. In contrast, OSHA based its analysis of the affected workers in general industry and maritime on the evidence-based assumption that they were engaged full time in activities with some silica exposure.

Small entities

[37] FTE affected workers becomes a relevant variable in the estimation of control costs in the construction industry in Chapter V of this FEA. The reason is that, consistent with the costing methodology, control costs depend only on how many worker-days there are in which exposures are above the PEL. These are the worker-days in which controls are required. For the derivation of FTEs, see FEA Chapters IV and V, ERG (2007a), and OSHA (2016).

Similar information to that provided in Table III-5 for all entities in each affected industry is also provided for all small entities, as defined by SBA, in each affected industry (in Table III-6) and for all small entities with fewer than 20 employees in each affected industry (in Table III-7).

	Totals – All Industries		**956,914**	**968,917**	**6,762,999**	**645,749**	**1,439,703**	**215,399**	**$1,499,265,564**	**$1,567**	**$1,547**

[a] Data were not available specifically for small entities with more than 500 employees. For SBA small business classifications specifying 750 or fewer employees, OSHA used data for small businesses with 500 or fewer employees. For SBA small business classifications specifying 1,000 or fewer employees, OSHA used data for all entities in the industry.

[b] US Census Bureau, Statistics of US Businesses, 2012.

[c] OSHA estimates of employees potentially exposed to silica and associated entities and establishments. Affected entities and establishments constrained to be less than or equal to the number of affected employees. Full-time equivalent estimate does not apply to general industry and maritime.

[d] State-plan states only. State and local governments are included under the construction sector because the silica risks for public employees are the result of construction-related activities.

[e] For NAICS 335224, affected SBA entities and affected employment for SBA entities total to values that fall between zero and one but were rounded to the nearest integer (zero) for presentation in this table. Later in this FEA, the costs and impacts presented for this industry reflect the use of the actual (non-zero) values for entities and employment.

[a] US Census Bureau, Statistics of US Businesses, 2012.

[b] OSHA estimates of employees potentially exposed to silica and associated entities and establishments. Affected entities and establishments constrained to be less than or equal to the number of affected employees. Full-time equivalent estimate does not apply to general industry and maritime.

[c] State-plan states only. State and local governments are included under the construction sector because the silica risks for public employees are the result of construction-related activities.

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA, 2016.

SILICA EXPOSURE PROFILE OF AT-RISK WORKERS

The preliminary exposure profile was presented in detail in the technological feasibility analysis in the PEA and relied on information from a wide variety of sources available to OSHA and reviewed in ERG's reports (ERG, 2008a; ERG, 2008b), including:

(1) Published literature;

(2) OSHA silica SEP inspection reports;

(3) NIOSH reports, including health hazard evaluations [HHE], control technology [CT] assessments, in-depth surveys, recommendations for exposure control, and engineering control feasibility studies;

(4) Workplace evaluation reports related to programs on "sentinel event notification system for occupational risks" (SENSOR) for silica from the states of Michigan, New Jersey, and Ohio;

(5) ERG and OSHA site visits;

(6) Unpublished information (e.g., unpublished data and research obtained through personal communications, meetings, and presentations); and

(7) Information available from other federal agencies, state agencies, labor organizations, industry associations, and other groups.

ERG also obtained OSHA IMIS data from 1979 through mid-2002, which were used primarily to identify the industries initially considered for inclusion in the preliminary technological feasibility analysis. ERG contractor reports primarily relied on information sources published from 1990 through 2001, updated with some information through 2007. In a few cases, where sources more recent than 1990 were limited and earlier information existed, information from the 1980s was used. Some sources of exposure data span several years, or even decades, and provide valuable insight into how exposure levels change as processes and controls are upgraded.

As noted above, OSHA primarily relied on the contractor reports, ERG (2008a) and ERG (2008b); however, OSHA considered and referenced additional material where available. The exposure profiles only included silica exposure data for workers in the United States. Information on international exposure levels was occasionally offered for perspective or in discussion of control options.

Public Comments on OSHA's Preliminary Exposure Profile

URS Corporation, an engineering consultant to the American Chemistry Council (ACC), objected to the sampling and analytical methodology applied in OSHA's determination of the exposure profile for the at-risk worker population. URS claims that OSHA's preliminary exposure analysis was based on exposure data collected using the current "American Conference of Government Industrial Hygienists (ACGIH) method," not the proposed "International Organization for Standardization/European Committee for Standardization (ISO/CEN) method," with the result that OSHA's data, and the Agency's resulting technological and economic feasibility determinations, could be defective because of differences that the two methods might produce:

> [T]he switch to the ISO/CEN definition will have two impacts on feasibility. First, it will add uncertainty regarding OSHA's technological feasibility determination because greater reductions in exposure will be required to achieve a 50 μg/m^3 PEL measured by the ISO/CEN definition than by the ACGIH definition that OSHA applied. Second, OSHA's use of the ACGIH definition to estimate compliance costs causes the Agency to underestimate the costs of achieving the 50 g/m^3 PEL because OSHA did not account for the additional workers whose exposures would exceed the proposed PEL under the ISO/CEN definition but who would be exposed below the proposed PEL if measured under the ACGIH definition (Document ID 2307, Attachment 8b, p. 8).

OSHA disagrees with URS's suggestion that OSHA's feasibility determinations might be affected by the distinction between sampling methodology. First, the device used by OSHA for its enforcement sampling, the Dorr Oliver cyclone, so closely adheres to the ISO/CEN that there should not be any significant difference in any of the data gathered by OSHA through this process. Many employers and researchers use other popular cyclones (e.g., SKC aluminum, Higgens-Dewell) allowed under the NIOSH silica method to assess compliance, and these sampling protocols also conform to the ISO/CEN, so much of the other data not gathered by OSHA is likely to meet the new standards as well.

Further, OSHA must fulfill its statutory mandate by relying on the best available data for the purpose of developing its exposure monitoring profiles and conducting rulemaking analyses. No data are available to show that a significant difference would have occurred if OSHA's exposure profile was re-tested using the devices OSHA will require after promulgation of the standard. Neither URS nor other commenters made available exposure data indicating that such significant differences would have occurred between these different sampling methodologies.

This issue is addressed at greater depth in the discussion on sampling and analysis methods in Chapter IV, Technological Feasibility.

Final Exposure Profile

The technological feasibility analyses presented in Chapter IV of this FEA contain data and discussion of worker exposures to silica throughout industry. Exposure profiles, by job category, were developed from individual exposure measurements that were judged to be substantive and to contain sufficient accompanying description to allow interpretation of the circumstance of each measurement. The resulting exposure profiles show the job categories with current overexposures to silica and, thus, the workers for whom silica controls would be needed in order to comply with the final rule.

Table III-8 summarizes, from the exposure profiles, the number of workers at risk from respirable crystalline silica exposure and the distribution of 8-hour TWA respirable crystalline silica exposures by job category for general industry and maritime sectors and for construction activities. Exposures are grouped into the following ranges: less than 25 μg/m^3; ≥ 25 μg/m^3 and ≤ 50 μg/m^3; > 50 μg/m^3 and ≤ 100 μg/m^3; > 100 μg/m^3 and ≤ 250 μg/m^3; and greater than 250 μg/m^3. These frequencies represent the percentages of production employees in each job category and sector currently exposed at levels within the indicated range.

Table III-9 presents data by NAICS code—for each affected general, maritime, and construction industry—on the estimated number of workers currently at risk from silica exposure, as well as the estimated number of workers at risk of silica exposure at or above 25 μg/m^3, above 50 μg/m^3, and above 100 μg/m^3, based on 8-hour TWAs. OSHA developed Table III-9 by mapping occupation shown in Table III-8 into industries using OES data. As shown, an estimated 1,249,250 workers (1,097,000 in construction; 152,300 in general industry and maritime) currently have silica exposures at or above the new action level of 25 μg/m^3; an estimated 948,100 workers (847,700 in construction; 100,400 in general industry and maritime) currently have silica exposures above the new PEL of 50 μg/m^3; and an estimated 578,000 workers (519,200 in construction; 58,800 in general industry and maritime) currently have silica exposures above 100 μg/m^3—an alternative PEL investigated by OSHA for economic analysis purposes.

Table III-10 compares classified OSHA OIS exposure data with unclassified OSHA OIS exposure data for construction, general industry overall, and general industry abrasive blasting. Classified data are exposure samples that could be grouped by NAICS into an application group or industry and could be identified as part of a job category associated with that application group or industry, whereas unclassified data could not be grouped by NAICS or identified by job category for an application group or industry. The analysis summarized in the table demonstrates that a significant percentage of unclassified exposures for construction and general industry overall fall below the new PEL. For unclassified general industry abrasive blasting, unclassified exposures are evenly divided between exposure above the new PEL and exposure below the new PEL.

		51%	49%
Unclassified Construction (Not a silica NAICS/job category)	56	41	15
		73%	27%

Table III-10: Comparison of Classified vs. Unclassified OSHA OIS Exposure Data for Respirable Crystalline Silica (“classified” status assigned where NAICS and job category identified) (contd.)

	Count of Exposure Samples		<=50 μg/m³	>50 μg/m³	
Classified General Industry	563		426	137	
			76%	24%	
Unclassified General Industry (Not a silica NAICS/job category)	169		140	29	
			83%	17%	

Classified vs. Unclassified Data

Classified data are exposure samples that could be grouped by NAICS into an application group or industry and could be identified as part of a job category associated with that application group or industry.

Unclassified data are exposure samples that could not be classified by NAICS into an application group, or by job description into a job category associated with an application group.

(a) Due to rounding, percentages within rows may not sum to 100%.

EMPLOYEE TURNOVER

For the PEA, OSHA applied employee turnover rates in the cost calculations for medical surveillance and training to account for the additional program costs incurred by employers resulting from the departure (separation) of existing employees and the hiring of new employees throughout a typical year.

In order to estimate turnover rates in general industry (including hydraulic fracturing) and maritime, OSHA used the hires rate of 27.2 percent as estimated by the Bureau of Labor Statistics (BLS, 2008). However, OSHA judged that not all new hires would require initial medical testing. As specified in the proposed rule, employees who had received a qualifying medical examination within the previous twelve months would be exempt from the initial medical examination, even if they had been with a different employer. OSHA estimated that 25 percent of new hires in general industry and maritime would be exempt from the initial medical examination.

In order to estimate turnover rates in construction, OSHA used the hires rate of 64.0 percent in construction as estimated by the BLS in its Job Opening and Labor Turnover Survey (JOLTS) (BLS, 2008). However, as for general industry and maritime, OSHA judged that not all new hires would require initial medical testing. As specified in the proposed rule, employees who had received a qualifying medical examination within the previous twelve months would be exempt from the initial medical examination. OSHA estimated that 60 percent of new hires in construction would be exempt from the initial medical examination.

Comments on Employee Turnover

Public comments on OSHA's preliminary application of turnover rates generally confirmed the necessity of including employee turnover estimates in any analysis of economic impacts. Only a few commenters examined this issue; all agreed that it was important to include a turnover rate, but none provided evidence to suggest that OSHA's preliminary turnover rate was inaccurate.

The executive director of a Wyoming policy center observed a high rate of turnover in his state's oil and gas industry:

> Continuing education is particularly important in this industry. The physical demands of much of the work, competition for workers, and the transient nature of these moving job sites result in continuous turnover. Moreover, booms in the industry induce the rapid expansion in numbers of jobs.

> In the first quarter of 2000, there were 7,809 jobs in oil and gas extraction, oil and gas drilling, and in jobs supporting oil and gas operations in Wyoming. A year later, those numbers climbed to 9,563, an inkling of the boom that hit full force in the middle of the decade. By the fourth quarter of 2008, there were 20,006 of those jobs in Wyoming. Job numbers declined to 16,248 in the first quarter of 2013, still a 108 percent increase compared to the first quarter of 2000.
>
> It's possible to track the turnover, too. In the first quarter of 2000, nearly 1,200 more workers than jobs – 8,971 – worked in oil and gas in Wyoming. At the peak of the boom in the fourth quarter 2008, 23,378 workers were paid wages by the industry, 3,372 more workers than jobs. We believe this makes a strong case for requiring continuing education and training of both supervisors and workers about the hazards of silica and how they can be avoided (Document ID 3601, p. 3)(citations omitted).

CISC did not object to OSHA's preliminary estimate for the construction turnover rate, and pointed to the "transient nature of the workforce" and "the turnover rate in the construction industry" as reasons why medical surveillance would be "impractical" (Document ID 4217, p. 21).

Dr. Ruttenberg questioned whether the figures reported in the BLS JOLTS database and applied by OSHA in the PEA accurately reflected employee turnover in the context of employer compliance with an OSHA standard, but Dr. Ruttenberg did not provide any evidence to contradict it other than to point to general statements about OSHA's general track record with estimating costs and benefits:

> . . .
>
> > 7. Oversimplification of Turnover Rates Inflates Cost. OSHA cites turnover rates of 64 percent for construction and 27.2 percent in general industry (FR, p. 56286) and uses these in assessing the costs of medical surveillance, training, etc. But, when individuals leave their jobs, it does not mean that they leave their industry. An abrasive blaster may well continue as an abrasive blaster on another job. A master craftsperson in drywall finishing, is more likely to stay in drywall finishing than not. Likewise with tuck-pointing or heavy equipment operating. Portability of training and medical surveillance will help avoid duplication of services (Document ID 2257, Attachment 4, pp. 2 and 6).

OSHA accepts Dr. Ruttenberg's argument that use of the BLS JOLTS figure for turnover rates may blur the distinction of intra-industry, inter-employer movement or workers from inter-industry employee movement. Nonetheless, lacking the means of refining the

BLS turnover rate, OSHA finds the BLS rate the most convenient, widely accepted measure of new hires. Moreover, as discussed in the section on medical surveillance and training costs, OSHA notes that its preliminary estimates did include portability of medical surveillance in those costs estimates, although in the discussion of training costs OSHA notes that silica training is unlikely to be as portable as Dr. Ruttenberg suggests.

The above comments address OSHA's use of turnover rates as defined by BLS. Other comments in the record associated with OSHA's use of turnover rates generally focused on broader methodological considerations in the areas of compliance costs and benefits; the issues raised by those comments are addressed in Chapter V, Costs of Compliance, and Chapter VII, Benefits and Net Benefits.

Seasonal employment

Joseph Liss, a master's candidate in the field of leadership and public policy, questioned the apparent absence of seasonality in OSHA's preliminary profile of construction workers:

> Additionally, there was no prominent mention of any adjustment for seasonal workers in OSHA's PEA or the preamble of its proposed rule, despite seasonality being a major part of the construction industry. Bureau of Labor Statistics data indicates that, in 1990, there was a more than 5% seasonal adjustments [sic] for construction employees . . . . (Document ID 1950, p. 10).

OSHA acknowledges that seasonal variations in employment can affect the estimation of the population at risk of exposure to toxic substances, including silica. OSHA's primary source of data on the affected workforce, the Bureau of Labor Statistics' OES Survey, defines "employment" as follows.

> ***Employment*** refers to the number of workers who can be classified as full- or part-time employees, including workers on paid vacations or other types of paid leave; salaried officers, executives, and staff members of incorporated firms; employees temporarily assigned to other units; and noncontract employees for whom the reporting unit is their permanent duty station regardless of whether that unit prepares their paychecks. The OES survey includes all full- and part-time wage and salary workers in nonfarm industries. Self-employed workers, owners and partners in unincorporated firms, household workers, and unpaid family workers are excluded.[38]

[38] Survey Methods and Reliability Statement for the May 2014 Occupational Employment Statistics Survey, p. 3. http://www.bls.gov/oes/current/methods_statement.pdf. Accessed July 29, 2015.

Seasonal workers are part-year employees; hence, such workers would be included in the OES survey response if they were present in the workplace sampling frame. Furthermore, in the OES survey methodology, over the course of a 3-year cycle, approximately 200,000 establishments are sampled twice each year, in May and November (for a total of 1.2 million establishments). Therefore, because average annual employment estimates produced by the OES survey would capture most seasonal workers, OSHA's final profile of the affected would also reflect seasonal employment factors.

Revised Employee Turnover Rates for the FEA

The comments received on employee turnover did not identify significant flaws in OSHA's preliminary estimates regarding employee turnover, so the Agency employed the same methodology and data source used in the PEA to update to the 2012 BLS JOLTS estimates of job turnover for this FEA. In order to estimate turnover rates, OSHA used the hires rate (resulting from layoffs, quits, retirements) of 25.0 percent in general industry (including hydraulic fracturing) and maritime and of 70.2 percent in construction as estimated by the BLS (BLS, 2012). As in the PEA, OSHA judged that not all new hires would require initial medical testing. As specified in the final rule, employees who receive a qualifying medical examination within the previous twelve months do not need a second "initial" medical examination when they change employers. As in the PEA, OSHA estimated that 25 percent of new hires in general industry and maritime and 60 percent of new hires in construction would not incur any additional costs for their employers due to the initial medical examination.

CURRENT COMPLIANCE

In the preliminary analysis of the proposed standard's economic impacts, OSHA estimated current compliance as indicated in the following table. For the reasons explained below, OSHA is applying the same baseline compliance judgments in the FEA.

Table III-11 Baseline Compliance Judgments Applied in the PEA

Requirement	General Industry	Construction
Engineering Controls	The percentage of at-risk workers with exposures below PEL (based on the exposure profile) were judged to be in compliance	Same as General Industry
Exposure Assessment	No baseline compliance	No baseline compliance
Regulated area/exposure control plan	No baseline compliance	No baseline compliance
Respirator Use	No baseline compliance	Compliance rate of 56% based on BLS/NIOSH respirator survey (2001)
Respirator program	50% compliance rate	56% compliance rate (see above)
Medical surveillance	No baseline compliance	No baseline compliance
Training	50% have existing silica training program	Same as General Industry

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis.

OSHA requested comment on the estimates of baseline practice (current compliance) in the PEA but the Agency received very little information with the exception of two comments discussed immediately below.

Compliance rate - general practices

James Hardie Building Products, Inc. (Hardie) submitted extensive comments on OSHA's preliminary estimate of current compliance. Hardie criticized OSHA's analysis for not identifying sufficient support for its baseline compliance estimates, but did not go so far as to state that OSHA should not account for any existing rate of compliance, nor did it provide any new data or information that would assist OSHA in identifying a different rate. The following excerpt presents Hardie's comments on OSHA's estimates of baseline compliance with the ancillary requirements of the proposed silica standard:

> In building its analysis, OSHA has made a number of assumptions regarding how work is currently performed in the industries that will be affected by the proposed change in the PEL. These assumed practices provide the basis for evaluating the impacts of proposed regulatory changes, i.e., the impact is assessed on the basis of how required future operating practices differ from current (baseline) practices.

Accordingly, it is quite important to characterize baseline conditions accurately. In this regard, I have several concerns with how OSHA has characterized existing practices in the residential construction industry and related industries. . . .

Job site air monitoring-As described below, the vast majority of firms in the residential construction industry, and the related industries that serve it, are very small. OSHA has not provided information in the record to indicate how much small residential construction firms are currently spending on exposure monitoring. Therefore, OSHA's apparent assumption that firms in these industries already are maintaining compliance with the existing standard through a combination of monitoring and active engineering controls is inappropriate, as are any adjustments to calculated cost impacts that are based on an assumed substantial level of activity in this regard (i.e., high baseline costs leading to low incremental compliance costs).

Respiratory protection-The residential construction industry, allied industries, and their representatives are aware of respiratory hazards on construction sites and with the use of respirators. It is reasonable to assume that most home builders and their subcontractors have at least half-face respirators available to employees who need them for work that is likely to generate large amounts of airborne dust. With that said, the extent to which such employees wear respirators during normal operations is unclear.

Training and hazard communication-The practice of workplace safety has come a long way during the past few decades, and there is now a high level of awareness across U.S. industry that training and effective communication are keys to achieving improved safety performance in industrial settings. Accordingly, many larger companies have established comprehensive, and in some cases, very sophisticated occupational safety and health programs. These programs may have designated senior corporate officials responsible for their deployment and performance, be supported by formal management systems, and include a variety of training courses, learning aids, and other tools that are useful in promoting the behavior-based approach to safety on the job that has proven to be most effective in achieving results. Although it is reasonable to infer that manufacturing firms and large construction companies have and operate safety programs with these attributes, it is not reasonable to assume that homebuilders and their major subcontractors, most of which are very small, do as well, in the absence of any substantiating evidence. OSHA has provided no such evidence in the record. Accordingly, any assumptions that OSHA may have made about such companies already providing training, tailored communications, employee health monitoring, and other such practices to their employees are unreasonable and may

> have artificially inflated OSHA's estimated baseline costs (Document ID 2322, pp. 9 and 11).

One CISC representative, Stuart Sessions, did not directly challenge OSHA's preliminary estimates of current compliance for anything other than respirator use, but speculated generally that compliance rates might be lower at small businesses:

> OSHA assumes that small and large businesses have an identical fraction of their employees at risk of silica exposure and an identical fraction of exposed employees who are overexposed. Both of these assumptions are debatable, particularly the second. I might guess that compliance rates are lower and exposure levels are somewhat higher at small businesses in contrast to large businesses, probably because of lesser ability to afford compliance expenditures and lesser ability to devote management attention to compliance responsibilities (Document ID 4231, p. 2).

Mr. Sessions then proceeded to theorize on possible differences related to economies of scale between large and small plants in terms of per-establishment cost impacts. However, Mr. Sessions did not provide evidence that compliance rates for small establishments are lower than those for large plants, nor did Mr. Sessions document the basis for theorizing that economies of scale exist universally across industry.

Nevertheless, in response to the concerns raised by Hardie and Sessions, OSHA has eliminated the compliance rate estimates in this FEA, as compared to the PEA. OSHA notes, as indicated in the PEA table, the industry-wide baseline level of exposure assessment was estimated to be zero, the baseline level of respiratory protection in construction was assigned a value of 56 percent (an estimate not inconsistent with Hardie's broad perceptions on current practices), and the baseline level of training was estimated to be 50 percent (an estimate not inconsistent with Hardie's perception across the size range of construction employers).

As noted above in relation to Hardie's comments, for this final analysis, OSHA has revised the preliminary estimates of baseline compliance to account for the absence of silica training (except for Hazard Communication training) and other occupational health programs at the baseline throughout affected employers, irrespective of entity size. Table III-12 outlines OSHA's final baseline compliance judgments. Further details on the final estimates of baseline compliance are given in Chapter V, Costs of Compliance.

Compliance rate - training

For this final analysis, OSHA has revised the preliminary estimates of baseline compliance with initial training from 50 percent to zero percent and assigned one hour of training to all affected employees. This initial training on silica hazards will supplement the training currently required by the Hazard Communication Standard (1910.1200, 1926.59), for which OSHA assigned 100 percent current (baseline) compliance and zero costs. The basis for the reduction in baseline compliance is discussed in greater detail in Chapter V of this FEA concerning the costs of compliance.

Compliance rate – respirators and engineering controls in construction

For the final analysis of baseline compliance for engineering controls in construction, OSHA (1) estimates zero baseline compliance for those currently above the PEL; and (2) applies an exception in cases where the construction equipment already comes with a control attached – for example, a cutting tool that comes with a water attachment because cutting "dry" would damage the blade. Details on the final estimates of baseline compliance for engineering controls in construction are given in Chapter V, Costs of Compliance.

Stuart Sessions, an economic consultant to CISC and ACC, disagreed with OSHA's preliminary estimate of the current rate of respirator usage and described his preferred alternative approach along with submitting an alternative worksheet:

> OSHA estimates 56% current compliance, via a generally plausible approach relying on the NIOSH respirator survey. However, we suggest some adjustments to the 56% figure that OSHA derived:
>
> 1. OSHA has not considered the frequency (days/yr) with which the workers who now use respirators will need to use them after the new rule in comparison with the frequency with which they use them now. The NIOSH Survey doesn't address how frequently a current respirator user uses one; it asks only about use/not use
> 2. OSHA appears to have omitted blasters in construction industries from the current compliance analysis. Blasters presumably already use respirators now, and will be required to continue using them
> 3. OSHA has not considered respirator needs among construction workers who, under the proposed rule, will need to use respirators because they are exposed above the proposed PEL when performing tasks that are not listed in Table 1, e.g., mixing cement, installing segmented concrete pavers (Document ID 4023, Att. 2, Excel spreadsheet Tab 12B- Reduce Credit for currUse)

OSHA includes a more complete discussion of its response to Mr. Sessions's critique of the respirator use in Chapter V, Costs of Compliance. For the purposes of this analysis, OSHA has significantly lowered its estimate of the existing compliance rate for respirator use, partly in response to changes in Table 1. In the preliminary analysis of the construction sector, only those workers currently above the PEL were judged to require Table 1 controls. For those workers (only those exposed above the PEL), OSHA estimated in the PEA zero baseline compliance with the engineering controls required in Table 1. In the final rule, OSHA assigned all tasks being performed by construction workers and listed in Table 1 as being covered by the requirements of Table 1. This change in Table 1 coverage requires that OSHA modify its baseline compliance estimates. As in the PEA, OSHA estimated zero compliance with the engineering controls required in Table 1 for those workers currently exposed above the PEL. However, based on OIS data in the record, for workers currently exposed at or below the final PEL of 50 $\mu g/m^3$ that are using Table 1, for this FEA, OSHA estimated baseline compliance rate of 44 percent for these workers. OSHA lowered this compliance rate from 56 percent in the PEA to account for the concerns raised by Mr. Sessions and for the changes to Table 1. In an appendix to this chapter, Tables III-A-1 and III-A-2 present the OIS exposure data supporting OSHA's baseline compliance estimate.

Table III-12 Baseline Compliance Judgments Applied in this FEA

Requirement	General Industry	Construction
Engineering Controls	The percentage of at-risk workers with exposures below PEL (based on the exposure profile) were judged to be in compliance	Based on the analysis in the appendix, OSHA estimates that 44% of workers with exposure below the PEL have such exposure as a result of using the controls required in Table 1, and the remainder will need to use the controls in Table 1.
Exposure Assessment	No baseline compliance	No baseline compliance
Regulated area/exposure control plan	No baseline compliance	No baseline compliance
Respirator Use	No baseline compliance	Compliance rate of 56% based on BLS/NIOSH respirator survey (2001)
Respirator program	50% compliance rate	56% compliance rate (see above)
Medical surveillance	No baseline compliance	No baseline compliance
Training	100% have existing HazCom training program; None have existing silica training program	Same as General Industry

REVENUES AND PROFITS

Revenue and Profit Estimates for General Industry/Maritime and Construction

For the PEA, revenues were estimated on the basis of six-digit NAICS codes by applying revenue data from the Census Bureau's *Statistics of U.S. Businesses* for 2006 (U.S. Census Bureau, 2010). Although that data source from the Census Bureau provides annual industry-specific estimates of employment, establishments, firms, and payroll, revenue data are published only for years that coincide with the Economic Census.[39] However, 2006 revenues were estimated by extrapolating the 2002 revenue data based on the assumption that the ratio of revenues to payroll for each industry would be unchanged between the two years. Revenues were then inflated to 2009 dollars and distributed

[39] Estimates were drawn from US Census 2006 County Business Patterns six-digit level NAICS establishment totals (U.S. Bureau of the Census, 2010).

among size categories (small entities, very small entities) in accordance with the proportion of total payroll found in those categories within each industry. For further details on the methodology used to estimate per-entity revenue by size class, see ERG (2007b).

Additionally, before-tax profit rates were estimated using corporate balance sheet data from the Internal Revenue Service's *Corporation Source Book* (IRS, 2007). For each of the years 2000 through 2006, profit rates were calculated as the ratio of net income to total receipts (numerator includes only firms with net income; denominator includes firms with and without net income) by NAICS group and averaged profit rates across the seven-year (2000-2006) period. Since some data provided by the IRS were not available at disaggregated levels for all industries and profit rates, data at more highly aggregated levels were used as proxy for such industries—that is, where data were not available for each six-digit NAICS code, corresponding four- and five-digit NAICS codes were used as appropriate.

Public comments on OSHA's Preliminary Estimates of Revenues and Profits

Among the profile data presented in Tables III-5, III-6, and III-7 of this FEA are revenue per business entity and revenue per establishment for, respectively, all affected entities, entities defined as small by the SBA, and entities with fewer than 20 employees. As described above, for the PEA, OSHA estimated current revenues by extrapolating the 2002 revenue data based on the assumption that the ratio of revenues to payroll for each industry would be unchanged between the years 2002 and 2006. Revenues were then inflated to 2009 dollars and distributed among size categories (small entities, very small entities) in accordance with the proportion of total payroll found in those categories within each industry.

Dr. Ruttenberg pointed out a statement on estimated revenues for hydraulic fracturing in the PEA that appeared to imply the need for an adjustment to the impacts analysis and suggested that OSHA make that adjustment:

> OSHA itself states, in its appendix of the PEA on Hydraulic Fracturing, "that the industry-wide average revenue estimate appears to underestimate the average revenues for hydraulic fracturing firms." (PEA, p. A-11) These higher revenues will reduce the burden of compliance to the hydraulic fracturing companies whose workers are exposed to silica (Document ID 2257, Attachment 4, p. 8).

In response to Dr. Ruttenberg, OSHA notes that it has revised its estimate of revenues for the hydraulic fracturing application group based on 2012 Census data and other sources.

In testimony at the hearings and in post-hearing comments, ACC's economist, Mr. Stuart Sessions, criticized OSHA's use of the IRS Corporation Source Book. From the ACC post-hearing testimony:

- The CSB provides data only for much larger 3- or 4-digit NAICS industries instead of the finer detail that is needed on the particular 6-digit NAICS industries that will be affected by the proposed standard. Use of CSB data at the 3- or 4-digit NAICS level to represent 6-digit industries results in two problems:

  i. OSHA has no ability to distinguish the likely differences in profitability and ability to bear regulatory costs across multiple affected 6-digit industries that are grouped within a single 3- or 4-digit CSB amalgamation. For example, OSHA purports to estimate the specific regulatory costs faced by the eight different affected 6-digit industries within the 4-digit "clay, refractory and other nonmetallic mineral processing" industry; yet because of reliance on the CSB, which provides no detail beyond the 4-digit level, OSHA is limited to assigning all eight of these industries an identical estimate of profitability. I cited information suggesting that these eight industries within this CSB grouping are likely to have quite different profitabilities, but OSHA misses the opportunity to reflect this differentiation.

  ii. In some instances, the 6-digit affected industry constitutes only a small portion of a qualitatively very different and much larger 3- or 4-digit industry for which the CSB provides data. I cited as an example the affected 6-digit industry "Asphalt Shingle and Coating Materials Manufacturing", to which OSHA assigns whatever profitability the CSB shows for the more-than-100-times-larger 4-digit industry that is dominated by petroleum refineries. There is little reason why the profitability of a relatively small residential construction-oriented industry such as asphalt shingle manufacturing should be identical to that for petroleum refining.

- The CSB is available now only through the year 2011, thus failing to provide more recent, timely and relevant information about the current profitability of the affected industries and their ability to bear regulatory costs three or four years from today when compliance with the proposed standard will be expected (Document ID 4013, Attachment 7, pp. 1-2).

To address these apparent shortcomings inherent in the use of CSB profit data, Mr. Sessions suggested that OSHA consider alternative data sources (specifically, Risk Management Association's (RMA's) Statement Studies, Bizminer, and Dun & Bradstreet's Industry Norms and Key Business Ratios) to supplement its use of CSB. Dr. Sessions declined to recommend the Dun & Bradstreet source because of size and accessibility issues that lower its profile relative to CSB, RMA, and Bizminer. Of the three remaining sources of data, Mr. Sessions's evaluation was as follows:

> - The CSB does not provide any profitability information at the 6-digit level. Using the CSB, profitability for every one of the affected 6-digit industries must be represented inaccurately by the profitability of the much larger overarching 3-digit or 4 digit industry.
>
> - RMA's Statement Studies provide much more granular information on profitability at the 5- or 6-digit level for more than half of the industries, but these estimates are likely biased high to an unknown degree.
>
> - Bizminer provides profitability information at the 6-digit level for all the affected industries. In nearly all instances, data have been obtained and compiled from a large number of entities within each 6 digit industry.
>
> In sum, I suggest that OSHA draw the available information on profitability of the affected 6-digit industries from both the CSB and from the alternative sources. OSHA should then judge for each industry, after considering the entire range of important factors (granularity/precision in representing the 6-digit industry, recentness, likelihood of bias) how to combine the data from the various sources into a best estimate of profitability (Document ID 4013, Attachment 7, pp. 5 and 7-8).

In a final (post-hearing) brief, Mr. Sessions summarized his specific recommendations for estimating profitability for affected industries:

> - OSHA should start with an unbiased source of information on industry profitability, specifically the CSB. OSHA should choose data from the CSB for the larger 3-or 4- (or more, if available) digit industry as representing the profitability of the component affected 6-digit general industry. OSHA should use "Net Income (less deficit)" in calculating profitability from the CSB data, thus reflecting the profitability of all companies within the affected industry, not only the profitable ones. OSHA should choose a reasonably long series of years of data, ending with the most recent year available in the CSB (2011 at present), as

representing an industry's likely future profitability when compliance with the Proposed Standard is expected. Averaging the profitability information from CSB over the twelve years from 2000 through 2011 (or the 13 years through 2012, if the additional year becomes available) seems reasonable.

- OSHA should use one of the other data sources, probably Bizminer or perhaps RMA, to obtain information on i) how profitability for a smaller component industry may diverge from the profitability of the larger 3- or 4-digit industry of which it is a part; and ii) how profitability for the large and small business segments of an industry may diverge from the profitability of the entire industry. The CSB can provide an unbiased "anchor" estimate of profitability, while Bizminer or RMA can be used to estimate the percentage by which profitability for a component industry lags or exceeds this anchor figure. I have described the specific two-step procedure that I recommend for developing this further detail in footnote 11 of this Post-Hearing Brief on pages 12 and 13. I expect that Bizminer would be better for this purpose than RMA, as I believe that Bizminer covers more of the affected six-digit general industries than does RMA, and I believe that for most industries, Bizminer has obtained profitability information from more companies than has RMA, and hence is likely less subject to bias. I do not recommend Dun & Bradstreet for this purpose (Document ID 4231, pp. 37-38).

In response, OSHA agrees that the use of six-digit NAICS profit rates would be the optimal metric for measuring the profitability of six-digit-level industries, and OSHA requested such data in the PEA. However, with few if any exceptions, stakeholders declined to submit into the record financial data that would enable the Agency to refine its preliminary estimate of profitability. Therefore, OSHA relied on the IRS CSB database for its final analysis of economic impacts, with an expanded analysis as described in this chapter and in Chapter VI, Economic Feasibility Analysis and Regulatory Flexibility Determination.

Responding to Mr. Sessions's criticism of OSHA's use of CSB financial data exclusively in lieu of RMA or Bizminer data, OSHA notes that RMA restricted OSHA's public display of its data, making it too difficult for OSHA to rely on it while providing the transparency appropriate for the rulemaking process (see Document ID 3768, Attachment 2). BizMiner's Terms of Service, as displayed on the company's web site,[40] also prohibit

[40] See http://www.bizminer.com/terms.php, accessed November 28, 2014, which provides in part:

> You may use a purchased report for internal personal or business purposes…but not to publish or otherwise distribute the Profile or the information in it. You may integrate the

publication of their data, thereby creating the same obstacle to its use in an OSHA rulemaking. Because the public display of RMA and BizMiner data carries severe limitations, OSHA's decision for this FEA is to rely almost exclusively on the IRS CSB data for estimating industry profitability. OSHA believes that despite any weaknesses, the CSB data represent the best publicly available collection of financial information nationwide.

In response to Mr. Sessions's objection to OSHA's calculation of profit rates using net income from one IRS database (firms with net income) and using total receipts from another IRS database (firms with and without net income), the Agency has recalculated profit rates for 2000 to 2012 using the source and method recommended by Mr. Sessions, where all data are taken from the IRS CSB: Net income for firms with and without net income / Total receipts for firms with and without net income.

This new approach has some advantages and some disadvantages. The major advantage is that it includes all potentially affected firms. The major disadvantage is that it unnaturally skews average profit rates downward by including firms that have large losses (negative profits) and have already closed or are in the process of closing irrespective of any action by OSHA. The inclusion of such firms cannot capture what OSHA is intended to assess for economic feasibility purposes-those firms that are viable in the absence of a regulation. Thus, OSHA's revised estimates underestimate true average profit rates and ultimately affect OSHA's economic impact determinations by making it seem like the cost of the rule has more impact on the industry as a percentage of profits than it actually does, but this conservative approach helps to ensure that OSHA's economic feasibility determinations are strong.

In another critique of OSHA's preliminary method for calculating average profit rates, the National Association of Home Builders argued in favor of an alternate approach involving more recent years:

> . . . [T]he main problem with the profit data is the time period from which it is drawn, which is historically far from typical and drastically different from the recent experience. The PEA's justification for the 2000-2006 period is "because of the weakness of the profitability data (e.g., missing data points) and the desire to average out short-term profit swings over a full business cycle." In residential construction, 2000-2006 comes

---

report or its content into a single valuation, business plan appraisal or other document intended for use with a single bona fide client.

This license does not extend to distributing or reselling the report or information in any report to multiple entities without the express written permission of BizMiner. No other print copies or electronic copies are permitted.

nowhere near capturing a business cycle. In the four decades between 1960 and 2000, total housing starts averaged about 1.5 million per year. In 2000-[2006], starts were above 1.5 million every year, and above 1.8 million for the last four of those years.

In contrast, 2008, 2009, 2010, 2011, 2012 and 2013 have been the six worst years for housing starts since World War II. This severe downturn was accompanied by a decline in nominal house prices at the national level, something that was also unprecedented since World War II.
The drastic changes in the industry after 2006 are also apparent in the average profit rates (owner's compensation and net income before taxes as a share of revenue) from NAHB's *Cost of Doing Business Study:*

Average Profit for Home Builders

2000	2002	2004	2006	2008	2010	2012
8.1%	9.9%	9.3%	9.0%	-1.3%	2.1%	5.7%

Source: NAHB Cost of Doing Business Study, various years

Not only did profit rates decline markedly for the home building industry as a whole after 2006, the relationship between large and small builders reversed itself (larger builders tended to be more profitable through 2006, smaller builders thereafter).

Average Profit for Single-family Home Builders, Based on Number of Starts

	2002	2004	2006	2008	2010	2012
Small Volume Builders (<26 starts)	10.3%	7.9%	6.7%	1.4%	4.7%	6.0%
Production Builders (26+ starts)	10.7%	9.5%	9.4%	-2.6%	1.2%	5.6%

Source: NAHB Cost of Doing Business Study, various years

Thus, the PEA uses C corporation profit from a 6-year boom period, mischaracterizes it as a full business cycle, applies the same rate indiscriminately to small entities, and ignores the drastically different state of the industry that has prevailed since 2006. For this reason, the economic feasibility section of the PEA for the Residential Construction Industry is not credible (Document ID 3522, pp. 9-10).

Commenters from the concrete industry also complained that the years selected for the analysis in the PEA were not representative of current revenues in their industry. Smithtown Concrete Products Corp., a small concrete products producer in New York, disagreed with OSHA’s preliminary estimate of revenues and profits for their industry:

Further, we believe that OSHA's economic justification for the rule is flawed relative to revenue projections for our industry based on data that

> they collected over the years of 2002-2006. These years represents [sic] strong economic times and OSHA fails to consider the impact of the recession on our businesses. To illustrate this point, our company's revenues in 2013 were more than 50% of our average revenues from 2000 to 2006. To make matters worse, our profits in 2013 are non-existent and have been for a considerable number of years. Therefore, the impact on this ruling on our business efficacy is much greater than OSHA portrays it to be (Document ID 2138, pp. 1-2).

Both sets of comments are representative of comments received from other producers who submitted similar letters.

As noted elsewhere in this chapter, OSHA's final estimate of profit rates is derived as an average over thirteen years of IRS corporate income data and thus is an expansion of the range of years covered in the preliminary calculation of average profit rates. The Agency's final estimate of per-entity revenue is based on the 2012 Economic Census. Both of these estimates now encompass recession-era data, as requested by the commenters. OSHA has revised its preliminary profit rate methodology to derive average profit rates for 2000 to 2012, with all data taken from the IRS CSB and calculated as follows: Net income for firms with and without net income / Total receipts for firms with and without net income. OSHA acknowledges the variation in revenues and profits among establishments within NAICS industries and the data sourcing employed in the final analysis is an attempt to capture the financial profile of the typical affected firm.

Table III-22, later in this section, presents yearly and multi-year averages of profit rates for affected NAICS codes using OSHA's revised methodology for the computation of profit rates. As shown for NAICS 236100, Residential Building Construction, using IRS data for the years reported in the NAHB cost study yields profit rates considerably lower than the rates reported by NAHB. Thus, OSHA's average profit rates for the home building industry may be conservatively low and may overstate the worst-case impacts of compliance costs on net earnings.

Revenue and Profit Estimates for Hydraulic Fracturing

Hydraulic fracturing - Revenues

OSHA's preliminary industry characterization for hydraulic fracturing firms estimated total revenues, revenues per entity, and revenues per establishment in the hydraulic fracturing portion of the industry and in the small business entities in the industry. Because small business entities typically have fewer than twenty employees, OSHA, in that analysis, did not report separately the results for entities with fewer than 20 employees.

Applying the following methodology, and as summarized in Table III-13, the reported Census figures for revenue per establishment for NAICS 213112 were revised to generate estimates of revenue that appeared reasonable for active hydraulic fracturing firms. First, estimates were developed of the likely revenue per stage for hydraulic fracturing work. At the low end, $25,000 per stage was estimated to be representative of the work on low-pressure, shallow, conventional wells. At the high end, estimates were drawn from the average revenue per stage ($136,335) reported by a large hydraulic fracturing company in its 2011 annual report (FTSI, 2011, Document ID 1583). The estimate in the second size category ($50,000) allowed for a mix of small hydraulic fracturing jobs and jobs on new wells. Work on new wells dominates the industry activities, and typical revenues per stage for hydraulic fracturing work on new wells are estimated to be much closer to the $100,000 figure. Thus, the $50,000 average revenue per stage was judged by OSHA to be a conservative estimate.

Table III-13: Preliminary Derivation of Adjusted Per-Establishment Revenue Estimates for Firms in the Hydraulic Fracturing (HF) Industry

Employee Size Category	HF Entities	Estimated HF Establishments	Census-Based Revenue Per Establishment Estimate (a)	Estimated HF Revenue Per Stage (b)	Estimated Establishment Revenues ($1,000) at Different Utilization Rates (Percent)(d)		
					25	50	75
10-19	100	100	$2,064,073	$25,000	$2,281	$4,563	$6,844
20-99	50	60	$5,158,959	$50,000	$4,563	$9,125	$13,688
100-499	46	184	$15,005,003	$100,000	$9,125	$18,250	$27,375
500+	4	100	$24,000,429	$136,335 (c)	$12,441	$24,881	$37,322
Hydraulic Fracturing Industry – Total Entities and Establishments; Weighted Average Revenue @ 50% Utilization Rate	200	444				$15,428	

(a) Estimated by ERG.

(b) Estimated by ERG.

(c) FTSI, 2011.

(d) Utilization is defined as performance of one stage per day for the specified percentage of days in the year. In actuality, many hydraulic fracturing jobs will accomplish more than one stage in a day.

Source: OSHA, Directorate of Standards and Guidance, based on ERG, 2013b.

A range of revenues was estimated using annual equipment utilization rates of 25, 50 and 75 percent.[41] For simplicity, utilization is defined for this estimate as the completion of one stage in a day. Although in this analysis, very small hydraulic fracturing firms are modeled to engage in a single stage of activity at a time, in fact, hydraulic fracturing firms of all sizes can often perform more than one stage per day. For small firms, this might mean traveling to a second well on a single day to perform a second hydraulic fracturing job. On large wells, the rate at which stages are completed varies with the depth at which stages are performed. Therefore, because of the mobility and flexibility of hydraulic fracturing firms, the definition of utilization applied in the PEA was a conservative factor in the definition of revenues.

In the final step of its model, revenues were calculated using the range of equipment utilization rates described above. Because the hydraulic fracturing industry has been extremely active for the last several years before this record closed, actual utilization rates were quite high and many firms purchased new equipment (PacWest Consulting Partners, 2012, Document ID 1597). For this analysis, however, to avoid overestimating revenues, a 50 percent utilization rate was used for estimating revenues per establishment. Nonetheless, uncertainty regarding utilization rates for the smallest operators in the hydraulic fracturing market remains. In addition, while most information suggests that new-well hydraulic fracturing dominates industry activities, OSHA has limited information on the scale of activities among the small hydraulic fracturing firms. The focus on the robust new-well hydraulic fracturing activity might overstate the market and the viability of the smallest hydraulic fracturing operators. Using the 50 percent utilization estimate, average revenues were estimated for hydraulic fracturing firms as ranging from $4.6 million for a 10-19 employee establishment to $24.9 million for one of the largest establishments. OSHA applied those revenue estimates in the PEA. OSHA requested data on equipment utilization rates among hydraulic fracturing firms and information on the scale of activities of all hydraulic fracturing firms, particularly firms defined as small by the SBA definition. In the following discussion, comments by the public and OSHA's response to those comments lead to the Agency's final resolution in those profile areas.

Table III-14a presents OSHA's preliminary estimate of revenues for firms in the hydraulic fracturing industry affected by the standard. For comparison, Table III-14b

[41] For purposes of a sensitivity analysis, ERG and OSHA also examined impacts at utilization rates of 40 percent, 60 percent, and 80 percent (see Document ID 1781, Workbook #1). This is the range that the commenters focused on, and thus is the range discussed most frequently in this part of the FEA. Throughout the discussion here and below, for hydraulic fracturing, OSHA and commenters may at times refer to a utilization range of 40 percent to 80 percent and also refer to a utilization range of 25 percent to 75 percent.

presents OSHA's final estimate of revenues, the derivation of which is explained following the table.

Table III-14a: Preliminary Revenue for Entities in the Hydraulic Fracturing Industry Affected by OSHA's Proposed Standard for Silica – NAICS 213112

Industry Portion	Revenues ($1,000)	Revenues Per Entity ($1,000)	Revenues per Establishment ($1,000)
Total for Entire NAICS	$34,524,044	$5,044	$4,311
Hydraulic fracturing firms only	$8,219,837	$41,099	$18,513
Hydraulic fracturing entities with fewer than 20 employees	$547,500	$5,475	$5,475
Hydraulic fracturing SBA entities	$547,500	$5,475	$5,475

Source: OSHA, Directorate of Standards and Guidance, based on ERG, 2013b.

Table III-14b: Final Revenues for Entities in the Hydraulic Fracturing Industry Affected by OSHA's Standard for Silica – NAICS 213112

Industry Portion	Revenues ($1,000)	Revenues Per Entity ($1,000)	Revenues per Establishment ($1,000)
Total for Entire NAICS	$78,060,509	$8,794	$7,180
Hydraulic fracturing firms only	$17,396,813	$86,984	$39,182
Hydraulic fracturing entities with fewer than 20 employees	$570,313	$5,703	$5,703
Hydraulic fracturing SBA entities [a]	$1,884,313	$12,562	$11,777

[a] The 2014 SBA size standard for NAICS 213112 was $38.5 million (changed from $7.5 million when the PEA was developed); therefore, because establishments with 20-99 employees fell within the SBA size standard (unlike in the PEA), SBA entities in the final analysis include establishments with 10-19 employees and 20-99 employees.

Source: OSHA, Directorate of Standards and Guidance, based on OSHA, 2016.

For most industries covered in this FEA, where an industry contained both establishments that used processes causing silica exposures and establishments that did not use such processes, OSHA has assumed that the establishments using processes that cause silica exposures are financially typical of the industry as a whole. In the case of hydraulic fracturing, however, such an assumption required further analysis. NAICS 213112 includes some firms with fewer than 10 employees. As discussed earlier, given that even the smallest hydraulic fracturing firms have substantial equipment requirements, and that minimal crew sizes imply a need for at least ten employees, OSHA in the PEA preliminarily determined that the number of fracturing firms with fewer than 10 employees was negligible.[42] Therefore, the Agency removed firms with 9 or fewer

[42] As mentioned above, NAICS 213112 includes a range of other oilfield service activities, such as other oil and gas field services; oil and gas exploration services; oil and gas well surveying; cementing oil and gas well; and running, cutting, and pulling casings, tubes, or rods. These activities, which do not involve hydraulic fracturing, can more reasonably be performed by firms with fewer than ten employees. Firms that perform these types of non-fracturing services are judged to dominate the smallest size categories in the industry.

employees from consideration for the preliminary analysis. OSHA did not receive any comments challenging this determination, so it has used the same approach in the FEA.

Even with this adjustment, the revenue data for typical firms in oil and gas well drilling support services still seemed to be low for hydraulic fracturing firms. For example, for the smallest size category considered (10-19 employees), based on ERG's analysis, OSHA estimated that such firms would not be performing any large-scale fracturing jobs but would be restricted to small jobs generating roughly $5,000 to $50,000 in revenues. Using an average revenue for the smallest fracturing jobs of $25,000 per job and the industry-wide Census Bureau revenue estimate of $2.1 million per year per firm, OSHA in the PEA estimated that the average hydraulic fracturing establishment with 10-19 employees would, on average, be able to perform only 84 hydraulic fracturing jobs per year without exceeding the Census revenue estimate. OSHA estimated that most of the jobs would be single-day jobs and that a firm could do far more than 84 jobs a year. Thus, OSHA concluded that the industry-wide average revenue estimate appeared to underestimate the average revenues for hydraulic fracturing firms.

OSHA requested comment on the typical lengths of time involved in the major stages of well fracturing work and the range of revenues earned for hydraulic fracturing jobs. API/IPAA generally endorsed OSHA's analytical approach, taking issue with only OSHA's utilization rate underlying its revenue estimate for small entities. Therefore OSHA has applied a similar methodology using updated Census data for NAICS 213112. Moreover, OSHA reiterates that an underestimation of revenues for hydraulic fracturing firms relative to the other oilfield service firms with equivalent numbers of employees would be expected because hydraulic fracturing firms use much more, and much more expensive, capital equipment than other firms, and as a result have higher costs which are, in turn, paid for by customers. For example, as noted in the PEA, companies can offer wireline services with relatively light, mobile rigs that are much less expensive than the equipment necessary for hydraulic fracturing. While commenters disagreed with some aspects of OSHA's revenue estimates, no one suggested that these estimates would be improved by using data from NAICS 213112 as a whole.

With respect to the utilization rates of small entities, API/IPAA preferred that OSHA use a higher rate of 80 percent rather than the lower percentage used in the proposal:

> Our only corrections relate to the assumptions on which the revenue estimate for small entities was built. More specifically, we agree that small entities "have sufficient capacity to handle only minor, low-pressure refracturing jobs on conventional oil and gas wells" and with OSHA's assumption that those jobs generate an average revenue of $25,000, but we do not agree with the 60% utilization rate OSHA and

ERG employed in order to estimate the average annual revenues these small businesses generate in performing these jobs. * * *

The "utilization rate," as defined by OSHA and ERG, represents the "performance of 1 stage per day for the specified percentage of days in the years," The 60% utilization rate, therefore, represents an assumption by OSHA and ERG that hydraulic fracturing establishments will fracture 219 stages per year. OSHA and ERG's sole basis for this conclusion is a 2012 press release from PacWest Consulting Partners, which stated that there was "a net reduction of frac capacity utilization of 26% over the course of 2012."

Both ERG and OSHA cite to the 2012 PacWest press release as evidence that "actual utilization rates are quite high and many firms have purchased new equipment." While the 2012 PacWest press release estimates a 75% capacity utilization rate, according to PacWest "[c]apacity utilization is defined as the average annual frac demand divided by average annual frac supply." The PacWest "utilization rate" estimate represents the relative balance between overall demand and supply in the hydraulic fracturing market – not the number of days per year on which hydraulic fracturing fleets are performing fractures. Nor can such conclusions be drawn from this data. If anything, the PacWest data show that ERG and OSHA's assumptions on fracture frequency are inflated. The 2012 PacWest press release reported that declining rig counts were driving down demand for hydraulic fracturing services at the same time the hydraulic fracturing industry was adding new capacity. As such, PacWest estimated that capacity would fall to 75 percent. This 75 estimate, however, does not support that companies are fracturing 274 stages per year (75% of 365). It means that, at any given time, one quarter of all hydraulic fracturing fleet capacity is sitting idle waiting for a customer.

Not only is ERG and OSHA's 60% utilization rate unsupported (and entirely undermined by the only evidence they cite), it makes no sense from an operational level. ERG and OSHA applied this 60% ration across all tiers of hydraulic fracturing entities. For entities with more than one establishment, ERG and OSHA assumed that each establishment would complete 219 fractures per year. This utilization may be plausible for some, however, because larger establishments can operate more than one fleet. With sufficient demand, establishments with multiple fleets may indeed fracture 219 stages per year. Additionally, larger companies conduct hydraulic fracturing in multi-day projects on large multistage wells. As such, they do not have to conduct site preparation activities, or transport, assemble, and then disassemble their equipment between each stage or between projects with anywhere near the frequency as small companies will need to do in completing single-day, single well projects.

Importantly, the Associations are not suggesting that a 60% fracture frequency is appropriate for large companies. We are simply pointing out that these large-entity utilization efficiencies are not shared by the small hydraulic fracturing entities. As OSHA notes, the small entities are one-fleet businesses that have only been able to enter the hydraulic fracturing market "by purchasing second-hand equipment that is in need of servicing and that is sufficient for use on relatively low-pressure jobs. These low-pressure jobs "typically only require one day to complete."

Consequently, OSHA's 60% fracture frequency assumes that small entities will be able to conduct hydraulic fracturing at 219 different well sites in a single year. This assumption is simply not realistic. OSHA's estimate allows for, at most, a single day's travel time between each well site and the next well site or the small entity's base if the fleet returns to reequip after a job. OSHA's utilization assumption does not build in time for site preparation, equipment assembly, equipment dismantling, crew member leave, supply coordination and delay, or the equipment servicing that OSHA assumes is required on small entities' second-hand equipment. Indeed, while OSHA is correct that the actual low-pressure refracturing of a shallow conventional well can typically be accomplished in a day, it significantly underestimates the preparation and mobilization time that is required for such an accomplishment.

As both ERG and OSHA note that these estimates for small entities are "uncertain," based on "limited information," and "might overstate the market and the viability of the smallest HF operators," the Associations herein provide a more realistic estimate of fracture frequency among small hydraulic fracturing entities. Based on the experiences of members of the Associations, we believe that it is more accurate to assume that small hydraulic fracturing companies with less than 20 employees could refracture 97 existing, shallow conventional wells per year, with typically one stage per well. With a reasonable time assumed for mobilization, site preparation, assembly, and deconstruction, this scenario presumes crews and equipment will be deployed 292 days per year for 80% utilization over the course of a year, with utilization being defined as having the fleet in the field, committed to a job and unavailable for another job. For the typical low pressure refracture job performed by a small firm and small fleet, we assume one day to travel from base to well site and set up and await completion of pre-fracture activities, one day to perform the fracture, and one day to take down, return to base and demobilize. Importantly, based on OSHA's estimate that small entities earn $25,000 in revenue per job, these small entities at 80% utilization for their fleets, would generate $2,425,000 per year in revenues – more than reasonable given their size and, significantly, only about $300,000 more than what the Census estimated as the average revenue for all service

> companies in NAICS 213112 with between 10 and 19 employees (Document ID 2301, pp. 25-27).

OSHA considered the API/IPAA comments on average earnings for firms performing hydraulic fracturing and derived alternative estimates of revenues using lower estimates of the number of stages. API/IPAA asserted that small crews could only manage one stage of fracturing every three days, with one day for set-up and one day for travel. OSHA judges that this assumption might underestimate the extent to which smaller operators might participate in multi-well pad operations where multiple stages are fractured from an individual location and overstate the average distances being traveled, considering that at least some jobs will be performed at sites that are close to each other. Travel times might be limited for hydraulic fracturing operations, for example, in regions of shallow drilling or with closely grouped wells. In any case, OSHA concludes that data are extremely limited on which to base these estimates and to vary the small crew estimates from the industry averages.

OSHA judges that, even allowing for some variability on the utilization issue, its estimates of hydraulic fracturing revenues and profits have been conservative and its estimate that small hydraulic fracturing firms are able to compete only for the single-zone, small (average $25,000) fracturing jobs remains very conservative.

Moreover, Mr. Kenny Jordan, Executive Director of the Association of Energy Service Companies testified in the public hearings that some small companies offer other services in addition to hydraulic fracturing, such as tool rental, and that such small hydraulic fracturing establishments operate only in very limited geographic areas (Document ID 3589, p. 4099). Mr. Jordan described a group of small hydraulic fracturing firms that do not appear to travel large distances at all, as has been presumed for small crews. OSHA therefore judges that if travel times are fairly minimal, crews would generally be deployable at a rate greater than one single-zone fracturing job in three days, assuming their services are in demand.

OSHA's estimates of the hydraulic fracturing revenue stream are based on estimates of the average revenue per stage of well fracturing and the number of stages fractured per year for average establishments. While OSHA identified some data on the number of stages fractured per year, OSHA did not find data on how the work is distributed across the size spectrum of industry firms.

For the PEA, total revenues for NAICS 213112 were estimated at $34.5 billion for 2006, extrapolating data from the 2002 Economic Census and assuming that the ratio of revenues to payroll was unchanged from 2002 to 2006. According to the updated version of the same data, the Economic Census data for 2012, revenues for NAICS 213112 total

$86.8 billion (Census Bureau, 2015a). Of this total, approximately $8.7 billion included receipts from secondary products and services (i.e., products not classified in this NAICS). Eliminating these secondary receipts from consideration, OSHA estimates that 2012 revenues from oil and gas field services totaled $78.1 billion.

Table III-15 summarizes the data for the entire NAICS code, and not just hydraulic fracturing. These data include an estimate of aggregate receipts; this total has been distributed across the entity and establishment size categories based on the distribution of payroll by size category. Tables III-16 and III-17 present OSHA's final profile characteristics of hydraulic fracturing entities and crews affected by the final rule, respectively.

Table III-15: Economic Census Statistics on Entities and Establishments in NAICS 213112, Oil and Gas Well Support Services, 2012

Employee Size Category	Entities (a)	Establishments (a)	Employ-ment (a)	Payroll ($1,000) (a)	Receipts ($1,000) (b) (c)	Revenue per Entity	Revenue per Establishment
Total NAICS	8,877	10,872	272,357	$21,739,034	$78,060,509	$8,793,569	$7,179,959
10-19	1,041	1,057	14,132	$826,000	$2,966,000	$2,849,184	$2,806,055
20-99	1,230	1,347	49,373	$3,280,279	$11,778,824	$9,576,279	$8,744,487
100-499	283	519	47,386	$3,388,438	$12,167,201	$42,993,643	$23,443,547
500+	127	1,745	145,834	$13,289,086	$47,718,441	$375,735,758	$27,345,812
Total for Selected Employment Size Categories (d)	2,681	4,668	256,725	$20,783,803	$74,630,466	$27,836,802	$15,987,675

(a) From Census, 2015a.

(b) Estimate for total receipts associated with oil and gas well drilling was derived from Census, 2015a (Economic Census. Report for Mining: Industry Series) by eliminating receipts for secondary production activities (see discussion in text above).

(c) Receipts distributed within size categories based on the share of payroll in each category, excluding establishments below 10 employees.

(d) Revenue per Entity and Revenue per Establishment are averages across all employee size categories in NAICS 213112.

16	100.00%	Total- Hydraulic Fracturing Crew		25,440

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA, 2016.

For the PEA, OSHA estimated that the smallest hydraulic fracturing firms would average $25,000 per stage of well fracturing activity. The estimate of $25,000 per stage was not tied to the Census figures and thus is not subject to revision with more recent data. Nevertheless, the increase in revenues for the NAICS code overall suggests that substantially higher revenues were being generated for fracturing firms in 2012 compared to 2006.

Data from PacWest, a marketing research firm, indicated in 2014 that approximately 92 percent of the stages on fractured wells during that year were expected to involve horizontal fracturing (PacWest, 2014). Thus, a very large majority of industry activities are of the sophisticated variety (i.e., horizontal fracturing) that is generally not performed by the smallest firms. Further, small firms most likely operate only a modest share of the remaining 8 percent of the total wells fractured, which consist of vertical wells. These data suggest that shallow, vertical well fracturing represents a very small share of all hydraulic fracturing activity and that there would be very few wells fractured for $25,000 in revenues per stage of well fracturing activity, which is the estimated average for the smallest establishments. Because the vast majority of hydraulic fracturing entities are small establishments (150 out of 200; see Table III-16), it is unlikely that there would be enough of these small wells to account for all of the entities. This evidence further suggests that even very small hydraulic fracturing firms might compete effectively for somewhat larger and more lucrative fracturing jobs, and thus would receive greater amounts of revenue than estimated by OSHA when these smaller entities were assumed to only operate small wells.

According to the Census, the average revenue reported for the 10-to-19-employee establishment size category for NAICS 213112 in 2006 was $2.1 million and the 2012 data raise that estimate to $2.8 million per year. In the PEA, OSHA noted that if the NAICS-wide average revenue was judged to be representative of hydraulic fracturing firms, the revenue total and the per-stage revenue estimate would suggest that small hydraulic fracturing entities were only performing 84 of these small fracturing jobs per year in 2006. OSHA judged this rate of activity to be too low to be representative of even the smallest spectrum of establishments given the industry data on well drilling discussed earlier.

In the PEA, OSHA also used utilization rates of 40, 60, and 80 percent to reflect possible and more likely revenue levels. At the mid-range (60 percent utilization figure), for example, OSHA calculated that hydraulic fracturing entities with 10 to 19 employees would complete 219 stages in a year and generate $5.5 million in revenues. Industry commenters pointed out, however, that any calculation of utilization rates for the industry must be distinguished from time expended for travel to and from jobs, a factor not considered in OSHA's preliminary estimates (Document ID 2301, pp. 26-27).

Table III-18 presents OSHA's final methodology for calculating per-establishment revenue in hydraulic fracturing. Although OSHA disagrees with API/IPAA on recent trends in the frequency of job stages and rate of well-pad usage, and has therefore included estimates of stages per day that moved upward since the PEA, the Agency finds persuasive the Associations' point that "declining rig counts were driving down demand for hydraulic fracturing services at the same time the hydraulic fracturing industry was adding new capacity" (Document ID 2301, p. 26). Therefore, for this final analysis, OSHA revised downward the preliminary range of utilization rates – from 40, 60, and 80 percent to 35, 50, and 65 percent – to reflect lower estimates of the number of days during the year in which a stage is fractured. Combined, the various changes generate a set of revenue estimates and an aggregate estimate of the stages fractured that do not alter OSHA's overall conclusion of economic feasibility for this application group (see Chapter VI**).** The middle estimate of 50 percent in the final range of utilization is equivalent to approximately 183 stages per year. At this rate, and assigning on average OSHA's preliminary estimate of $25,000 per stage performed, the smallest strata of hydraulic fracturing establishments (10-19 employees) would generate revenues of $4.6 million per year.

Finally, as reflected in Table III-19, OSHA arrayed the stages per-day estimates from 1.25 for the smallest strata to 5 and 6 stages per day for the larger establishments.

In response to criticism by API/IPAA on OSHA's preliminary estimate of hydraulic fracturing utilization rates, OSHA considered the possibility that a 50-60 percent mid-level utilization rate might overstate the number of days per year in which the smallest firms are actually performing hydraulic fracturing. Nevertheless, OSHA disagrees with the Associations that such firms are likely to complete no more than one stage at one job for every three days during the year, with a complete day before and after the job for travel. Even small fracturing jobs on shallow wells might involve drill pads with multiple wells where different wells or different stages of the same wells are fractured on the same day or on consecutive days. Some small jobs only take an hour, once set-up is completed (OSHA, 2016). Also, the smallest firms are unlikely to travel very far. Finally, even small hydraulic fracturing crews mobilize more than $1 million of equipment. Their revenues must sustain a return on that investment, as well as cover all labor and operating costs. To do that, they would need to be engaged in more fracturing stages per day than the commenters asserted.

Table III-19 presents the remaining unit data supporting OSHA's final methodological approach to profiling the hydraulic fracturing industry. In response to the criticism noted above that the preliminary per-stage revenue estimates were too high, OSHA lowered the per-stage hydraulic fracturing revenue for the larger establishments. Table III-20 shows the calculation of the number of stages fractured in a year.

Table III-16, presented earlier in this section, summarizes the overall revenue figures for the NAICS industry and the estimated hydraulic fracturing sector, which are drawn from the estimates listed in Table III-19. Although the revenue for small businesses has actually increased significantly, OSHA has conservatively reflected only a very small increase in per-establishment revenue in this final analysis. The per-establishment revenue for the smallest strata of hydraulic fracturing entity (10 to 19 employees) is estimated at $5.7 million per year; whereas the corresponding per-establishment revenue estimate in the PEA was $5.48 million. For the small entities, revenues for the entity and for the establishment are the same on the assumption that these smallest firms are only operating out of one facility.

Table III-18: Final Methodology for Estimating Per-Establishment Revenue among Hydraulic Fracturing Establishments (Preliminary Per-Stage Revenue)

Employee Size Category	Estimated Number of Entities in Hydraulic Fracturing	Estimated No. of Establishments per Entity	Total Establish-ments (a)	Preliminary Estimated HF Revenue Per Stage (b)	Estimated Per Establishment Revenues at Varied Estimates of the Days per Year of Frac Operations (Percent) (c)		
					35%	50%	65%
10-19	100	1	100	$25,000	$3,193,750	$4,562,500	$5,931,250
20-99	50	1.2	60	$50,000	$6,387,500	$9,125,000	$11,862,500
100-499	46	4	184	$100,000	$12,775,000	$18,250,000	$23,725,000
500+	4	25	100	$136,335	$17,416,796	$24,881,138	$32,345,479
Total	**200**		**444**				

(a) Estimates of the number of entities and the number of establishments per entity remain unchanged from the PEA.

(b) Estimated revenues per stage derived in the PEA. The revised per-stage revenue estimates are presented in the next table.

(c) The utilization rates have been revised from the PEA to account for travel time. Utilization is defined as performance of one stage per day for the specified percentage of days in the year.

Table III-19: Final Methodology for Estimating Per-Establishment Revenue among Hydraulic Fracturing Establishments

(Final Per-Stage Revenue)

Employee Size Category	Estimated Number of Entities in Hydraulic Fracturing	Estimated No. of Establish-ments per Entity	Total Establish-ments (a)	Estimated HF Revenue Per Stage (b)	Stages Per Day of Frac Operations (c)	Estimated Per Establishment Revenues at Varied Estimates of the Days per Year of Frac Operations (Percent) (d)			Aggregate HF Revenues (e)
						35%	50%	65%	50%
10-19	100	1	100	$25,000	1.25	$3,992,188	$5,703,125	$7,414,063	$570,312,500
20-99	50	1.2	60	$40,000	3	$15,330,000	$21,900,000	$28,470,000	$1,314,000,000
100-499	46	4	184	$50,000	5	$31,937,500	$45,625,000	$59,312,500	$8,395,000,000
500+	4	25	100	$65,000	6	$49,822,500	$71,175,000	$92,527,500	$7,117,500,000
Total	**200**		**444**						$17,396,813

(a) Estimates of the number of entities and the number of establishments per entity were unchanged from the PEA.

(b) The revised revenues per stage are lower than previous estimates to reflect available data.

(c) Stages per day revised from the PEA.

(d) The utilization rates have been revised from the PEA to account for travel time. Utilization is defined as performance of one stage per day for the specified percentage of days in the year.

(e) Aggregate revenue estimate derived here matches that generated by the Census data for hydraulic fracturing activity (Census, 2015b).

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA, 2016.

Table III-20: Derivation of Estimates of the Annual Number of Stages Fractured in OSHA's Final Hydraulic Fracturing Profile

Employee Size Category	Estimated Number of Entities in Hydraulic Fracturing	Estimated No. of Establishments per Entity	Total Establish-ments (a)	Stages Per Day of Frac Operations (b)	Percent of Days on Which Fracking Occurs/Number of Stages Per Year (c)			Aggregate HF Stages
					35%	50%	65%	50%
10-19	100	1	100	1.25	160	228	297	22,813
20-99	50	1.2	60	3	383	548	712	32,850
100-499	46	4	184	5	639	913	1186	167,900
500+	4	25	100	6	767	1,095	1,424	109,500
Total	**200**		**444**					333,063

(a) Estimates of the number of entities and the number of establishments per entity were unchanged from the PEA.

(b) Stages per day revised from the PEA.

(c) The utilization rates have been revised from the PEA to account for travel time. Utilization is defined as performance of one stage per day for the specified percentage of days in the year.

Hydraulic Fracturing – Profits

Table III-21a presents OSHA's preliminary estimate of profits in the hydraulic fracturing industry, with the revenue information included for reference.

Table III-21a: Preliminary Profit and Revenue for Entities in the Hydraulic Fracturing Industry Affected by OSHA's Proposed Standard for Silica – NAICS 213112

Industry Portion	Profit Rate [a]	Revenues ($1,000)	Profit ($1,000)	Revenues Per Entity ($1,000)	Profit Per Entity ($1,000)	Revenues per Establishment ($1,000)	Profit Per Establishment ($1,000)
Total for Entire NAICS	10.31%	$34,524,044	$3,559,429	$5,044	$520	$4,311	$444
Hydraulic fracturing firms only	10.31%	$8,219,837	$847,465	$41,099	$4,237	$18,513	$1,909
Hydraulic fracturing entities with fewer than 20 employees	10.31%	$547,500	$56,447	$5,475	$564	$5,475	$564
Hydraulic fracturing SBA entities	10.31%	$547,500	$56,447	$5,475	$564	$5,475	$564

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA, 2016.

API/IPAA objected to, but acknowledged that they could not provide an alternative to, OSHA's preliminary estimate of profitability for hydraulic fracturing companies:

> As opposed to revenues, which the Associations believe are largely determinable within a reasonable range of precision, the Associations do not believe that profits are determinable for the hydraulic fracturing industry. OSHA derived its profit estimates from its estimates of industry revenues. It utilized a presumed . . . profit rate of 10.31% and, once again, applied it equally across all sizes of hydraulic fracturing companies. * * * [I]t is wrong of ERG to attempt to estimate profitability for an entire industry by reviewing tax return data for only those companies in the industry that earned positive profits in the year in question. Profitability for an entire industry ought to reflect the financial performance of both those firms that made money and those that did not
> (Document ID 2301, pp. 27-28)(citations omitted).

OSHA's profit estimates are consistent with the methodology for calculating profit rates used in other recent OSHA economic analyses, and the Associations did not supply data that would allow OSHA to reach a different determination for the subset of affected hydraulic fracturing entities within the overall NAICS industry. OSHA therefore based its final profits estimate on the best available data for the NAICS industry (213112) most closely associated with hydraulic fracturing. OSHA notes that it was limited to six-digit NAICS industries because of limitations in the IRS data required for the calculations.

However, as discussed more fully earlier, OSHA has made several adjustments in its profit calculations, one of which addresses concerns raised by the Association. OSHA included firms without net income when it calculated profit rates as the ratio of net income for firms (with and without net income) to total receipts for the same group of firms. Applying this methodology to calculate profit rates for all establishments in NAICS 213112, OSHA estimates that the average profit rate for 2000-2012 was 7.09 percent for the hydraulic fracturing industry; this average profit rate was applied by the Agency in its impact analysis, presented in Chapter VI. Table III-21b below represents OSHA's final profit estimates for the hydraulic fracturing industry, with the revenue information included for reference.

Table III-21b: Final Profit and Revenue for Entities in the Hydraulic Fracturing Industry Affected by OSHA's Standard for Silica – NAICS 213112

Industry Portion	Profit Rate [a]	Revenues ($1,000)	Profit ($1,000)	Revenues Per Entity ($1,000)	Profit Per Entity ($1,000)	Revenues per Establish-ment ($1,000)	Profit Per Establish-ment ($1,000)
Total for Entire NAICS	7.09%	$78,060,509	$5,533,076	$8,794	$623	$7,180	$509
Hydraulic fracturing firms only	7.09%	$17,396,813	$1,233,119	$86,984	$6,166	$39,182	$2,777

SURVEY DATA AND OSHA ECONOMIC ANALYSES

As stated in the introduction to this chapter, the methodological basis for the industry and at-risk worker data presented in this chapter comes from the PEA, the ERG analysis supporting the PEA (2007a, 2007b, 2008a, and 2008b), and ERG's final supporting analysis. The actual data used in this chapter come from the rulemaking record (Docket OSHA-2010-0034), the technological feasibility analyses presented in Chapter IV of this FEA, and from OSHA (2016), which updated its earlier data to reflect the most recent industry data available.

Dr. Ronald Bird, an economic consultant to the U.S. Chamber of Commerce, suggested that OSHA's analysis would be inadequate without support from a national survey:

> The question of economic feasibility of the proposed standard cannot be answered with ***any*** degree of economic certainty without the results of a comprehensive national statistically representative survey for each affected industry of baseline exposures, current control practices, and assessment of the specific compliance engineering retrofit costs (including where applicable, complete rebuilding costs, as suggested by ERG) for each facility in the sample. **Such a survey could have been done by OSHA over the past ten years, such a survey should have been done after the 2008 ERG report alerted OSHA to the problem of compliance cost variability, and such a survey must be done before the present rulemaking moves forward** (Document ID 2368, p. 8)(emphasis in original)**.**

In response, OSHA observes that the Agency has never used surveys to ascertain the kind of detail about controls that Dr. Bird suggests should have been gathered through a survey. For past FEAs, OSHA has used surveys, and the Agency uses older surveys in this analysis for general information (such as the number of respirator types used, the presence of medical surveillance programs, and the prevalence of general safety and health practices).

Indeed, Dr. Bird's description of the key analytical inputs derived from a survey and applied to an economic analysis was for the kinds of general information about whether an occupational safety or health practice is followed, such as OSHA has used in the past and continues to use in this analysis. However, OSHA has not found surveys useful for purposes of assessing the needs for, and cost of, engineering controls. The ideal way to assess baseline data on the cost and deployment of engineering controls is to combine data on engineering controls with data on exposures. This exercise is difficult to accomplish using a survey because, in the absence of a regulation, very few firms will have exposure data, and those that do have exposure data may be reluctant to provide it to OSHA.

Combining exposure data with engineering control data can also be extremely complicated, normally requiring an on-site visit of several hours or a prolonged interview. Even given the opportunity for firms to present data anonymously, there are no instances in the record of a complete summary of engineering control data matched with exposure control data. Some commenters suggested that time constraints limited their responses,[43] but if such data could not be submitted in a multi-month process, it surely cannot be easily gathered through a survey of manageable length and reasonable response time. The basic problem with Dr. Bird's suggestion is that the kinds of data needed to assess engineering control costs are both too extensive and too hard to gather through a survey instrument.

APPENDIX III-A
Background Occupational Exposure Data Supporting OSHA's Baseline Compliance Estimate

The OSHA Information System (OIS) is OSHA's comprehensive data collection and management system for information related to OSHA programs, including workplace exposure information. OSHA maintains OIS to store information collected during compliance inspections. The OIS database contains the results of air sampling conducted to assess compliance with air contaminant standards.

The OIS dataset (Docket ID 3985) analyzed for the FEA contains personal breathing zone silica results for samples collected by OSHA between 2011 and April 17, 2014 during worksite inspections. Using the process described in the Methodology subsection of Chapter IV (Technological Feasibility), OSHA calculated airborne silica concentrations for these samples based on the measured amount of respirable dust for that sample and on the PEL for the sample (related to the percentage of silica in the respirable dust).

To determine the percentage of construction workers currently using dust controls, information on samples obtained for construction workers (identified by establishment NAICS and in some cases job/activity description) were evaluated to determine whether dust controls had been in use at the time the sample was collected (regardless of whether the control was effective or not) (Docket ID 3985).

The data presented in this appendix on exposure severity by control method support the analysis of current industry practice ("current compliance") discussed in the section CURRENT COMPLIANCE in this chapter and later in this FEA, in Chapter V, Costs of Compliance. With regard to how frequently controls are currently in use, Table III-A-1 below shows the number of measurements in the OIS dataset by control method and compliance with the current and proposed PEL.

Appendix Table III-A-2 presents by silica application group, OIS exposure data for respirable crystalline silica and information on the NAICS industry code, job title, job activity, and work environment associated with the sampling site. Furthermore, where the use of exposure controls was recorded in OIS, information on the type of control is shown in the third column in the table. According to analysis of the data, OSHA determined that controls were in use during 40 percent of the 171 construction samples taken. Of all the samples taken, 26 percent exceeded the preceding PEL (i.e. Sev.>1), and 35 percent exceeded the new PEL (RCS> 50 $\mu g/m^3$).

Moreover, of the 40 percent of the samples where controls were used, 29 percent had an RCS>50, compared with 39 percent with RCS>50 for no controls. Finally, of the 65 percent of the samples that had an RCS<50, 44 percent had controls, and 56 percent had no controls. OSHA is using this 44 percent result as the basis for its estimate of the percentage of construction workers with exposures at or below 50 μg/m^3 who are already using engineering controls in compliance with Table 1.

Table III-A-1: OSHA Information System Sampling Data for Respirable Crystalline Silica

Control Method	Total	Sev.<1 [a]	Sev.>1	%Sev.<1	RCS<=50 [b]	RCS>50	%RCS<50
Wet Method	37	31	6	84%	28	9	76%

CHAPTER IV: TECHNOLOGICAL FEASIBILITY

1. INTRODUCTION

This chapter presents an overview of the technological feasibility assessment process for the final rule for respirable crystalline silica, including a description of the structure of the technological feasibility assessments for each individual industry sector or application group. It then addresses general comments received from stakeholders on technological feasibility; these comments are addressed here because they are applicable to the entire technological feasibility analysis or to more than one industry sector or application group. Comments pertinent to a particular sector or application group are addressed in the individual technological feasibility analyses. Comments received regarding the sampling and analysis are addressed in Section IV-3 Feasibility of Measuring Respirable Crystalline Silica Exposures at the Final Rule's PEL and Action Level.

The OSH Act requires OSHA to demonstrate that a proposed health standard is technologically feasible (29 U.S.C. § 655(b)(5)). As described in the preamble to the final rule (see Section II, Pertinent Legal Authority), technological feasibility has been interpreted broadly to mean "capable of being done" (*Am. Textile Mfrs. Inst. v. Donovan*, 452 U.S. 490, 509-510 (1981) ("*Cotton Dust*")). A standard is technologically feasible if the protective measures it requires already exist, can be brought into existence with available technology, or can be created with technology that can reasonably be expected to be developed, i.e., technology that "looms on today's horizon" (*United Steelworkers of Am., AFL-CIO-CLC v. Marshall*, 647 F.2d 1189, 1272 (D.C. Cir. 1980) ("*Lead I*"); *Amer. Iron & Steel Inst. v. OSHA*, 939 F.2d 975, 980 (D.C. Cir. 1991) ("*Lead II*"), and *American Iron and Steel Institute v. OSHA*, 577 F.2d 825 (3rd Cir. 1978)). Courts have also interpreted technological feasibility to mean that, for health standards, a typical firm in each affected industry will reasonably be able to implement engineering and work practice controls that can reduce workers' exposures to meet the permissible exposure limit in most operations most of the time without reliance on respiratory protection (see *Lead I*, 647 F.2d at 1272; *Lead II*, 939 F.2d at 990).

1.1 TECHNOLOGICAL FEASIBILITY ANALYSIS

The technological feasibility analysis is organized by industry sector in general industry and maritime and by application group in construction, with the term application group referring to a specific construction task or activity, such as abrasive blasting. General industry and maritime is mostly analyzed by job, which may incorporate more than one activity or task; construction, which comprises a single industry, is analyzed by task (e.g., hole drilling). The only maritime sector considered to have silica exposures within the range of interest warranting a feasibility analysis is the shipyard sector, which engages in substantial abrasive blasting.

For each industry sector and application group, the available exposure data is summarized by job title or activity to characterize exposures to respirable crystalline silica and to identify exposures above 50 μg/m^3 where additional engineering controls and work practices will be necessary to reduce exposures to at or below the permissible exposure limit (PEL) of 50 μg/m^3 as an 8-hour time-weighted average (TWA) that the rule sets as an enforceable maximum limit. As explained below, exposures are characterized by their median, mean, and range of values within the different job titles, application groups and industry sectors. Additional controls to further reduce exposures could include upgrading or installing engineering controls, or improving work practices such as implementing better housekeeping and routine maintenance procedures, the most common of which are the use of water to suppress dust or local exhaust ventilation to remove and collect dust. In the cases where the exposure data for a specific operation were lacking, OSHA used analogous operations to characterize these operations. OSHA finds that, with a few exceptions discussed below, employers will be able to reduce exposures to 50 μg/m^3 or below in most operations most of the time through the use of engineering and work practice controls. In many industry sectors and application groups, OSHA's analysis demonstrates that most exposures are already at or below the final PEL.

The technological feasibility assessment for each affected industry sector or application group is structured into four main parts: Description; Exposure Profile and Baseline Conditions; Additional Controls; and Feasibility Finding(s).

1.1.1 Description

The description in each section identifies the affected industry sector or application group and provides the following: 1) description of the manufacturing or industrial process or construction activity that has potential exposure to respirable crystalline silica; 2) discussion of each job category or construction task with potential exposure; and 3) major activities and sources of exposure.

1.1.2 Exposure Profile and Baseline Conditions

To establish baseline exposure levels, OSHA examined the available exposure monitoring data from OSHA inspection reports and enforcement data, site visits conducted by NIOSH and by OSHA's contractor, Eastern Research Group, Inc. (ERG), and other data and published reports submitted to the rulemaking record.

The available exposure monitoring data by job category or task within that sector or application group are presented in an exposure profile that displays the entire range and distribution of the available exposure measurements, including the median[1] and mean values. The median indicates the mid-point of a distribution, i.e., the value at which half the numbers are above and half are below, and provides a measure of central tendency for the exposure distribution. An arithmetic mean (or average) will be equal to the median if exposures are equally distributed above and below the median (e.g., a normal distribution), but will be considerably above the median where there are some very high exposures well above the median (i.e., for a distribution that is skewed toward higher exposures, such as a lognormal distribution). It is well recognized that occupational exposures to chemicals exhibit a skewed distribution such that the average exposure of a group of workers will typically exceed the median exposure (Document ID 0845). The exposure profiles are the primary basis for describing current, or baseline, exposure levels and include samples from both well-controlled and poorly controlled workplaces.

[1] In some cases, depending on the distribution of the exposure data, the geometric mean was used by OSHA or in published articles to better represent the central tendencies of the distribution. The geometric mean is the n^{th} root of the product of n samples. This type of analysis will tend to "normalize" the range and will not be overly influenced by extremely high values in non-normal distributions.

1) INTRODUCTION

OSHA used the exposure profiles to develop estimates of the percentage of workers in an industry sector or application group that are currently exposed to silica levels above the new PEL of 50 μg/m^3, and therefore require the use of additional engineering or work practice controls to achieve compliance. When the exposure profile indicates that most exposures for a particular job category are already at or below 50 μg/m^3, OSHA considers this to be evidence showing a PEL of 50 μg/m^3 to be technologically feasible for that job, because compliance is already being achieved using existing controls. When the exposure profile indicates that most exposures for a particular job category or application group exceed 50 μg/m^3, OSHA identifies additional control measures that the Agency has determined are capable of reducing exposures as needed to achieve or substantially approach compliance with the PEL.

The final exposure profiles take the exposure data that were used for the same purpose in OSHA's Preliminary Economic Analysis (PEA) and build upon them, using new data in the rulemaking record. The sampling data that were used to identify the affected industries and to develop the exposure profiles presented in the PEA were obtained from a comprehensive review of the following sources of information: OSHA compliance inspections conducted before 2011, OSHA contractor (ERG) site visits performed for this rulemaking, NIOSH site visits, NIOSH Health Hazard Evaluation reports (HHEs), published literature, submissions by individual companies or associations and, in a few cases, data from analogous operations (Document ID 1720, pp. IV-2 – IV-3). The exposure profiles presented in the PEA were updated for the Final Economic Analysis (FEA) using exposure measurements from the OSHA Information System (OIS) that were taken during compliance inspections conducted between 2011 and 2014 (Document ID 3958). In addition, exposure data submitted to the record by rulemaking participants were used to update the exposure profiles. The criteria used for determining whether to include exposure data in the exposure profiles are described in Section IV-2 – Methodology of this chapter. As explained there, some of the original data is no longer used in the exposure profiles based on those selection or screening criteria. OSHA considers the exposure data relied upon for its analysis to be the best available evidence of baseline silica exposure conditions.

OSHA considers controls to be "baseline conditions" when such controls are regularly used in an industry sector or application group. This should not be interpreted to mean that OSHA believes everyone currently uses these controls, but rather that the controls are widely available and commonly used in the industry. Thus, the baseline conditions described in OSHA's feasibility assessments can include both controlled and uncontrolled exposures; in fact, the range of exposures for a particular job category or task can provide a useful indication of how substantially exposures can be reduced using currently available controls. Information on controls used in specific industry sectors or application groups was obtained from several different sources, including site visits conducted to evaluate current exposures, NIOSH research reports, industry experts, industry associations, published literature, and submissions to the rulemaking record.

1.1.3 Additional Controls

The third section of each technological feasibility assessment describes additional controls identified by OSHA that could be implemented to reduce exposures to 50 $\mu g/m^3$ or below. OSHA often based its determination that the engineering and work practice controls can reduce exposures to or below the PEL on evidence that the additional controls are already in use at other facilities in the same application group or industry sector. Where OSHA had limited data on an industry sector or activity, OSHA evaluated the effectiveness of controls in similar industry sectors or analogous operations. In some cases, OSHA applied an estimate of the percent reduction in exposure achieved through the use of controls based on experimental studies reported in the published literature.

There were some tasks for which OSHA determined that some workers' exposures would likely remain above 50 $\mu g/m^3$, even with the implementation of additional controls. In these cases, OSHA concluded that the supplemental use of respirators is needed.

1.1.4 Feasibility Finding(s)

After describing the additional controls that can reduce exposures, OSHA includes a conclusion regarding the technological feasibility of achieving the final PEL of 50 $\mu g/m^3$ or less for each of the jobs or tasks described, along with a general finding of feasibility for the industry sector or application group where that sector or group involves more than one described and profiled job or task. OSHA considers the PEL technologically feasible when the evidence in the record, including exposure monitoring data, indicates that most operations will be able to achieve exposures at or below 50 μg/m^3 most of the time with the use of engineering and work practice controls. For these purposes, "operation" and "job or task" are equivalent terms. The feasibility findings are the result of overlaying the additional controls analysis on the exposure profiles, which are necessarily based on number of individual workers sampled rather than number of discrete operations performed.

In determining technological feasibility, OSHA reviewed the feasibility for each job category and then made an overall feasibility determination for each industry sector or application group. When OSHA anticipates that additional controls can effectively reduce exposures to below the PEL for most but not all workers in a specified job category, OSHA concludes that the PEL is technologically feasible for that job category. In general industry, OSHA used several different methods to determine feasibility for each job category depending on the available data. First, if most workers' exposures in a specific job category were already below the PEL, then OSHA determined the PEL is feasible. However, for workers above the PEL, OSHA reviewed the baseline controls and any additional controls necessary to reduce exposures to the PEL or below for these workers. For example, the exposure profile developed for the mixer operator in the paint and coating industry sector (see FEA Section IV-4.13) indicated that 75 percent of the workers already had exposures below the PEL. However, OSHA found that additional controls, including local exhaust ventilation and bag disposal systems, are necessary to achieve the PEL for the 25 percent of these workers who are exposed above the PEL (Document ID 1720, p. IV-237).

When most workers are not currently below the final PEL, OSHA described additional controls that could be applied to reduce exposures below the PEL. In some cases, OSHA applied the expected exposure reduction from use of controls to the baseline distribution of exposures to develop an estimate of the range of exposures that can be expected when controls have been implemented. For example, bag filling operations can generate high exposures to respirable dust. Four of the six samples in the exposure profile for packaging operators in the concrete products industry exceed 50 μg/m^3. However, at one facility, installing a more powerful fan motor and new filter bag for the bag-filling machine LEV and moving the hoods closer to the packaging operator's position reduced respirable dust exposure by 92 percent. After these improvements, a concrete packaging operator had a full-shift silica exposure below the limit of detection (LOD) (in this case, 11 μg/m^3) (Document ID 0126, pp. 7-8). At another facility, the installation of a ventilation system for bag-filling operations, described as an overhead air supply island system (OASIS) (Document ID 1365, p. 5-26; 1326), was shown to reduce respirable dust exposure by 98 percent and 82 percent for packaging operators at two mineral processing facilities. Thus, OSHA applied the percent effectiveness of the controls to the current exposure profile and concluded that these types of controls would reduce silica exposures of packaging operators in the concrete products industry to below the PEL.

In other cases, OSHA demonstrated that specific controls can reduce workers' exposures to the PEL or below based on direct observation in facilities that installed controls compared with facilities that had not installed controls. In the cut stone industry sector, for example, OSHA showed that a combination of engineering controls can reduce machine operator exposure substantially and under these conditions, the operator exposure level dropped from 220 μg/m^3 to 26 μg/m^3 (Document ID 1365, p. 11-25; 0178).

In the foundry industry, OSHA noted baseline conditions that covered a wide range of exposures, and included relatively well-controlled foundries with most samples already below the final PEL, and some poorly-controlled foundries with most samples above the final PEL. The relatively well-controlled facilities were more likely to have installed enclosures and local exhaust ventilation (LEV) for dusty activities, such as for sand-handling equipment, shakeout, knockout, and cleaning/finishing tasks. Relatively well-controlled foundries were also more likely to have automated processes that allow for remote operation of equipment, such as for mold making or core making, routine grinding, shot-blasting, and conveying parts into enclosures for dustier processes (e.g., shakeout, shot blast equipment). This allows workers to control these processes from control booths or behind partitions. Additionally, whether automated or not, relatively well-controlled foundries are more likely to have controls in place to reduce airborne silica dust, such as pneumatic sand transport equipment, using washed lake sand (with low respirable-sized particle content), and purchasing sand additives premixed (because the mixing process released additional dust) (Document ID 1365, pp. 2-18 – 2-19; 1409, p. 2; 0268, pp. 7-8; 0147, pp. 53, 72-75; 0082, pp. 88-89, 91, 120, 135). Thus, OSHA concluded that the same types of controls used to reduce exposure levels below the PEL at well controlled foundries could be also be used at poorly-controlled foundries.

Alternately, when OSHA did not have direct evidence that engineering controls had been implemented in a specific industry sector, the additional controls needed to reduce exposures to or below the PEL were determined based on analogous operations where effective controls have been implemented. In the pottery industry, OSHA described additional control measures to reduce exposures to or below the PEL that included covering conveyors and increasing ventilation at existing enclosed transfer points to meet the ACGIH recommended air velocity of 250 fpm/ft^2 across all openings in the enclosures (Document ID 3883, p. 13-81). OSHA did not have in the record a specific example where these controls had been implemented in the pottery industry sector; however, in several other industries that convey similar quantities of silica sand, enclosed conveying systems are an effective part of comprehensive respirable dust management programs, which results in exposure levels below the final PEL (e.g., Sections IV-4.9 – Glass Products, IV-4.13 – Paint and Coatings and IV-4.21 – Structural Clay). OSHA concluded that these controls would be equally effective in the pottery industry sector.

OSHA recognizes that for some operations exposures will exceed the final PEL even when all feasible engineering controls have been implemented. Therefore, for general industry and maritime, the individual employer is obligated to conduct exposure monitoring to identify the specific job categories and work activities during which the supplemental use of respiratory protection is required to achieve compliance. For workers in the construction industry engaged in any of the tasks listed in Table 1, employers can achieve compliance by fully and properly implementing the specified exposure controls measures and providing respiratory protection when required by Table 1. Alternatively, employers in the construction industry must assess and limit exposures in accordance with the more traditional regulatory approach of compliance with the PEL contained in paragraph (d).

1.2 GENERAL TECHNOLOGICAL FEASIBILITY COMMENTS

1.2.1 Feasibility and Variability

During the rulemaking proceeding, there were comments from various industry groups disputing the technological feasibility of achieving exposures of 50 μg/m^3 or less. The American Chemistry Council's Crystalline Silica Panel (ACC) stated that OSHA had not shown that the proposed standard would be technologically feasible in all affected industry sectors (Document ID 4209, Attachment 1, p. 97). Representatives from the American Foundry Society (AFS) and from the Asphalt Roofing Materials Association argued that, due to day-to-day variability, OSHA must demonstrate that average exposures can be reduced to 25 μg/m^3 or less in order to demonstrate that compliance with a PEL of 50 μg/m^3 is technologically feasible (see, *e.g.*, Document ID 2291, p. 5; 3584, Tr. 2654-2655; 3580, Tr. 1282-1284, 1289). The Construction Industry Safety Coalition (CISC) made a similar argument regarding the need to control exposure levels to well below the PEL due to the variability of silica exposures on construction worksites (Document ID4217, p. 11). It stated in its comments, "… if there is one piece of evidence that is virtually undisputed in the rulemaking record, it is that respirable crystalline silica exposures in the construction environment are highly unpredictable and variable" (Document ID 4217, p. 11).

OSHA recognizes that differences in exposure can occur due to workplace variables that are not under the direct control of the employer (e.g., fluctuations in environmental conditions or air movement). These factors contribute to random excursions in exposure that are often greater than variation attributable to the sampling and analytical errors. The Agency has acknowledged and discussed exposure variability in past rulemakings where the same issue was raised (*e.g.*, Benzene, 52 FR 34534; Asbestos, 53 FR 35609; Lead in Construction, 58 FR 26590; Formaldehyde, 57 FR 22290; Cadmium, 57 FR 42102; and Hexavalent Chromium, 71 FR 10099).

However, OSHA disagrees with CISC's statement that the variability in exposure necessarily means unpredictability in exposure. Several studies were submitted to the docket that used multivariate statistical models to identify factors associated with increased exposure to silica during various construction activities (Document ID 3608, 3803, 3956, 3998, Attachment 5h). These studies reported that as much as 80% of the variability in respirable quartz exposures could be attributed to various factors that were observable and controlled by the employer (e.g., location of work – indoor/outdoor, equipment used, type of controls used), clearly indicating that not all variability in exposure is due to random variation or environmental factors; rather, many high exposures are the result of known or observable factors that the employer can readily identify and address in efforts to improve exposure control. This was attested to at the hearing by Dr. Frank Mirer of the CUNY School of Public Health, representing the AFL-CIO: "[e]xposures go up and down not by magic but by particular conditions, differences in work methods, differences in control efficiency, differences in adjacent operations" (Document ID 3578, Tr. 971). Likewise, Scott Schneider of the Laborers' Health and Safety Fund of North America testified that "we know there are certain variables that are more important than others…[T]he goal of controlling exposure variability is to limit the number of variables to the most important ones and set limits or parameters on those" (Document ID 3589, Tr. 4251-4252). The International Union of Operating Engineers asserted that variables affecting silica exposure in construction are manageable because, among other reasons, many construction tasks are highly repetitive, and the variables affecting exposure are predictable (Document ID 4234, Attachment 2, pp. 31-38).

As indicated by these commenters, increasing the consistent use of engineering controls and appropriate work practices will reduce exposure variability. By implementing controls and work practices to reduce worker exposures to the final PEL or below, employers will, in addition to reducing the incidence of serious and fatal illness, substantially reduce exposure variability, reduce the number of workers needing to wear respiratory protection, and provide employers with greater confidence that they will be in compliance with the revised PEL.

OSHA does, however, acknowledge that exposure controls cannot entirely eliminate variability. Some day-to-day variability in silica exposure measurements may remain, despite an employer's conscientious application and maintenance of all feasible engineering and work practice controls. As stated above, this issue of variability in exposure levels is not new; it has been addressed in a number of other rulemakings (*e.g.*, Asbestos preamble, 51 FR 22612, 22653 (6/20/1986)). Reviewing courts have agreed that OSHA's obligation is to show that a PEL can be achieved in most operations most of the time, despite the presence of random exposure variability. In particular these courts have approved of OSHA's flexible enforcement policies, which allow the Agency to take such exposure variability into account before issuing a citation (*e.g., Building & Constr. Trades Dept. v. Brock*, 838 F.2d 1258 (D.C. Cir. 1988) ("*Asbestos II*")). In the *Asbestos II* case, for example, the D.C. Circuit approved of OSHA's policy of allowing for a possible re-inspection if OSHA measured an asbestos exposure above the PEL during an inspection. If the employer appeared to be using, to the extent feasible, work practices and engineering controls, OSHA could agree to re-inspect at a later time. Such a re-inspection would help determine if that over-exposure was typical or simply a random, uncontrollable fluctuation; OSHA could then determine whether or not to issue a citation accordingly (*Asbestos II* at 1268; see 51 FR 22653). Thus, OSHA has, in the past, adopted fair and flexible enforcement policies to deal with the issue of exposure variability and intends to do the same for enforcement of the new silica standards. Furthermore, an employer who fully and properly implements the exposure controls required by Table 1 of the final standard for construction eliminates the risk of being subject to citation for exposures that exceed the PEL.

1.2.2 OSHA's Exposure Profile and its Representation of Baseline Conditions

CISC was critical of several aspects of OSHA's feasibility analysis. CISC commented that OSHA failed to consider exposures from secondary or adjacent sources and that OSHA should factor this into its analysis (Document ID 2319, p. 30; 4217, p. 13). CISC also argued that OSHA did not account for the varying amounts of crystalline silica that could exist in materials being disturbed by workers, meaning that "the same task could be judged as being able to meet the PEL when its *real* ability to meet any PEL is contingent on the percentage of silica in the material being disturbed" (Document ID 2319, pp. 26-27).

OSHA disagrees with CISC because the sampling results relied on by OSHA to characterize silica exposures includes a wide range of silica content that is representative of the range of silica content in materials worked on by construction workers. A total of 881 samples were used in the FEA to develop the exposure profiles for construction tasks. The silica content in these samples ranged from less than 1 percent (non-detected) to 50 percent, with an average silica content of 9.1 percent (see Section IV-2 – Methodology for a description of the percent silica content of the OIS samples specifically). OSHA concludes that the exposure results obtained from these varied construction tasks, including a range of silica content, are representative of typical construction work environments, and OSHA could find no evidence in the record to suggest otherwise.

CISC also indicated that OSHA did not account for differences in exposure results "due solely to what part of the country the activity took place in" (Document ID 2319, p. 27). Similar to the discussion above about the range of quartz content, OSHA relied on exposure data taken from many different parts of the country under varying weather conditions. OSHA's construction database contains data ranging from the east coast (*e.g.*, New York, Georgia) to the Midwest (*e.g.*, Ohio, Minnesota) to the western states (*e.g.*, Arizona and Colorado). Again, OSHA believes that its large exposure database, containing results obtained from varied construction tasks in a variety of locations under different weather conditions, is representative of the broad range of conditions encountered in construction. OSHA could find no evidence in the record to prove otherwise.

Additionally, some commenters questioned whether OSHA had adequately considered the difficulties in complying with the PEL for maintenances activities. The National Association of Manufacturers (NAM), for example, quoted one of its members, which stated:

> [t]here are occasional conditions where maintenance cleaning is performed inside conveyor enclosures where the enclosure is ordinarily a part of the dust control systems. This is just one example of where a control would have to be breached in order to properly maintain it as well as the operating equipment. It is simply not technically feasible to establish engineering controls for all possible maintenance activities (Document ID 2380, Attachment 2, p. 1).

OSHA has addressed maintenance activities in each sector's technological feasibility analysis, but the standard itself acknowledges the challenges of using engineering and work practice controls in some maintenance activities. Paragraph (g)(1)(ii) of the general industry and maritime regulatory text (paragraph (e)(1)(ii) in construction) requires respiratory protection "where exposures exceed the PEL during tasks, such as certain maintenance and repair tasks, for which engineering and work practice controls are not feasible" (see the Summary and Explanation section of this preamble on Respiratory Protection for more information).

1.2.3 Operations not Covered

OSHA's technological feasibility analysis of the construction industry focused on the application groups (tasks and activities) for which OSHA found substantial evidence that, when performed without dust controls, worker exposure to respirable crystalline silica routinely exceeded the final PEL. These tasks involve the use of handheld power tools and some types of larger equipment that can generate significant levels of visible dust and lead to elevated silica exposures; these tasks include cutting, grinding, drilling, or crushing silica-containing materials. CISC submitted comments suggesting that the technological feasibility analysis was incomplete because it did not cover every construction-related task for which there is the potential for exposure to silica dust. It listed more than 20 operations, including cement mixing, cutting concrete pavers, demolishing drywall or plaster walls/ceilings, overhead drilling, demolition of concrete and masonry structures, and grouting floor and wall tiles, that it stated OSHA must examine, in addition to the application groups already covered by the Agency's analysis, in order to establish feasibility (Document ID 2319, pp. 19-21). CISC asserted that, because of the many types of silica-containing building materials used in the construction industry, as well as the presence of naturally occurring silica in soil, additional data collection and analysis by OSHA should be conducted before promulgating a final rule (Document ID 2319, pp. 25-26; 4217, p. 3).

As explained in the NPRM, OSHA's analysis for construction focuses on tasks for which the available evidence indicates that significant levels of respirable crystalline silica may be created, due primarily to the use of powered tools or large equipment that generates visible dust. OSHA notes that many of the examples of tasks for which CISC requested additional analysis are tasks involving the tools and equipment already covered in this feasibility analysis. For example, overhead drilling is addressed in Section IV-5.4 – Hole Drillers Using Handheld or Stand-Mounted Drills, and the demolition of concrete and masonry structures is addressed in Section IV-5.3 – Heavy Equipment Operators and Ground Crew Laborers. In other cases, such as for concrete mixing, there is no evidence in the record that the task is likely to result in significant exposure. OSHA discussed the use of dust controls to reduce exposures that can occur when cleaning dried concrete from mixers in Section IV-4.17 – Ready-Mixed Concrete. Other tasks listed by CISC involve working with wet or intact concrete, for which there is no evidence of significant exposure. Furthermore, CISC did not submit to the record any air monitoring data to support its assertion that these activities result in significant exposures. Therefore, OSHA has not added these additional activities to the feasibility analysis.

1.3 FEASIBILITY OF RESPIRABLE CRYSTALLINE SILICA CONTROLS

The exposure control methods described in this chapter to reduce exposures to respirable crystalline silica rely primarily on the use of water (wet methods) to suppress airborne dust at the point of generation, or on the use of local exhaust ventilation (LEV) that removes airborne dust and collects it in a baghouse or filtered dust collector. OSHA received a number of general comments on the feasibility of wet methods and LEV as well as on challenges faced when employing these dust control strategies in specific work settings.

Most of these comments addressed the use of water on construction sites; several rulemaking participants argued that it is not always possible for employers to use water for dust suppression. For example, in its post-hearing submission, CISC discussed "significant obstacles" to using wet dust suppression technologies on construction sites, including freezing weather, which contraindicates water use, and a lack of running water onsite, which requires employers to deliver water, a practice which, according to CISC, is both "costly and time consuming" (Document ID 4217, pp. 18-19). In addition, CISC stated that indoor work precludes the use of water because water could damage existing floors, drywall, or the possessions of the property owner. Use of wet methods, stated CISC, also can create excessive runoff and cause environmental problems (Document ID 4217, pp. 18-19).

However, many other participants commented that these barriers can be overcome. For example, Phillip Rice, of Fann Contracting, Inc., stated his company uses water trucks to haul water to sites and includes the cost of doing so in his bids. He added that "when someone says they can't get water on their project there is something wrong" (Document ID 2116, Attachment 1, p. 33). Representatives of the International Union of Bricklayers and Allied Craftworkers (BAC) pointed out that water is essential for work in the masonry trades and, without it, no mortar can be mixed to set materials (Document ID 3585, Tr. 3059-3060). They testified that, in their experience, it was rare to work on sites that did not have water or electricity available, but when they did, they brought in water trucks and gas-powered generators to run saws (Document ID 3585, Tr. 3061-3063). With respect to weather conditions, heated water or heated shelters can be used (Document ID 3585, Tr. 3095-3096). Water runoff can also be managed by training operators to achieve a balance between using sufficient water for effective dust control and avoiding pooling to minimize runoff (Document ID 3583, Tr. 2384).

These comments and testimony indicate that many of the barriers to wet dust suppression raised by CISC have been overcome in various construction settings. OSHA recognizes that there will be limited instances where the use of wet dust suppression is not feasible, particularly where its use can create a greater hazard. For example, water cannot be used for dust control in work settings where hot processes are present due to the potential for steam explosions (Document ID 2291, p. 13; 2298, p. 3), and it may not always be possible to use water where it can increase slip and fall hazards, such as on a roof

(Document ID 2214, p. 2). Use of water for dust suppression can also create electrical safety hazards, and therefore requires use of ground-fault circuit interrupters (GFCI) on electrical tools. Nevertheless, in the individual feasibility analyses that follow, the evidence discussed makes it clear that many employers currently use wet dust suppression, that there are many commercially available products with integrated water systems for dust suppression, and that these products can be used in most work settings to control exposures to respirable crystalline silica. OSHA understands the concerns regarding the use of wet methods and the increased risk for falls; however, OSHA also heard testimony that proper planning can enable employers to use wet methods. Therefore, OSHA is not persuaded by the arguments of CISC and others that the barriers they identify would prohibit use of wet dust suppression in most operations where it would otherwise be an effective means of dust control.

1.3.1 Commercial Availability of Effective Dust Controls

In order to demonstrate technological feasibility where current (baseline) exposures are above the final PEL, OSHA has to show that there are dust controls available or reasonably foreseeable on the horizon that are capable of reducing exposures to the PEL or below. To meet this burden, OSHA reviewed a large quantity of evidence in the record on the commercial availability of engineering controls, including wet methods and local exhaust ventilation, that can effectively reduce workers' exposures to respirable crystalline silica. For example, for construction activities, Eileen Betit, testifying on behalf of the Building and Construction Trades Department (BCTD), AFL-CIO, stated, "each year, there seem to be more and more types of tools coming out that control silica… So new innovations keep happening" (Document ID 3581, p. 1673). Chris Trahan, a certified industrial hygienist with BCTD, stated that tool manufacturers regularly work with users to create innovative solutions for industry problems. She stated, "almost all of the good tool manufacturing lines…are creating tools with integral engineering work practice controls built in" (Document ID 3581, p. 1701). She went on to describe a recent experience at a trade show where a well-known tool manufacturer presented its catalogue of options for controlling dust at the source for a variety of handheld masonry tools (Document ID 3581, pp. 1701-1702).

Several representatives of the International Union of Bricklayers and Allied Craftworkers (BAC) also spoke to the availability of engineering controls. Tommy Todd, a bricklayer with decades of experience, commented on the changing state of dust control technology, stating “new tools and equipment are coming out daily in the masonry trade and other trades as well” (Document ID 3585, p. 3073; also 3585, p. 3072). Dennis Cahill, also from BAC, testified about the introduction onto jobsites of cutoff saws, and the ways in which they have been adapted to fit with engineering controls for reducing dust. He stated, “all modern cut-off saws have a fitting to hook them up to water or to hook them up to vacuums. So they -- as these problems appear the technology tries to solve the problem. And I think we're doing a pretty good job, but if we don't apply these answers to these problems they're not going to get solved” (Document ID 3585, pp. 3073-3074).

In addition to the testimony described above, studies have demonstrated that employers and manufacturers can create their own engineering controls for use on their particular worksites or with their own products. Shepherd (2006) reported on one employer’s approach to reducing respirable dust from overhead grinding by using an extension arm equipped with a vacuum system to lift and maneuver a grinder that effectively reduced both exposure to respirable silica dust and the ergonomic stress associated with overhead grinding (Document ID 3998, Attachment 13o). Another example is the development of a circular saw equipped with a vacuum system for cutting cement-fiber board, which demonstrated one manufacturer’s ingenuity in designing tools that contain built-in dust controls with proven effectiveness specifically for use with its product (Document ID 2322, Attachment 1, pp. 9-10).

The British Health and Safety Executive (HSE) evaluated the use of on-tool controls and their effectiveness in controlling respirable dusts, based on approximately 30 studies (Document ID 3791, p. 2). The HSE stated that on-tool controls were a solution to the challenges posed by construction crews’ mobility across temporary worksites, which limits the feasibility of using stationary exhaust systems (Document ID 3791, p. i). The HSE found that:

> [a] large body of work has been carried out in the last 10 – 15 years on controls. These studies have demonstrated that significant reductions in

> exposure to workers in excess of 90% are achievable for the following activities: tuck-point grinding, surface grinding and polishing, floor sanding, drywall sanding and block, slab and tile cutting using both on-tool LEV and water suppression methods (Document ID 3791, p. iii).

The HSE noted no significant difference in the effectiveness of on-tool LEV versus water suppression methods (Document ID 3791, p. v).

Similarly, in general industry the use of enclosed and ventilated equipment is on the rise. Many industries have switched from manual transfer of raw materials to integrated bag dumping stations equipped with well-ventilated enclosures and bag compactors. For example, as discussed in the PEA, site visits indicate that the primary controls for mixer operators in the paint and coatings production industry sector are bag dumping stations equipped with well-ventilated enclosures and bag compactors (also ventilated) (Document ID 0199, pp. 9-10; 0943, p. 87; 1607 p. 10-19; 1720, p. IV-237). Neither the Society for Protective Coatings nor the American Coatings Association disputed this assertion, even though they commented on other aspects of the proposed rule (Document ID 2120; 2239). Therefore, OSHA concludes that this type of system is already being used and can be adapted to other industry sectors for use during material transfer operations (see Sections IV-4.13 – Paint and Coatings, IV-4.14 – Porcelain Enameling, IV-4.9 – Glass, and IV-4.3 – Concrete Products of this FEA for additional information).

Based on the evidence described above and in the individual sections of the technological feasibility analysis, OSHA finds that many engineering control options are currently commercially available to control respirable dust. These controls will reduce workers' exposures to respirable crystalline silica when the workers are performing the majority of tasks that create high exposures today. OSHA's finding is based on numerous studies, conducted both in experimental settings in which the tools, materials, and duration of the task are controlled by the investigator, and in observational field studies of workers performing their normal duties in the field. More than 30 studies were submitted to the docket that report substantial reductions in exposure when using controls compared with uncontrolled situations. The specific reports that OSHA relied upon to estimate the range of reductions that can be achieved through the implementation of engineering controls are discussed in greater detail in the relevant sections of the technological feasibility analyses. These studies, along with other evidence in the record, also demonstrate the responsiveness of manufacturers to industry needs in solving the problem of dust exposure. Continual technological improvements in engineering controls, which are expected to continue after promulgation of this final rule, demonstrate the effectiveness of that working relationship.

2. METHODOLOGY

The technological feasibility analysis, which is part of the Final Economic Analysis (FEA), addresses the capability of employers to implement the engineering controls and work practices necessary to comply with OSHA's new standard on occupational exposure to respirable crystalline silica (sometimes referred to as "crystalline silica" or simply "silica" throughout the preamble). Crystalline silica occurs in multiple forms (polymorphs). In the final rule, OSHA is setting the same PELs for all three of the major polymorphs of crystalline silica (quartz, cristobalite, and tridymite). The term "respirable crystalline silica" is defined in the final rule as "quartz, cristobalite, and/or tridymite contained in airborne particles that are determined to be respirable …" (see Summary and Explanation for paragraph (b) (Definitions)). The vast majority of crystalline silica encountered by workers in the United States is in the quartz form, to such an extent that investigators often use the terms crystalline silica and quartz interchangeably. Nevertheless, the data available to OSHA contain a few samples in which detectable levels of cristobalite were reported, either alone or in addition to quartz. These results, when discussed individually, are specifically identified as including detectable cristobalite. In the FEA, the concentrations of the detected forms were added together to compare against the final rule's PEL. Tridymite was not reported as a component of any of the silica samples available to OSHA.

The silica sample results included in the exposure profiles in this technological feasibility analysis are measurements of respirable crystalline silica as determined by taking personal breathing zone (PBZ) samples of respirable dust and analyzing the samples for crystalline silica. PBZ samples are taken by attaching the sampling device directly to an employee's shirt collar or lapel to measure the respirable dust in the air that the worker is breathing. This device is worn by the worker for the duration of the sampling period. (Criteria relating to duration of sampling period are discussed below). The results of other types of samples, including area samples and respirable dust samples not analyzed for silica, are also discussed when they are relevant to evaluating the effectiveness of engineering controls, but are not used in the exposure profiles. When a sample result is not a PBZ respirable crystalline silica sample, the sample type is clearly identified to avoid confusion.

2.1 SOURCES OF DATA

OSHA's technological feasibility analysis relies on information from a wide variety of sources available to the Agency, as noted in the Introduction, and described in the Preliminary Economic Analysis (PEA) and the Notice of Proposed Rulemaking (NPRM), issued September 12, 2013 (78 FR 56274). Thus, each section in this chapter includes an exposure profile that summarizes all the available exposure data for the specific industry sector or application group, including the post-1990 monitoring data previously presented in the PEA as well as the additional monitoring data obtained subsequent to publication of the PEA.

The sources of the exposure monitoring data presented in the PEA are summarized in two reports prepared by an OSHA contractor (ERG).

- Technological Feasibility Study of Regulatory Alternatives for a Proposed Crystalline Silica Standard for General Industry (Document ID 1365).
- Technological Feasibility Study of Regulatory Alternatives for a Proposed Crystalline Silica Standard for Construction (Document ID 1431).

These two reports included exposure monitoring data from the following sources, as described in greater detail in the PEA (Document 1720, p. IV-2):

- OSHA silica Special Emphasis Program (SEP) inspection reports.
- NIOSH reports, including health hazard evaluations [HHE], control technology [CT] assessments, in-depth exposure monitoring surveys with recommendations for exposure control, and studies on the effectiveness of engineering controls.
- Workplace evaluation reports related to the "sentinel event notification system for occupational risks" (SENSOR) for silica from the states of Michigan, New Jersey, and Ohio.
- ERG and OSHA site visits specifically conducted for this rulemaking.
- Published literature.

- Unpublished information (e.g., unpublished data and research obtained through personal communications, meetings, and presentations).
- Information available from other federal agencies, state agencies, labor organizations, industry associations, and other groups.

The contractor reports primarily relied on the results of air monitoring conducted between 1990 and 2001, updated with some information through 2007. In a few cases, where sources more recent than 1990 were limited and earlier information existed, sampling results from the 1980s were used.

After the NPRM was published, OSHA received comments from stakeholders that, in some cases, included additional information on exposure to respirable crystalline silica, such as exposure monitoring data and examples of engineering controls that have been implemented to reduce exposures. OSHA reviewed all comments and supporting materials submitted to the rulemaking record and incorporated additional sampling results into the exposure profiles presented in the FEA. OSHA also updated the exposure profiles using the most recent exposure monitoring data from OSHA compliance inspections from 2011 to 2014, available through the OSHA Information System (OIS) (Document ID 3958). This data set is described in greater detail below.

The exposure profiles used in the PEA were updated for the FEA by removing the most of the results of samples collected prior to 1990 (n=290), leaving a total of 2,512 of the samples from exposure profiles presented in the PEA. OSHA added to the exposure profiles presented in the FEA samples submitted by commenters during the rulemaking (n=153) and the samples obtained from the OIS database (n=699), resulting in a total of 3,364 samples (2,483 for general industry and 881 for construction) in the final exposure profiles. Table IV.2-A summarizes the number of samples in the final exposure profiles that were used in the PEA, along with the number of additional samples used in the exposure profiles that came from commenters and from the OIS database. OSHA considers these samples to be the best available information regarding current exposures to respirable crystalline silica.

Table IV.2-A
Number of Samples Included in the Final Exposure Profiles

	General Industry	Construction	Total
PEA Samples	1,877	635	2,512
Docket Comment Samples	14	139	153
OIS Database Samples	592	107	699
Grand Total	**2,483**	**881**	**3,364**

OSHA has submitted to the docket as a background document for the FEA a file that contains the results of all 3,364 samples used in the exposure profiles with the Docket ID Numbers that identifies the source document from which each of these samples was obtained.

2.2 NOTES ON DATA SOURCES, CHARACTERISTICS, AND HANDLING

2.2.1 General Data Handling and Assumptions

OSHA used several criteria to ensure that the exposure data relied on for the technological feasibility analysis were of sufficient quality and handled uniformly. The data included in the exposure profiles in the FEA met the following criteria:

The sample results are reported as either respirable crystalline silica concentrations, or as respirable dust concentrations along with percent silica content of the dust. In some cases, the percent silica content was calculated based on the reported PEL for the sample (see Section IV-2.3 – Calculation of Respirable Crystalline Silica Exposures for more detail).

- The units of measurement are either micrograms per cubic meter of air (μg/m^3), milligrams per cubic meter or air (mg/m^3), or, in some cases, millions of particles per cubic foot (mppcf). All sample results were converted to units of micrograms per cubic meter when used in the exposure profiles.
- The sample duration is reported or, where sample durations were not reported, the results are reported to be representative of 8-hour TWA exposures.

- They are samples collected in U.S. workplaces.[2]
- For sample results reported as "non-detect" or "0" in the PEA, the sample duration was 120 minutes or more, resulting in a maximum possible silica concentration below 25 μg/m^3. For the sample results from the OIS database, all samples were used regardless of duration. (see Section IV-2.3.1 – Limits of Detection for Silica Data for more detail).
- There is sufficient information to identify the sector, job category, and activity performed for general industry, or the application group and activity performed for construction.

2.2.2 Integrated Management Information System (IMIS)

To identify affected industries and application groups for the PEA, OSHA initially reviewed the silica sampling results contained in OSHA's IMIS data (1979 through mid-2002). The IMIS data identified the sector for general industry, or the application group for construction, in which OSHA performed the monitoring. The IMIS data contain sampling results from compliance inspections conducted by both Federal and State OSHA plans. The IMIS dataset contains three separate files (two in one docket entry, one in another): IMIS sampling data from 5/1/1979 through 4/29/1998 and from 1/1/1998 through 5/1/2002 (Document ID 1698), and data from 2009 through April 2014 (Document ID 4185).

The IMIS report includes the job title of the worker sampled, but does not provide information on the worker's activities or on the presence of exposure controls. Furthermore, the IMIS data do not include the sample duration. Thus, while the IMIS system is useful as a management tool for identifying industries in which OSHA has monitored silica exposures, OSHA was unable to use IMIS samples in the exposure profiles unless they were part of a more detailed Special Emphasis Program report.

[2] Information on international exposure levels is occasionally offered for perspective or in discussion of control options.

2.2.3 OSHA Special Emphasis Program (SEP) Inspection Reports

The OSHA SEP inspection reports primarily include files from inspections conducted by OSHA compliance safety and health officers (CSHOs) between 1993 and 2000 that contain silica sample results. Under this national SEP, OSHA provided extensive outreach on hazard recognition and engineering control measures for crystalline silica, and conducted inspections at randomly selected workplaces where exposures to crystalline silica were possible due to such tasks as grinding, cutting, , drilling, chipping, or polishing on granite and other stone materials containing crystalline silica. The SEP inspection reports contain silica exposure samples that are also included in the IMIS system. However, these SEP reports include substantially more information about worker activities than is available through the IMIS reports, including working conditions, sample duration, and, in some cases, post-abatement follow-up results. OSHA relied heavily on information from the 191 OSHA SEP reports from 1993 to 2000, as referenced in the ERG contractor reports (Document ID 1365; 1431).

2.2.4 OSHA Information System (OIS)

For this FEA, OSHA has updated to the exposure profiles to include the more recent data from OSHA's OIS database. The OIS is an information management system that contains information related to OSHA compliance inspections, including the results of air samples taken by CSHOs to assess employee exposures. In 2011, OSHA began a phased transition during which the OIS system replaced the IMIS; this transition was completed by 2014. When compared with the older IMIS system, the OIS database has significantly increased OSHA's ability to store and retrieve more detailed information about the results of air sampling conducted to assess compliance with air contaminant standards. The OIS system includes more detailed information on the worksite and individual exposure samples. In addition to job title, the OIS includes supplemental information recorded by the CSHO during the inspection on sampling worksheets, including the sources of exposure, worker activities, type of tools in use, and the presence or absence of exposure controls. Therefore, OSHA considers the data contained in the OIS database to be the highest quality information for characterizing baseline exposure levels in the affected industries and application groups.

2) METHODOLOGY

The samples in the OIS database were collected during workplace inspections to assess compliance with the existing PEL, and therefore the measurements are specifically collected to represent 8-hour TWA exposures for enforcement purposes. These samples were all collected by CSHOs using the same sampling procedures (OSHA Method ID-142) and all samples were analyzed using the same validated analytical methods at the OSHA Salt Lake Technical Center laboratory. These samples were all collected between 2011 and 2014, and therefore are more representative of current workplace conditions than the samples in the PEA, which were collected mostly between 1990 and 2001.

The OIS samples used in the FEA include sample results with the IMIS substance codes 9010 (Silica Crystalline Quartz, Resp. Dust), 9015 (Silica, Crystalline Cristobalite Resp. Dust), and 9017 (Silica, Crystalline Tridymite, Respirable Dust). Only samples specifically designated as PBZ were used. As a quality control measure, only samples with units “milligrams per cubic meter” or “million particles per cubic foot” were retained to ensure consistency in units. Samples with an entry of CSHO as the job title were excluded, since these were presumed to be exposures measured on the CSHO rather than an employee.

OSHA reviewed the descriptive information on the establishment, job title, and work activity for each sample in the OIS in order to identify the industry sector and specific job category for the general industry samples, and the application group and activity for the construction industry samples. OSHA also determined, when possible based on the available information, whether any exposure controls were used during the sampling period.

OSHA examined 1,097 samples that were taken after the PEA was completed for possible inclusion in the FEA (see Document ID 3958, Attachment 1). Of these, OSHA had sufficient information to calculate a respirable crystalline silica concentration for 964 samples. A smaller subset of 699 samples from 322 inspections had sufficiently detailed information to clearly identify the industry sector and job category. These samples are included in the final exposure profiles, in addition to the more recent data provided by commenters. Appendix 1 of this chapter includes a complete list of the samples from the

OIS database used in this analysis, sorted by the industry sector or application group that was assigned to the sample by OSHA during its review of the OIS database.

Summaries of the OIS silica data used in the FEA for general industry, maritime, and construction appear in Tables IV.2-B and IV.2-C. For general industry, the OIS data contains 592 samples taken during 266 inspections, including 29 samples taken during abrasive blasting operations. Among the 563 samples from general industry (not including abrasive blasting), 18 percent exceed the preceding general industry PEL for respirable dust containing crystalline silica, and 24 percent exceed the new PEL for respirable crystalline silica of 50 $\mu g/m^3$. Thus, 6 percent of OIS general industry samples (other than abrasive blasting) are between the preceding PEL and the new PEL.

Because the exposures measured during abrasive blasting operations are substantially higher than other OIS samples, the samples for abrasive blasting are summarized separately. There were 29 samples taken during abrasive blasting in general industry, of which 41 percent exceed the preceding PEL and 52 percent exceed the final PEL. The comparable OIS data for abrasive blasting in construction, where most abrasive blasting occurs, show, 67 percent (8 out of 12 samples) exceeding both the preceding and final PEL.

For the construction industry, the OIS database contains the results of 107 samples taken during 56 inspections. Among the 95 sample results other than abrasive blasting, 36 percent exceed the preceding PEL for construction, and 46 percent exceed the new PEL of 50 $\mu g/m^3$. Thus, 10 percent of OIS construction samples are below the preceding PEL but above the new PEL

The results of the OIS samples not added to the exposure profiles are presented in Table IV.2-D. These are the samples for which a silica concentration could be calculated, but the sampling information could not be matched to a specific general industry sector and job category or construction application group. Thus, OSHA could not use them in the final exposure profiles. These sample results (n=265) were, on average, lower than the results of the OIS values that were added to the profiles. For general industry other than abrasive blasting, 16 percent of the samples exceed the final PEL, compared with 24 percent of the samples that were added to the profiles. For construction, 25 percent exceed the final PEL compared with 46 percent of the samples that were added to the profile. The set of OIS samples not used in the exposure profiles also had a lower average percent silica content of 5.4 percent, compared with 7.9 percent for the samples added to the profile.

The construction industry expressed concerns regarding the large variability in the silica content of different building types of building materials (Document ID 2329, p. 31). In response, OSHA analyzed the distribution of silica content in the OIS samples. The average silica content of the OIS samples was 7.8 percent for the general industry samples and 7.9 percent for the construction samples. The distribution in the percent silica content of the respirable dust samples included in the OIS database is presented in Table IV.2-E. A silica content of less than 10 percent was detected in 71 percent of the samples from general industry, and 65 percent of samples from construction. A silica content of less than 25 percent was detected in 91 percent of the samples from general industry and 94 percent of the samples from construction. Thus, the OIS data include samples with a range of silica content, with over 90 percent of the samples containing less than 25 percent silica.

2.3 CALCULATION OF RESPIRABLE CRYSTALLINE SILICA EXPOSURES

In order to compare baseline exposures in the FEA to OSHA's final PEL for respirable silica, OSHA had to ensure that all exposure results were presented in the same units as the final PEL (i.e., micrograms per cubic meter of air or $\mu g/m^3$). Where the data included exposures to respirable crystalline silica in $\mu g/m^3$, OSHA used these values directly. However, most exposure values were not expressed in $\mu g/m^3$. This is because the preceding PEL for general industry was based on the air concentration of respirable dust (including but not limited to silica) expressed in units of milligrams per cubic meter of air (mg/m^3). Therefore, the results of samples in the SEP reports and the OIS database, which were taken to assess compliance with the previous PELs, were reported as the air concentration of respirable dust in units of milligrams per cubic meter of air rather than as the concentration of respirable crystalline silica.

In order for OSHA to use these results in the FEA, the air sampling results for respirable dust reported in units of mg/m^3 were converted to the equivalent respirable crystalline silica dust concentrations in units of $\mu g/m^3$. This was a two-step process. OSHA first multiplied the respirable dust concentration by the percent silica content (as reported in the sample or calculated from the reported PEL) for that sample to convert the respirable dust concentration into the respirable silica dust concentration. This value was then multiplied by 1,000 to convert from mg/m^3 to $\mu g/m^3$ to be consistent with the units for the final PEL.

In most cases, the sampling result did not report the percent silica content but rather reported the calculated PEL for silica (a level that fluctuates depending on the percentage of silica in the dust sample), from which the percent silica content could be derived. For general industry, the preceding PEL for respirable dust containing crystalline silica was calculated from the formula:

PEL = 10 ÷ (% silica + 2) (in mg/m^3);

where % silica refers to the percent silica content of the dust.

Therefore, when the PEL was provided with a sample result, OSHA calculated the percent silica content using the formula:

% silica = (10-2*PEL) ÷ PEL.

The reported respirable dust concentration was than multiplied by the percent silica content to obtain the respirable silica dust concentration, as described above (i.e., by multiplying the concentration expressed in milligrams by 1,000).

Similar to general industry, the sampling results from construction and maritime were most often reported as respirable dust concentrations. However, the concentrations were presented in units of either mg/m^3 or, in some cases, millions of particles per cubic foot of air (mppcf), for comparison with OSHA's previous PELs for the construction and maritime industry. For construction, the preceding PEL in mppcf for dust containing respirable crystalline silica was calculated using the formula:

PEL = 250 ÷ (% silica + 5) (in mppcf)

When the sample result was presented in mppcf, OSHA calculated the silica content using the formula:

% silica = (250 -5*PEL) ÷ PEL.

When the sample result was presented in mg/m^3, OSHA calculated the silica content using the formula:

% silica = (25 – 5*PEL) ÷ PEL

The reported respirable dust concentration was then multiplied by the percent silica content to calculate the respirable silica dust concentration and then by 1000 to convert to units of µg/m^3.

For SEP reports in which the original laboratory results were available, the silica concentration was calculated directly from the reported mass of silica detected on the filter in units of micrograms (µg), divided by the air volume sampled in units of cubic meters (m^3), for a result expressed in µg/m^3.

Finally, when the sample duration was less than 8 hours or multiple samples were taken on one worker during a shift, OSHA calculated the 8-hour time-weighted average using the equation contained in 29 CFR 1910.1000(d)(1)(i), which is: $(C_1*T_1 + C_2*T_2…+C_nT_n)$ ÷ 480; where C_n is the concentration for a single sample taken for time T_n in minutes.

2.3.1 Limits of Detection for Silica Data

When sample results were reported as "non-detect" or as a value of "0", this was interpreted to mean the sample result was less than the limit of detection (LOD) of the analytical method. The LOD for an analytical method refers to the smallest mass of silica that can be detected on the filter used to collect the air sample. Many laboratories currently report a LOD of 10 µg or lower for quartz samples (Document ID 0666) (see Section IV-3 – Feasibility of Measuring Respirable Crystalline Silica Exposures at the Final Rule's PEL and Action Level). For the results reported as non-detects in the PEA, OSHA calculated the maximum silica concentration that could be detected for that sample volume based on the analytical LOD. The maximum silica concentration was calculated by dividing the analytical LOD by the volume of air sampled (measured in cubic meters). For example, if the analytical LOD is 10 µg and the air volume sampled is 816 liters (0.816 m^3), the maximum silica concentration for a sample reported as a non-detect would be calculated as 10 µg/0.816 m^3 or about 12 µg/m^3.

For respirable dust samples obtained with a nylon cyclone at a fixed flow rate of 1.7 liters per minute (lpm), a shorter sampling period will result in a smaller volume of air sampled, so that a sample collected over a shorter period with a result below the analytical LOD will result in a higher calculated detection limit than a sample collected at the same flow rate over a longer period. Two results obtained on the same date at the same location, but involving different sample durations, will have different maximum silica concentrations. Table IV.2-F displays the maximum silica concentrations for silica samples analyzed using a method with an analytical LOD of 10 µg for sample durations ranging from 30 minutes to 480 minutes. The maximum silica concentration for a 120-minute air sample is 49 µg/m^3, which means that if a sample with a duration of 120 minutes is reported as a non-detect, the silica concentration must be less than 49 µg/m^3. For 480-minute samples, the maximum silica concentration for samples with no detectable silica is 12 µg/m^3.

Table IV.2-F
Maximum Silica Concentrations for Silica Results Reported as Non-Detected, Obtained Using a Method With an Analytical LOD of 10 µg

Sample Duration*	Air Volume Sampled	Maximum Silica Concentration
480 minutes (8 hours)	816 Liters (0.816 m^3)	12 µg/m^3
360 minutes (6 hours)	612 Liters (0.612 m^3)	16 µg/m^3
240 minutes (4 hours)	408 Liters (0.408 m^3)	24 µg/m^3
120 minutes (2 hours)	204 Liters (0.204 m^3)	49 µg/m^3
30 minutes (½ hour)	51 Liters (0.051 m^3)	196 µg/m^3

* Also assumes that the air sample was obtained at 1.7 lpm, the rate used for a standard nylon cyclone.

For non-detect values in the exposure profiles from the PEA, OSHA calculated the maximum silica concentration based on the analytical LOD and air volume sampled, as discussed above. These values have not been changed for the FEA. For the OIS data, which are presented as 8-hour TWAs, OSHA assigned a value of 12 µg/m^3 (the maximum silica concentration for an 8-hour sample) to all results that were reported as "0" (i.e., non-detect) regardless of the sample duration. For construction samples reported as non-detect, the maximum silica concentrations for partial shift samples were converted to corresponding 8-hour TWAs. For example, a 120-minute sample reported as non-detect has a maximum concentration of 49 µg/m^3 which, when multiplied by 120/480 minutes, corresponds to an 8-hour TWA of 12 µg/m^3. When discussing individual PBZ samples in which silica was not detected, OSHA typically includes a parenthetical notation (e.g., "(LOD)") indicating that the reported value (e.g., 12 µg/m^3) is based on a calculated silica concentration. Using the maximum silica concentration value for samples reported as non-detects slightly overestimates exposure levels because the actual exposures will always be less than the maximum silica concentration calculated under the LOD formula.

For general industry and maritime, OSHA relied primarily on sampling results having a duration of 360 minutes or greater. Because the maximum silica concentration for samples taken over at least 360 minutes is 16 μg/m^3, relying on samples of greater than 360 minutes minimized the number of results reported as LOD. For the construction industry, where task-based sampling is sometimes the most practical option, OSHA relied primarily on samples having a duration of 120 minutes or greater, for which the maximum silica concentration is 49 μg/m^3 (or 12 μg/m^3 as a 8-hour TWA). As a result of the practices described above, the values assigned to results below the LOD have only a limited impact on the technological feasibility analysis.

2.4 METHODS TO ASSESS FEASIBILITY OF CONTROL TECHNOLOGY

2.4.1 Feasibility of Control Technology

OSHA's technological feasibility analysis considers maritime (shipyards) to be 1 sector, and divides general industry into 21 sectors and the construction industry into 12 application groups. The basic division between general industry/maritime and construction is done for analytical, purposes in this FEA, it is not relevant to future enforcement practices; thus, it is possible that a sector is classified as general industry but performs some construction tasks that are covered by the standard for construction. In this respect, OSHA notes in particular that the railroad industry is one of the general industry sectors analyzed even though the primary operations within that industry that expose its employees to respirable crystalline silica (ballast dumping, associated heavy equipment operations) are construction activities (specifically, the use of heavy equipment under Table 1 of the standard for construction).

<u>Sector Analysis for General Industry and Maritime</u>

The technological feasibility analyses for general industry and maritime workplaces are grouped by industry sector based primarily on the NAICS classifications. If the sample description clearly showed that the worker’s activity is not typical of the sector, but is typical of another, the sample was in some cases assigned to a different sector based on the description of the worker’s activity, materials, or work area. Within each sector, data are further divided into job categories representing groups of workers using similar materials, work processes, equipment, and available exposure control methods. OSHA notes that these job categories are intended to represent job functions (some of which involve more than one activity); actual job titles and responsibilities might differ depending on the facility. OSHA recognizes that many other job categories exist in these sectors, but those job categories are not associated with substantial direct silica exposure and are not included in the analyses. For general industry, all samples with sufficient information to categorize the industry and job category or activity were assigned to a job category in the industry. Consequently, the exposure profiles include the job categories for which monitoring data were available, and does not include any job category for which there were no samples from that industry or from an industry performing closely analogous operations or processes. In other words, the exposure profiles only include job categories for which monitoring data were available and does not include jobs for which there was no monitoring data. The absence of any sampling data was considered by OSHA to be indicative of the absence of substantial exposures above the LOD for any job categories not included in the exposure profiles.

Application Group Analysis for Construction Industry

OSHA determined that the best method for analyzing silica exposure levels in the construction industry was to group workers by application group, with the term application group referring to a specific construction activity or task (e.g., sawing, drilling, crushing rock). By discussing individual construction industry activities, which sometimes involve more than one job function (e.g., operators and helpers), OSHA can apply the exposure profile and exposure control methods for these activities to workers who perform these activities in any segment of the construction industry. Collectively, the 12 application groups analyzed encompass the common construction tasks with substantial silica exposure, identified based primarily on compliance sampling data.

Coverage of Abrasive Blasting

As previously noted, certain activities are common to construction and some segments of general industry. Abrasive blasting is an activity that occurs in construction and across several general industry sectors, either as a routine part of the production process, or as an infrequent activity not directly related to the core business. In the FEA, abrasive blasting is included as a specific application group within the construction industry (Section IV-5.1). However, OSHA also evaluated abrasive blasting in general industry based on how abrasive blasting was used in that particular industry sector. In four general industry sectors (concrete products, cut stone, foundries, and shipyards), OSHA had sampling data for abrasive blasters and therefore included abrasive blasting as a job category. In these sectors, abrasive blasting is an integral part of the industry and the samples collected by OSHA were used in the overall exposure profile for that sector. Two other general industry technological feasibility analyses (for dental laboratories and jewelry), discuss abrasive blasting, but do not include sampling data in the exposure profile because abrasive blasting is typically carried out sporadically across the industry and then only in small-scale operations involving self-contained abrasive blasting cabinets. OSHA has also identified 44 abrasive blasting samples from other general industry sectors not covered in the FEA, but this activity more closely resembles the work described in the construction application group for abrasive blasting. Abrasive blasters in these sectors may need respiratory protection if the exposure assessments required by the standard for general industry and maritime show exposures above the PEL even with the use of available engineering and work practice controls.

Treatment of Railroads

The railroad industry is grouped with other general industry sectors for purposes of OSHA's feasibility analysis in this rulemaking, even though the railroad activities that can cause silica exposures are related to track work covered by OSHA's construction standard. The core business of this industry, operating railroads, is not construction and railroads are usually grouped with other employers in general industry for purposes of economic analysis; economic impacts on the railroad industry are traditionally distinct from economic impacts on the "construction industry." The grouping for this analysis has a distinct purpose from OSHA's enforcement policies and thus has no impact on enforcement: OSHA intends to enforce the construction standard with respect to the silica exposures that it has identified as resulting from track work.

2.4.2 Data Handling for General Industry and Maritime

When compiling the sampling data used in the exposure profiles for general industry and maritime (shipyards), OSHA relied primarily on full-shift samples with a duration of 360 minutes or longer. By using this criterion, OSHA ensured that the samples included in the analysis were collected for at least three-quarters of a typical 8-hour shift and therefore captured most if not all activities involving exposure to silica at which the worker spends a substantial amount of time (Document ID 0845, pp. 38-40). Due to the routine nature of most job activities in general industry, OSHA assumed constant exposure during the unsampled time. OSHA considers the 6-hour (360-minute) minimum sampling requirement to be a reasonable criterion for including a sample and characterizing it as "full-shift" because it limits the extent of uncertainty about general industry/maritime workers' true exposures, as no more than 25 percent of an 8-hour shift would be unsampled.

Sampling durations of 6 hours or more have less uncertainty related to maximum concentrations for samples reported as non-detects. As noted previously in the discussion of LODs, when using a nylon cyclone operated at a flow rate of 1.7 lpm, a sample with a duration of 360 minutes that is reported as a non-detect means maximum silica concentration is 16 μg/m^3. At the other end of the range, a sample taken for only 30 minutes with a reported result of "0" or "non-detect" will have a maximum silica concentration of 196 μg/m^3 (see Table IV.2-F**)**. Using the maximum silica concentration for such a sample would indicate only that the result is somewhere between 0 μg/m^3 and 196 μg/m^3, a range too large to provide meaningful information for OSHA's feasibility analysis. Thus, relying primarily on samples with a duration of 360 minutes or greater allows OSHA to draw the conclusion that any sample results reported as non-detect are below 16 μg/m^3, and well below the action level of 25 μg/m^3. This also applies to the 480-minute (full-shift) samples reported as non-detects, for which OSHA assigned a value of 12 μg/m^3.

Other than for abrasive blasting, the sampling results for the maritime industry (i.e., shipyards for purposes of this rule) have been handled in the same manner as data for general industry. For abrasive blasting in the maritime industry, OSHA concluded that this activity was similar to abrasive blasting in construction and OSHA, therefore, as explained below, assumed zero exposure during the period not sampled.

2.4.3 Data Handling for Construction

Construction workers can perform a variety of different tasks that generate respirable crystalline silica. They also perform these tasks for varying amounts of time, depending on the job. Some workers may only occasionally perform one of the construction industry tasks discussed in this technological feasibility analysis; others may perform the task daily, but for only a portion of their shift. Other workers spend their entire shifts intermittently performing the same task or a mix of several of these dusty tasks. Some construction workers more often perform tasks that continue uninterrupted over an entire work shift (e.g., heavy equipment operator). However, these workers often spend some portion of their shifts in transit between job sites, setting up or preparing to depart a site, or waiting for another construction trade to complete an activity (Document ID 0676).

The sampling results in the exposure profiles include a wide variety of construction site working conditions and worker activity patterns. The sampling results include both shorter-duration task-based samples and sampling over more extended periods, including results obtained over entire 8-hour work shifts. Furthermore, a portion of the sample results available to OSHA cover periods when the workers performed multiple activities, sometimes involving more than one of the tasks analyzed here by OSHA. For the purposes of this analysis, however, any sample collected over a period when the worker performed multiple activities was assigned to the specific construction task judged likely to have had the greatest influence on the worker's silica exposure level.

Because of the variation in the duration of the sampled exposures within the construction industry, OSHA, while relying on samples of 120 minutes or more (compared to 360 minutes or more for general industry/maritime), standardized the exposure levels to 8-hour TWAs by assuming, in general, that the sampled period in construction encompassed all of the workers' silica exposure. Thus, in calculating the 8-hour TWAs for construction tasks, OSHA assumed zero exposure to respirable crystalline silica for the unsampled portion of the shift. Among the 881 samples in the construction profiles, the sample durations exceeded 240 minutes in 70 percent of the samples, and exceeded 120 minutes in 89 percent of the samples (Table IV.2-G).

The only exception to this approach was made in cases where information associated with an exposure result clearly indicates that, although only a portion of the shift was sampled, the same exposure continued for the entire shift. In those cases, OSHA, relying upon the judgment of the CSHO who obtained the sample, calculated the 8-hour TWA assuming that exposure continued at the same concentration over the unsampled portion of the shift. When sampling duration was longer than 8 hours, the result was used to represent the 8-hour TWA.

CISC objected to using an assumption of zero exposure for the unsampled portion of the work shift when calculating 8-hour TWAs for the construction exposure profiles (Document ID 2319, pp. 21-25). It claimed this underestimated TWA exposure levels when compared with the alternative assumption that the exposure level measured during the sampled time period continued at the same exposure level during the unsampled period, as was done for general industry. CISC argued that, without further information about workers' activities after sampling ceased, OSHA's zero-exposure assumption cannot be supported (Document 2319, p. 21).

OSHA disagrees with CISC because of the widely-recognized differences in work patterns between general industry and construction operations. In general industry, most operations are at a fixed location and involve manufacturing processes that remain relatively constant over a work shift. Construction, however, is much more variable with respect to the location of the work site and the duration of tasks performed. Tasks that generate exposure to respirable crystalline silica are often performed on an intermittent basis (e.g., Document ID 0677). OSHA concludes that the variability in sample durations for the samples taken by OSHA in the construction industry more closely and accurately reflects the actual variability observed in the duration of tasks than would an assumption of continued, constant exposure. Further, as stated above, where OSHA had information indicating that silica exposure continued after the sampling stopped, OSHA adjusted the TWA for that sample accordingly.

For the construction samples, OSHA assumed no additional exposure during the unsampled period because this is consistent with the approach used for calculating 8-hour TWA for assessing compliance with the PEL. When CSHOs collect partial shift samples for comparison with a PEL, they calculate 8-hour TWA exposures using the assumption that no further exposure occurred during the unsampled period.

Support for the approach used by OSHA to calculate TWA exposures based on partial shift samples is provided by Flanagan et al. (2003), who reported the average percentage of time a worker performed dust generating tasks during the period sampled based on a large database of exposure samples from a variety of construction sites. The authors report that air sampling was conducted for the entire period of time during a work shift that a worker was engaged in a dust-generating task, and also included the time required to perform other activities such as set-up, clean-up, and other tasks in support of the task being monitored (Document ID 0676, p. 320). Based on worksite observations, they reported the percentage of time during the sampling period that the dust-generating task was performed was 31 percent for concrete cutting, 40 percent for surface grinding, and 51 percent for demolition with handheld power tools (Document ID 0676, p. 323). When applied to a 480-minute shift, these percentages result in average task durations, for the dust-generating tasks, ranging from 150 to 240 minutes. In comparison, among the 881 samples in the construction profiles, the sample durations exceeded 240 minutes in 70 percent of the samples, and exceeded 120 minutes in 89 percent of the samples (Table IV.2-G). Thus, the partial shift samples included in the construction exposure profile were of sufficient duration to include the entire portion of a work shift that a dust generating task is typically performed.

Table IV.2-G Distribution of Sampling Durations for Sample Results in FEA Exposure Profiles			
Construction			
	Duration (minutes)	**Count**	**Percent**
	120 or fewer	93	10.6%
	121-240	172	19.5%
	241-360	241	27.4%
	361 or more	375	42.6%
	Total	**881**	
General Industry			
	Duration (minutes)	**Count**	**Percent**
	120 or fewer	47	1.9%
	121-240	41	1.7%
	241-360	97	3.9%
	361 or more	2,298	92.5%
	Total	**2,483**	
Note: OSHA submitted to the rulemaking record a database of all samples used in the FEA exposure profiles.			

Information based on research at construction sites provided by the Building and Construction and Trades Department (BCTD) of the AFL-CIO, further describes the intermittent patterns of exposure when performing silica-generating tasks. The Center to Protect Workers' Rights developed a task-based exposure assessment model for the construction industry, which combines air sampling with task observations and task durations in order to assess construction workers' exposure to workplace hazards (Susi et al., 2000, Document ID 4073, Attachment 8c). This model, when applied to masonry jobsites, found that workers spent much of their shifts performing non-silica-generating tasks, both before and after the task involving silica exposure (Document ID 4223, p. 16; 4073, Attachment 3a, pp. 1-2). BCTD indicated that it was reasonable to assume these types of work patterns would be similar for other construction tasks. BCTD supported OSHA's assumptions on work patterns, stating "OSHA correctly treated the unsampled time as having 'zero exposure' in its technological feasibility assessment" (Document ID 4223, pp. 16-17).

Thus, the distribution of the durations of the samples used to develop the exposure profiles for construction tasks reflects the intermittent work patterns of construction workers performing these silica-generating tasks, and supports the assumption, relied upon in calculating the 8-hour TWA exposures for the exposure profile, that no additional exposure occurred during the unsampled portions of these work shifts.

2.4.4 Respirable Dust Properties and Use in Evaluating Control Options

In evaluating available control technologies, OSHA has considered studies of ventilation and water applications as methods for suppressing silica dust. In some cases, these researchers reported reductions in respirable dust rather than just respirable silica dust. Respirable crystalline silica particles comprise only a portion of the respirable dust in a worker's breathing zone. The remainder of the respirable dust is composed of other minerals and other types of fine particles (Document ID 0787, p. 590). When sampling for respirable dust, silica and other particles of respirable size are separated from larger particles based on aerodynamic properties. Size-selective samplers for respirable dust particles operate on the principle that the collected particles have similar aerodynamic properties and therefore have similar collection efficiencies when sampled in air. Based on this principle, OSHA concludes that the results of ventilation control measure testing, which evaluates capture of airborne respirable dust particles, will be equally applicable to the respirable silica component of respirable dust as to all other components of the dust (Document ID 3883, p. 3-2).

Researchers from Canada published a report that evaluated the effectiveness of dust control methods for reducing occupational exposures to crystalline silica at construction sites (Document ID 2287, p. iii). They reviewed studies that included both wet methods (i.e., 'spraying'), and LEV used with more than ten tools, on a variety of materials, including soil, concrete, brick, block, and joint compound (Document ID 2287, pp. 29-30). The exposure reduction using respirable dust measurements ranged from 12 percent to greater than 99 percent, and for respirable quartz measurements, exposure reductions ranged from 0 to 98 percent (Document ID 2287, pp. 29-30). The researchers observed similar percent reductions in both the respirable dust and respirable silica dust concentrations (Document ID 2287, p. 34). Respirable silica is a component of respirable dust, and therefore, OSHA concludes that reductions in respirable dust concentrations result in corresponding reductions in respirable crystalline silica concentrations.

In addition, OSHA finds that there is considerable evidence that water spray droplet size is a primary factor in the efficiency of water sprays used to control dust. The most effective spray uses a droplet size similar to the size particles that the spray is intended to control (Spray Systems, Document ID 1152). Therefore, studies of wet dust control methods applied to respirable dust will be similarly applicable to the silica portion of respirable dust.

Use of Surrogate Data

In the few instances when exposure information from a specific job category or sector was not available, OSHA based that portion of the exposure profile on “surrogate” data from one or more similar job categories in related industries. The surrogate data were selected based on strong similarities in raw materials (e.g., source of silica, percent silica, particle size), equipment, worker activities, and exposure duration in the job categories. Although other factors may differentiate the industries, the individual job categories were determined by OSHA to be sufficiently similar to represent baseline conditions in that sector or job category. When used, OSHA has clearly identified the surrogate data and the relationship between the industries or job categories. Similarly, in some cases, exposure control information from one industry was used as an example why another industry with similar process/materials/exposures should be able to achieve similar exposure results using the same methods.

Use of Short-Term Sampling Results

Short-term samples are defined by OSHA, for purposes of this technological feasibility analysis, as samples of less than 120 minutes in duration. The sample results used in the exposure profiles are representative of 8-hour TWAs; and most of them are samples of between 360 and 480 minutes. Only 2% of samples used in the exposure profiles for general industry and 10% of the samples for construction had sample durations of less than 120 minutes.

Some short-term samples taken during experimental studies were considered for the purpose of investigating the efficiency of dust controls when developing its technological feasibility analysis, but OSHA did not include these samples in the exposure profiles, which include only samples used to estimate 8-hour TWA exposures. Short-term samples can provide important information about the effectiveness of controls. Short-term samples also permit multiple trials of controlled and uncontrolled activities. In studies of this nature, investigators measure intensive periods of an activity (such as concrete sawing), without pauses in the process or supplemental activities that can complicate comparisons of airborne dust during controlled and uncontrolled conditions. Results of brief samples, even just a few minutes in duration, can provide useful comparative information, and OSHA considers these experimental results in the discussion of additional controls for specific groups of workers (e.g., Document ID 1142).

2.5 DISCLAIMER

References to specific commercial products or manufacturers in this technological feasibility analysis are included for reference or informational purposes only, and do not constitute endorsements by OSHA of such products or manufacturers.

3. FEASIBILITY OF MEASURING RESPIRABLE CRYSTALLINE SILICA EXPOSURES AT THE FINAL RULE'S PEL AND ACTION LEVEL

As explained in Pertinent Legal Authority (Section II of the preamble to the final rule), a finding that a standard is technologically feasible requires that "provisions such as exposure measurement requirements must also be technologically feasible" (see *Forging Indust. Ass'n v. Sec'y of Labor*, 773 F.2d 1436, 1453 (4th Cir. 1985), Thus, part of OSHA's technological feasibility assessment of a new or revised health standard includes examining whether available methods for measuring worker exposures have sufficient sensitivity and precision to ensure that employers can evaluate compliance with the standard and that workers have an accurate information regarding their exposure to hazardous substances. Consistent with the Supreme Court's definition of "feasibility", OSHA finds that it is feasible to measure worker exposures to a hazardous substance if achieving a reasonable degree of sensitivity and precision with sampling and analytical methods is "capable of being done" (*Am. Textile Mfrs. Inst., Inc. v. Donovan*, 452 U.S. 490, 509-510 (1981)). OSHA also notes that its analysis of the technological feasibility of the sampling and analysis of respirable crystalline silica must be performed in recognition of the fact that, as recognized by federal courts of appeals, measurement error is inherent to sampling (*Nat'l Min. Assoc. v. Sec'y, U.S. Dep't of Labor*, Nos. 14–11942, 14–12163, slip op. at 55 (11th Cir. Jan. 25, 2016); *Am. Mining Cong. v. Marshall*, 671 F.2d 1251, 1256 (10th Cir. 1982)). "Since there is no perfect sampling method, the Secretary has discretion to adopt any sampling method that approximates exposure with reasonable accuracy." *Am. Mining Cong. v. Marshall*, 671 F.2d at 1256.

Since the late 1960s, exposures to respirable crystalline silica (hereinafter referred to as "silica") have typically been measured using personal respirable dust samplers coupled with laboratory analysis of the crystalline silica content of the collected airborne dust. The laboratory analysis is usually performed using X-ray diffraction (XRD) or infrared spectroscopy (IR). A colorimetric method of analysis that was used by a few laboratories has now been phased out (Harper et al., 2014, Document ID 3998, Attachment 8, p. 1). OSHA has successfully used XRD analysis since the early 1970s to enforce its previous PELs for crystalline silica, which, for general industry, were approximately equivalent to 100 micrograms per cubic meter ($\mu g/m^3$) for quartz and 50 $\mu g/m^3$ for cristobalite and tridymite (and within the range of about 250 µg/m^3 to 500 µg/m^3 for quartz in construction). There are no other generally accepted methods for measuring worker exposure to respirable crystalline silica.

The ability of current sampling and analytical methods to accurately measure worker exposures to respirable crystalline silica was a subject of much comment in the rulemaking record. In particular, the Chamber of Commerce (Chamber) and American Chemistry Council (ACC) submitted comments and testimony maintaining that existing methods do not measure respirable crystalline silica exposures with sufficient accuracy to support OSHA's proposal in the Notice of Proposed Rulemaking to reduce the PEL to 50 µg/m^3 and establish the 25 µg/m^3 action level (Document ID 2285; 2288, pp. 17-21; 2307, Attachment A, pp. 198-227; 4209, pp. 129-155; 3436, p. 8; 3456, pp. 18-19; 3460; 3461; 3462; 4194, pp. 17-21). Similar views were expressed by several other rulemaking participants (e.g., Document ID 2056, p. 1; 2085, p. 3; 2174; 2185, pp. 5-6; 2195, Attachment 1, p. 37; 2276, pp. 4-5; 2317, p. 2; 2379, Comments, pp. 28-30; 4224, pp. 11-14; 4232, Attachment 1, pp. 3-24). Specifically, these commenters argue that, due to several asserted sources of error, current sampling and analytical methods do not meet the NIOSH accuracy criterion of ± 25 percent (NIOSH Manual of Analytical Methods, http://www.cdc.gov/niosh/docs/95-117/). Their arguments include: (1) that there is sampling error attributed to bias against the particle-size selection criteria that defines the performance of the samplers and variation in performance between sampling devices; (2) that the accuracy and precision of the analytical method at the low levels of silica that would be collected at the revised PEL and action level is less than that in the range of the previous PELs for silica, particularly in the presence of interfering substances; and (3) variation between laboratories analyzing comparable samples adds an unacceptable degree of uncertainty. After considering all of the testimony and evidence in the record, OSHA rejects these arguments and, as discussed below, concludes that it is feasible to obtain measurements of respirable crystalline silica at the final rule's PEL and action level with reasonable accuracy.

OSHA is basing its conclusions on the following findings, which are described in detail in this section. First, although there is variation in the performance of respirable dust samplers, studies have demonstrated that, for the majority of work settings, samplers will perform with an acceptable level of bias (as defined by international standards) as measured against internationally recognized particle-size selection criteria that define respirable dust samplers. This means that the respirable dust mass collected by the sampler will be reasonably close to the mass that would be collected by an ideal sampler that exactly matches the particle-size selection criteria. In addition, OSHA finds that the measure of precision of the analytical methods for samples collected at crystalline silica concentrations equal to the revised PEL and action level is only somewhat higher (i.e., somewhat less precise) than that for samples collected at concentrations equal to the previous, higher PELs. Further, the analytical methods can account for interferences such that, with few exceptions, the sensitivity and precision of the method are not significantly compromised. Studies of measurement variability between laboratories, as determined by proficiency testing, have demonstrated a significant decline in inter-laboratory variability in recent years. Improvements in inter-laboratory variability have been attributed to changes in proficiency test procedures as well as greater standardization of analytical procedures among laboratories. Finally, although measurement variability increases at low sample loads compared to sample loads in the range of the former PELs, OSHA finds, based on these studies, that the magnitude of this increase has also declined in recent years.

Several rulemaking participants commented that OSHA's analysis of the feasibility of sampling and analytical methods for crystalline silica was well supported and sound (Document ID 2080, pp. 3-4; 2244, p. 3; 2371, Attachment 1, p. 5; 3578, Tr. 941; 3586, Tr. 3284; 3577, Tr. 851-852; 4214, pp. 12-13; 4223, pp. 30-33). Gregory Siwinski, CIH, and Dr. Michael Lax, Medical Director of Upstate Medical University, an occupational health clinical center, commented that current laboratory methods can measure respirable crystalline silica at the 50 $\mu g/m^3$ PEL and 25 $\mu g/m^3$ action level, and that they have measured exposures below the action level (Document ID 2244, p. 3). Celeste Montforton of the George Washington School of Public Health testified that "[i]ndustrial hygienists, company safety personnel, consultants, and government inspectors have been conducting for decades workplace sampling for respirable silica …" and that some governments, such as Manitoba and British Columbia, are successfully collecting and analyzing samples to determine compliance with their occupational exposure limits of 25 $\mu g/m^3$ (Document ID 3577, Tr. 851-852). Frank Mirer of the CUNY School of Public Health, formerly with the UAW and on behalf of the AFL-CIO, stated that "[a]ir sampling is feasible at 25 $\mu g/m^3$ and below for [a] full shift and even for part shift. It was dealt with adequately in the OSHA proposal" (Document ID 3578, Tr. 941).

The ACC, Chamber, and others base their argument that sampling and analytical methods for respirable crystalline silica are insufficiently precise on strict adherence to NIOSH's accuracy criterion of ±25 percent at a 95-percent confidence level for chemical sampling and analysis methods (http://www.cdc.gov/niosh/docs/95-117/). The ACC pointed out that "OSHA standards typically reflect the NIOSH Accuracy Criterion by requiring employers to use a method of monitoring and analysis that has an accuracy of plus or minus 25 percent…," and cited a number of OSHA standards where the Agency has included such requirements (Benzene, 29 CFR 1910.1028; Lead (which requires a method accuracy of ±20%), 29 CFR 1910.1025; Cadmium, 29 CFR 1910.1027; Hexavalent Chromium, 29 CFR 1910.1026) (Document ID 4209, p. 129). However, the NIOSH accuracy criterion is not a hard, bright-line rule in the sense that a sampling and analytical method must be rejected if it fails to meet this level of accuracy, but is rather a goal or target to be used in methods development. Where evidence has shown that a method does not meet the accuracy criterion at the PEL or action level, OSHA has stipulated a less rigorous level of accuracy to be achieved. For example, OSHA's Acrylonitrile standard requires use of a method that is accurate to ±35 percent at the PEL and ±50 percent at the action level (29 CFR 1910.1045), and several OSHA standards require that ±35 percent accuracy be obtained at the action level (Arsenic, 29 CFR 1918; Ethylene Oxide, 29 CFR 1910.1047; Formaldehyde, 29 CFR 1910.1048; Butadiene, 29 CFR 1051; Methylene Chloride, 29 CFR 1910.1052). As discussed below, the precision of the sampling and analytical method for crystalline silica, as currently implemented using OSHA Method ID-142 for X-ray diffraction, is about ±21 percent for quartz and cristobalite.

In the remainder of this section, OSHA first describes available respirable dust sampling methods and addresses comments and testimony related to the performance and accuracy of respirable dust samplers. Following that discussion, OSHA summarizes available analytical methods for measuring crystalline silica in respirable dust samples and addresses comments and evidence regarding analytical method precision, the presence of interfering materials, and reported variability between laboratories analyzing comparable samples.

3.1 Respirable Dust Sampling Devices

Respirable dust comprises particles small enough that, when inhaled, they are capable of reaching the pulmonary region of the lung where gas exchange takes place. Measurement of respirable dusts requires the separation of particles by size to assess exposures to the respirable fraction of airborne dusts. A variety of different industrial hygiene sampling devices, such as cyclones and elutriators, have been developed to separate the respirable fraction of airborne dust from the non-respirable fraction. Cyclones are the most commonly used size-selective sampling devices, or "samplers," for assessing personal exposures to respirable dusts such as crystalline silica. The current OSHA (ID-142, revised December 1996, Document ID 0946) and NIOSH (Method 7500, Document ID 0901; Method 7602, 0903; Method 7603, http://www.cdc.gov/niosh/docs/2003-154/pdfs/7603.pdf) methods for sampling and analysis of crystalline silica specify the use of cyclones.

Although respirable dust commonly refers to dust particles having an aerodynamic diameter of 10 µm (micrometer) or less, it is more precisely defined by the collection efficiency of the respiratory system as described by a particle collection efficiency model. These models are often depicted by particle collection efficiency curves that describe, for each particle size range, the mass fraction of particles deposited in various parts of the respiratory system. These curves serve as the "yardsticks" against which the performance of cyclone samplers should be compared (Vincent, 2007, Document ID 1456). Figure IV.3-A below shows particle collection efficiency curves for two particle size selection criteria: the criteria specified in the 1968 American Conference of Governmental Industrial Hygienists (ACGIH) Threshold Limit Value (TLV) for respirable dust, which was the basis for the prior OSHA general industry silica PEL, and an international specification by the International Organization for Standardization (ISO) and the Comité

Européen de Normalisation (CEN) known as the ISO/CEN convention, which was adopted by ACGIH in 1994 and is the basis for the definition of respirable crystalline silica in the final rule. In addition to the curves, which cover the full range of particle sizes that comprise respirable dust, particle size collection criteria are also often described by their 50-percent respirable "cut size" or "cut point." This is the aerodynamic diameter at which 50 percent of the particle mass is collected, i.e., the particle size that the sampler can collect with 50-percent efficiency. Particles with a diameter smaller than the 50-percent cut point are collected with an efficiency greater than 50 percent, while larger-diameter particles are collected with an efficiency less than 50 percent. The cut point for the 1968 ACGIH specification is 3.5 µm and for the ISO/CEN convention is 4.0 µm (Lippman, 2001, Document ID 1446, pp. 107, 113).

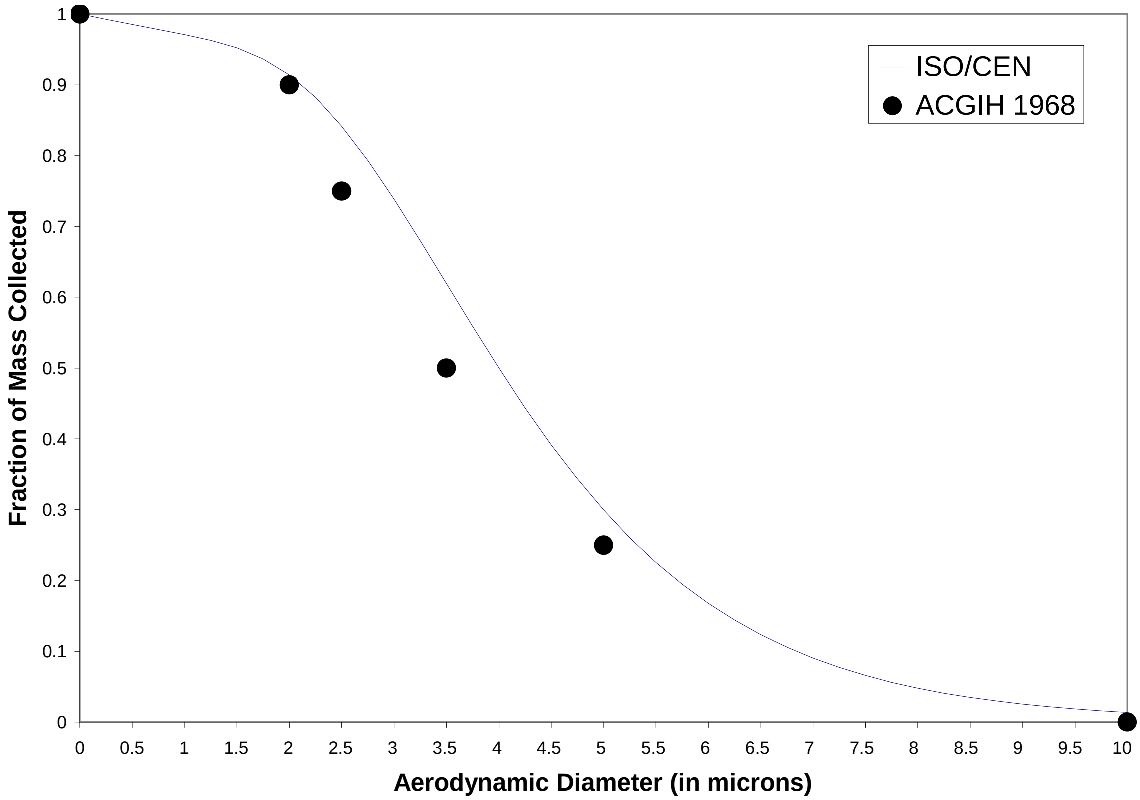

Figure IV.3.1. Comparison of the 1968 ACGIH and ISO/CEN Particle Size Collection Criteria

Source: Document ID 1720, p. IV-18

For most workplace conditions, the change in the criteria for respirable dust in the final rule would theoretically increase the mass of respirable dust collected over that measured under the previous criteria by an amount that depends on the size distribution of airborne particles in the workplace. Soderholm (1991, Document ID 1661) examined these differences based on 31 aerosol size distributions measured in various industrial workplaces (e.g., coal mine, lead smelter, brass foundry, bakery, Shielded Metal Arc [SMA] welding, spray painting, pistol range) and determined the percentage increase in the mass of respirable dust that would be collected under the ISO/CEN convention over that which would be collected under the 1968 ACGIH criteria. Soderholm concluded that, for all but three of the 31 size distributions that were evaluated, the increased respirable dust mass that would be collected using the ISO/CEN convention for respirable dust instead of the 1968 ACGIH criteria would be less than 30 percent, with most size distributions (25 out of the 31 examined, or 80%) resulting in a difference of between 0 and 20 percent (Document ID 1661, pp. 248-249, Figure 1). In the PEA, OSHA stated its belief that the magnitude of this effect does not outweigh the advantages of adopting the ISO/CEN convention. In particular, most respirable dust samplers on the market today are designed and calibrated to perform in a manner that closely conforms to the international ISO/CEN convention.

Incorporating the ISO/CEN convention in the definition of respirable crystalline silica will permit employers to use any sampling device that conforms to the ISO/CEN convention. There are a variety of these cyclone samplers on the market, such as the Dorr-Oliver, Higgins-Dewell (HD), GK2.69, SIMPEDS, and SKC aluminum. In the PEA, OSHA reviewed several studies demonstrating that these samplers collect respirable particles with efficiencies that closely match the ISO/CEN convention (Document ID 1720, pp. IV-21 - IV-24). In addition to cyclone samplers, there are also personal impactors available for use at flow rates from 2 to 8 L/min that have been shown to conform closely with the ISO/CEN convention (Document ID 1834, Attachment 1). Cyclones and impactors both separate particles by size based on inertia. When an airstream containing particles changes direction, smaller particles remain suspended in the airstream and larger ones impact a surface and are removed from the airstream. Cyclones employ a vortex to separate particles centrifugally, while impactors use a laminar airflow around a flat surface such that particles in the desired size range impact onto the surface.

3) FEASIBILITY OF MEASURING RESPIRABLE CRYSTALLINE SILICA EXPOSURES AT THE FINAL RULE'S PEL AND ACTION LEVEL

The current OSHA sampling method for crystalline silica, ID-142, is the method used by OSHA to enforce the silica PELs and is used by some employers as well. It specifies that a respirable sample be collected by drawing air at 1.7 ± 0.2 liters/minute (L/min) through a Dorr-Oliver 10 millimeter (mm) nylon cyclone attached to a cassette containing a 5-µm pore-size, 37-mm diameter polyvinyl chloride (PVC) filter (Document ID 0946). NIOSH sampling and analysis methods for crystalline silica (Method 7500, Method 7602, Method 7603) have also adopted the ISO/CEN convention with flow rate specifications of 1.7 L/min for the Dorr-Oliver 10-mm nylon cyclone and 2.2 L/min for the HD cyclone (Document ID 0901; 0903). Method 7500 also allows for the use of an aluminum cyclone at 2.5 L/min. NIOSH is revising its respirable dust method to include any sampler designed to meet the ISO/CEN criteria (Document ID 3579, Tr. 218).

The devices discussed above, when used at the appropriate flow rates, are capable of collecting a quantity of respirable crystalline silica that exceeds the quantitative detection limit for quartz (the principle form of crystalline silica) of 10 µg for OSHA's XRD method (Document ID 0946). For several scenarios based on using various devices and sampling times (8-hour, 4-hour, and 1-hour samples), OSHA calculated the amount of respirable quartz that would be collected at quartz concentrations equal to the existing general industry PEL, the proposed (and now final) rule's PEL, and the proposed (and now final) rule's action level. As seen in Table IV.3-A, computations show that the 10-mm nylon Dorr-Oliver operated at an optimized flow rate of 1.7 L/min, the aluminum cyclone operated at 2.5 L/min, the HD cyclone operated at 2.2 L/min, and the GK2.69 operated at 4.2 L/min will all collect enough quartz during an 8-hour or 4-hour sampling period to meet or exceed the 10 µg quartz limit of quantification for OSHA Method ID-142. Therefore, each of the commercially available cyclones is capable of collecting a sufficient quantity of quartz to exceed the limit of quantification when airborne concentrations are at or below the action level, provided that at least 4-hour air samples are taken. Table IV.3-A also shows that the samplers can collect enough silica to meet the limit of quantification when the airborne respirable silica concentration is below the action level of 25 µg/m^3, in one case as low as 5 µg/m^3.

Table IV.3-A
Amount of Quartz Collected by Various Personal Cyclones by Respirable Quartz Concentration and Sampling Time

Cyclone Sampler	Lowest Detectable Concentration (µg/m³)[a]		25 µg/m³ (Action Level)		50 µg/m³ (PEL)		100 µg/m³ (Previous PEL)	
	4 hr	8 hr	4 hr	8 hr	4 hr	8 hr	4 hr	8 hr
Dorr Oliver 10 mm nylon (at 1.7 L/min)	25	12	10	20	20	41	41	82
HD (at 2.2 L/min)	19	9.5	13	26	26	53	53	106
Aluminum (at 2.5 L/min)	17	8	15	30	30	60	60	120
GK2.69 (at 4.2 L/min)	10	5	25	50	50	101	101	202

[a] The lowest concentration of airborne respirable crystalline silica that will result in the collection, over the specified sampling period, of at least 10 µg, which is the limit of quantification for quartz for OSHA Method ID-142. Calculated as (1,000 L/m³ X 10 µg) / (flow rate (L/min) X Duration (min))

* Shaded boxes represent scenarios that will allow for the collection of enough quartz to meet or exceed the 10 µg limit of quantification for OSHA Method ID-142 (revised December 1996).

Source: Adapted from Document ID 1720, Table IV.B-2, pp. IV-24 - IV-25.

A comment from the National Rural Electric Cooperative Association (NRECA) stated that the current OSHA and NIOSH analytical methods require sampling to collect a minimum of 400 liters of air, and that at the flow rates specified for current samplers, sampling would have to be performed for approximately 2.5 to 4 hours; however, this is considerably longer than most construction tasks performed in electrical transmission and distribution work, which tend to last 2 hours or less (Document ID 2365, pp. 2, 6-7). OSHA does not view this discrepancy to be a problem. The minimum sampling times indicated in the OSHA and NIOSH methods contemplate that exposure occurs over most of the work shift. Construction operations frequently involve shorter-term tasks after which there is no further exposure to respirable crystalline silica. In those situations, OSHA often does not itself continue sampling during inspections and does not expect employers to continue sampling when there is no exposure to silica, and considers the sampling result that is obtained from shorter-term task sampling to be sufficient to represent a worker's 8-hour time-weighted-average (TWA) exposure, which can be calculated assuming no exposure for the period of the shift that is not sampled. If the airborne concentration of silica for the task is low, the sampling result would likely be below the limit of quantification. In that case, it would be safe for the employer to assume that the exposure is below the action level.

3.1.1 Transition to ISO-CEN Criteria for Samplers

In the final rule, OSHA is adopting the ISO/CEN particle size-selective criteria for respirable dust samplers used to measure exposures to respirable crystalline silica. Under the ISO/CEN convention, samplers should collect 50 percent of the mass of particles that are 4 µm in diameter (referred to as the cut point), with smaller particles being collected at higher efficiency and larger particles being collected at lower efficiency. Particles greater than 10 µm in diameter, which are not considered to be respirable, are to be excluded from the sample based on the ISO/CEN convention (Document ID 1446, pp. 112-113).

Several rulemaking participants supported OSHA's proposed adoption of the ISO/CEN criteria for respirable dust samplers (Document ID 1730; 1969; 3576, Tr. 290; 3579, Tr. 218-219; 4233, p. 4). For example, a representative of SKC, Inc., which manufactures samplers used to collect respirable crystalline silica, stated that:

> Adoption of the ISO/CEN performance standard for respirable dust samplers by OSHA will bring the U.S. regulatory standards in line with standards/guidelines established by other occupational health and safety agencies, regulatory bodies, and scientific consensus organizations around the world. It will also align OSHA performance criteria for respirable dust samplers to that of NIOSH (Document ID 1730, pp. 1-2).

As discussed above, OSHA's previous (and currently enforceable) general industry PEL for crystalline silica was based on a 1968 ACGIH definition, which specified a model with a cut point of 3.5 µm. Based on available studies conducted over 40 years ago, the Dorr-Oliver 10-mm cyclone was thought to perform closely to this specification. As such, it is the sampling device specified in OSHA's respirable dust sampling and analytical methods, including Method ID-142 for respirable crystalline silica (Document ID 0946). For most sizes of respirable particles, the ISO/CEN convention specifies a greater efficiency in particle collection than does the 1968 ACGIH model; consequently, samplers designed to meet the ISO/CEN convention will capture somewhat greater mass of airborne particle than would a sampler designed to the 1968 ACGIH model, with the magnitude of the increased mass dependent on the distribution of particle sizes in the air. For most particle size distributions encountered in workplaces, the increase in dust mass theoretically collected under the ISO/CEN convention compared to the ACGIH model would be 25 percent or less (Soderholm, 1991, Document ID 1661).

Several rulemaking participants commented that moving from the 1968 ACGIH model to the ISO/CEN convention effectively decreased the PEL and action level below the levels intended, since more dust would be collected by samplers that conform to the ISO/CEN convention than by those that conform to the 1968 ACGIH model (Document ID 2174; 2195, p. 30; 2285, pp. 3-4; 2307, Attachments 10, p. 19, and 12, p. 3; 2317, p. 2; 3456, p. 10; 4194, pp. 15-16). For example, the Chamber commented that adopting the ISO/CEN specification "can result in citations for over exposure to quartz dust where none would have been issued prior to the adoption of this convention" (Document ID 2288, p. 16). OSHA disagrees with this assessment because, based on more recent evaluations (Bartley et al., 1994, Document ID 1438, Attachment 2; Lee et al., 2010, 3616; 2012, 3615), the Dorr-Oliver 10-mm cyclone that has been used by the Agency for enforcement of respirable dust standards for decades has been found to perform reasonably closely (i.e., with an acceptable level of bias) to the ISO/CEN specification when operated at the 1.7 L/min flow rate specified by OSHA's existing method. Consequently, OSHA and employers can continue to use the Dorr-Oliver cyclone to evaluate compliance against the final PEL of 50 $\mu g/m^3$ without having to change equipment or procedures, and thus would not be collecting a greater quantity of dust than before. Furthermore, OSHA notes that other ISO/CEN-compliant samplers, such as the SKC 10-mm aluminum cyclone and the HD cyclone specified in the NIOSH Method 7500, are already widely used by investigators and employers to evaluate exposures to respirable crystalline silica against benchmark standards. Therefore, the change from the ACGIH convention to the ISO/CEN convention is more a continuation of the status quo than a drastic change from prior practice.

Other rulemaking participants argued that moving to the ISO/CEN convention effectively invalidates OSHA's risk and feasibility analyses since the exposure data that underlie these analyses were obtained using devices conforming to the 1968 ACGIH specification. For example, Thomas Hall, testifying for the Chamber, stated that moving to the ISO/CEN convention "would produce a difference in [current] exposure results from…historical measurements that have been used in the risk assessments" (Document ID 3576, Tr. 435). Similarly, in its pre-hearing comments, the ACC argued that:

> When OSHA conducted technological feasibility studies for attaining the proposed 50 μg/m^3 PEL, the Agency based its decisions on samples collected using the current ACGIH method, not the proposed ISO/CEN method. Thus, the switch to the ISO/CEN definition will have two impacts on feasibility. First, it will add uncertainty regarding OSHA's technological feasibility determination because greater reductions in exposure will be required to achieve a 50 μg/m^3 PEL measured by the ISO/CEN definition than by the ACGIH definition that OSHA applied. Second, OSHA's use of the ACGIH definition to estimate compliance costs causes the Agency to underestimate the costs of achieving the 50 μg/m^3 PEL because OSHA did not account for the additional workers whose exposures would exceed the proposed PEL under the ISO/CEN definition but who would be exposed below the proposed PEL if measured under the ACGIH definition (Document ID 2307, Attachment 8, p. 9).

OSHA rejects these arguments for the following reasons. First, with respect to the risk information relied on by the Agency, exposure data used in the various studies were collected from employer records reflecting use of several different methods. Some studies estimated worker exposures to silica from particle counts, for which the sampling method using impingers does not strictly conform to either the ACGIH or ISO/CEN conventions (e.g., Rice et al., Document ID 1118; Park et al., Document ID 0405; Attfield and Costello, Document ID 0285; Hughes et al., Document ID 1060). Other studies used measurements taken using cyclone samplers and modern gravimetric methods of silica analysis (e.g., Rice et al. and Park et al., data obtained from cyclone pre-separator up through 1988, Document ID 1118, 0405; Hughes et al., data from 10-mm nylon cyclone through 1998, Document ID 1060). OSHA believes it likely that exposure data collected using cyclones in these studies likely conformed to the ISO/CEN specification since flow rates recommended in the OSHA and NIOSH methods were most likely used. The studies by Miller and MacCalman (Document ID 1097) and by Buchannan et al. (Document ID

0306) used exposure measurements made with the MRE 113A dust sampler, which does conform reasonably well with the ISO/CEN specification (Gorner et al., Document ID 1457, p. 47). The studies by Chen et al. (2001, Document ID 0332; 2005, Document ID 0985) estimated worker exposures to silica from total dust measurements that were converted to respirable silica measurements from side-by-side comparisons of the total dust sampling method with samples taken using a Dorr-Oliver cyclone operated at 1.7 L/min, which is consistent with the ISO/CEN convention (see Section V, Health Effects, of the Final Rule Preamble and OSHA's Preliminary Review of Health Effects Literature and Preliminary Quantitative Risk Assessment, Document ID 1711). Thus, it is simply not the case that the exposure assessments conducted for these studies necessarily reflect results from dust samples collected with a device conforming to the 1968 ACGIH particle size-selective criteria, and OSHA finds that no adjustment of OSHA's risk estimates to reflect exposure measurements consistent with the ISO/CEN convention is warranted.

Second, with respect to the feasibility analysis, OSHA relied on exposure data and constructed exposure profiles based principally on measurements made by compliance officers using the Dorr-Oliver cyclone operated at 1.7 L/min, as the Agency has done since Method ID-142 was developed in 1981, well before the 1990 cut-off date for data used to construct the exposure profiles. As explained earlier in the section, recent research shows that the Dorr-Oliver cyclone operated at this flow rate performs in a manner consistent with the ISO/CEN specification. Other data relied on by OSHA comes from investigations and studies conducted by NIOSH and others who used various cyclones that conform to the ISO/CEN specification. Thus, OSHA finds that the exposure profiles being relied on to evaluate feasibility and costs of compliance do not reflect sample results obtained using the 1968 ACGIH model. Instead, the vast majority of sample results relied upon were collected in a manner consistent with the requirements of the final rule. NIOSH supported this assessment, stating that, given the Dorr-Oliver sampler operated at a flow rate of 1.7 L/min conforms closely to the ISO/CEN convention, "there is continuation with historic exposure data" (Document ID 4233, p. 4). For these reasons, OSHA finds that it is appropriate to rely on the feasibility and cost analyses and underlying exposure data without adjustment to account for the final rule's adoption of the ISO/CEN specification for respirable dust samplers.

3.1.2 Sampling Error

Several commenters raised issues concerning the accuracy of respirable dust samplers in relation to the ISO/CEN criteria, asserting that sampling respirable dust is uncertain and inaccurate, and that there are numerous sources of error. Chief among these were Dr. Thomas Hall of Industrial Hygiene Specialty Resources, LLC, testifying for the Chamber, and Paul K. Scott of ChemRisk, testifying for the ACC.

The Chamber's witnesses and others referenced studies showing that all samplers were biased against the ISO/CEN particle-size selection convention. This means that the sampler would collect more or less mass of respirable particulate than would an ideal sampler that exactly conforms to the ISO/CEN convention. OSHA discussed this issue in the PEA, noting that most samplers tend to over-sample smaller particles and under-sample larger particles, compared to the ISO/CEN convention, at their optimized flow rates. This means that, for particle size distributions dominated by smaller particles, the sampler will collect more mass than would be predicted from an ideal sampler that exactly conforms to the ISO/CEN convention. For particle size distributions dominated by larger particles in the respirable range, less mass would be collected than predicted. In the PEA, OSHA evaluated several studies that showed that several cyclone samplers exhibited a bias of 10 percent or less for most particle size distributions encountered in the workplace. Some of these studies found biases as high as ±20 percent but only for particle size distributions having a large mass median aerodynamic diameter (MMAD) (i.e., 20 µm or larger) and narrow distribution of particle sizes (i.e., a geometric standard deviation (GSD) of 2 or less) (Document ID 1720, pp. IV-21 – IV-24). Such particle size distributions are infrequently seen in the workplace; for well-controlled environments, Frank Hearl of NIOSH testified that the GSD for typical particle size distributions would be about 2 (Document ID 3579, Tr. 187). Dr. Hall (Document ID 3576, Tr. 502) testified, similarly, that it would be around 1.8 to 3 for well-controlled environments and higher for uncontrolled environments (see also Liden and Kenny, 1993, Document ID 1450, p. 390, Figure 5; Soderholm, 1991,1661, p. 249, Figure 1). Furthermore, a particle size distribution with a large MMAD and small GSD would contain only a very small percentage (< 10%) of respirable dust that would be collected by a sampler optimized to the ISO/CEN criteria (Soderholm, 1991, Document ID 1661, p. 249, Figure 2). According to Liden and Kenny (1993), "samplers will perform reasonably well providing the absolute bias in sampling is kept to within 10 percent… this aim can be achieved … over the majority of size distributions likely to be found in field sampling" (Document ID 1450, p. 390).

Dr. Hall commented that "sampling results differ depending on the choice of sampler used" and that published evaluations have shown that they "have different collection efficiencies, specifically with respect to particle collection in aerosol clouds with large [MMADs greater than] 10 µm" (Document ID 2285, p. 16). He cited the work of Gorner et al. (2001, Document ID 1457), who noted that the cut points achieved by different samplers varied considerably and that flow rates were optimized to bring their respective cut points closer to the ISO/CEN convention, as evidence that commercial samplers do not provide consistently similar results. However, OSHA interprets the findings of Gorner et al. as actually providing evidence of samplers' consistency with the ISO/CEN convention for most particle size distributions encountered in the workplace. This study, which was reviewed in OSHA's PEA, evaluated 15 respirable dust samplers, most of them cyclones, against 175 different aerosol size distributions and evaluated the bias and accuracy of sampler performance against the ISO/CEN convention.[3] Gorner et al. found that most of the samplers they tested met the international criteria for acceptable bias and accuracy (described by Bartley et al., 1994, Document ID 1438, Attachment 2 and Gorner et al., 2001, 1457); under those criteria, bias is not to exceed 10 percent and inaccuracy is not to exceed 30 percent for most of the size distributions tested (Document ID 1457, pp. 49, 52; Document ID 1438, Attachment 2, p. 254). Gorner et al. concluded that the samplers "are therefore suitable for sampling aerosols within a wide range of particle size distributions" (Document ID 1457, p. 52). Gorner et al. also stated that sampler performance should be evaluated by examining bias and accuracy rather than

[3] Bias means the difference in particle mass collected by a sampler as compared to the mass that would be collected by a hypothetical ideal sampler that exactly matched the ISO/CEN convention. Accuracy includes bias and other sources of error related to the testing procedure (e.g., errors in flow rate and particle mass analysis) (Document ID 1457, p. 49).

simply comparing cut points and slopes against the ISO/CEN convention (Document ID 1457, p. 50), as Dr. Hall did in his comments.

The ACC's witness, Mr. Scott, noted several potential sources of sampling error in addition to the conventional 5-percent pump flow rate error that is included in OSHA's estimate of sampling and analytical error (SAE, discussed further in Section IV-3.2.4 – Precision of Measurement). These included variation in performance of the same cyclone tested multiple times (estimated at 6%) and variation between different cyclones tested in the same environment (estimated at 5%) (Document ID 2308, Attachment 6, pp. 7-8). Based on published estimates of the magnitude of these kinds of errors, Mr. Scott estimated a total sampling error of 9.3 percent after factoring in pump flow rate error, inter-sampler error, and intra-sampler error; this would increase the SAE by 4 percent, for example, from 15 to 19 percent at 50 μg/m^3 (Document ID 2308, pp. 8-9). This means that, if all sampler error were factored into the SAE, an employer would be considered out of compliance with the PEL for an exposure exceeding 59.5 μg/m^3, rather than at 57.5 μg/m^3 if only pump error were considered, a difference of only 2 μg/m^3 in silica concentration. OSHA therefore concludes that intra- and inter-sampler error of the types described by Mr. Scott do not materially change how OSHA would enforce, or how employers should evaluate, compliance with the final rule PEL.

As described above, many different respirable dust samplers have been evaluated against the ISO/CEN convention for different particle size distributions and, in general, these biases are small for the vast majority of particle size distributions encountered in the workplace. OSHA concludes that Mr. Scott's estimate likely overstates the true total sampling error somewhat because the measurements of sampler bias against the ISO/CEN criteria involve accurately measuring and maintaining consistent pump flow rates during the testing of the samplers; therefore, adding pump flow rate error to estimates of inter- and intra-sampler measurement error is redundant. Furthermore, if an employer relies on a single type of cyclone sampler, as is OSHA's practice, there would be no inter-sampler variability between different field samples. If an employer is concerned about this magnitude of uncertainty, he or she can choose simply to use the same sampling device as OSHA (i.e., the Dorr-Oliver cyclone operated at a flow rate of

1.7 L/min, as specified in Method ID-142) and avoid any potential measurement uncertainties associated with use of different sampling devices.

The American Foundry Society (AFS) commented that the ASTM Standard D4532 for respirable dust sampling includes errors for sampling, weighing, and bias, none of which is included in OSHA's pump flow rate error (Document ID 2379, p. 29). This ASTM standard describes procedures for sampling respirable dust using a 10-mm cyclone, HD cyclone, or aluminum cyclone in a manner identical to that prescribed in the OSHA and NIOSH methods for sampling and analysis of silica. Thus, the kinds of errors identified by AFS are the same as those reflected in Mr. Scott's testimony described above, which, as OSHA has shown, do not result in substantial uncertainties in exposure measurement.

OSHA further observes that the kinds of sampling errors described by rulemaking participants are independent of where the PEL is established and are not unique to silica; these biases have existed since OSHA began using the Dorr-Oliver cyclone to enforce the previous PELs for crystalline silica, as well as many other respirable dust standards, over 40 years ago. OSHA also believes that sampling error within the range quantified by Mr. Scott would be unlikely to change how an employer makes risk management decisions based on monitoring results. One Chamber witness, Gerhard Knutson, President of Knutson Ventilation, testified that the type of cyclone used to obtain exposure measurements for crystalline silica was not typically a consideration in designing industrial ventilation systems (Document ID 3576, Tr. 521-522). Dr. Hall, another Chamber witness, also testified that he has used all three sampling devices listed in the NIOSH Method 7500 and has not historically made a distinction between them, though he might make different decisions today based on the aerosol size distribution encountered in a particular workplace (Document ID 3576, Tr. 522-523). In his pre-hearing submission, Dr. Hall cited the Gorner et al. (2001, Document ID 1457) study as recommending that "rough knowledge of the aerosol size distribution can guide the choice of an appropriate sampling technique" (Document ID 2285, p. 8). OSHA concludes it unlikely that, in most instances, it is necessary to obtain such data to minimize sampling bias for risk management purposes, given the overall magnitude of the bias as estimated by Mr. Scott (i.e., an error of less than 10%).

3.1.3 High Flow Samplers

OSHA's PEA also described high-flow samplers, in particular the GK2.69 from BGI, Inc., which is run at a flow rate of 4.2 L/min in contrast to 1.7 L/min for the Dorr-Oliver and 2.5 L/min for the aluminum cyclone. High-flow devices such as this permit a greater amount of dust to be collected in low-dust environments, thus improving sensitivity and making it more likely that the amount of silica collected will fall within the range validated by current analytical methods. For example, a Dorr-Oliver run at 1.7 L/min where the silica concentration is 50 µg/m^3 would collect 41 µg of silica over 8 hours, compared to the GK2.69 run at 4.2 L/min, which would collect 101 µg of silica (see Table IV.3-A), well within the validation range of the OSHA method (i.e., the range over which precision is determined, 50 to 160 µg) (Document ID 0946, p. 1). Several rulemaking participants supported OSHA's proposal to permit use of high-flow samplers that conform to the ISO/CEN convention (Document ID 2256, Attachment 3, p. 12; 3578, Tr. 941; 3586, Tr. 3286-3287; 4233, p. 4). For example, William Walsh, representing the American Industrial Hygiene Association (AIHA) Laboratory Accreditation Programs, stated that he could measure concentrations of silica at the 25 µg action level with sufficient precision by using a high-flow device (Document ID 3586, Tr. 3287).

The performance of high-flow samplers has been extensively studied, particularly by Lee et al. (2010, Document ID 3616; 2012, 3615), Stacey et al. (2013, Document ID 3618), and Kenny and Gussman (1997, Document ID 1444). The Kenny and Gussman study, which was reviewed in OSHA's PEA, found the GK2.69 had good agreement with the ISO/CEN convention at the 4.2 L/min flow rate, with a cut point of 4.2 µm and a collection efficiency curve that was steeper than the ISO/CEN (i.e., it was more efficient for smaller particles and less so for larger particles). For particle size distributions up to an MMAD of 25 µm and GSD of 1.5 to 3.5, bias against the ISO/CEN convention was generally between +5 and -10 percent. Bias was greater (-20%) for particle size distributions having an MMAD above 10 µm and a low GSD which, according to the authors, are not likely to be encountered (Document ID 1444, p. 687, Figure 7).

The Lee et al. (2010, Document ID 3616; 2012, 3615) and Stacey (2013, Document ID 3618) studies of high-flow sampler performance are the product of a collaborative effort between NIOSH and the United Kingdom's Health and Safety Executive (HSE) that examined the performance of three high-flow samplers; these were the GK2.69, the CIP10-R (Arelco ARC, France), and the FSP10 (GSA, Germany). The FSP10 runs at flow rates of 10 L/min and the combination of large cyclone and heavy-duty pump may be burdensome for workers to wear. The CIP-10 also runs at 10 L/min and is much smaller and lighter, but uses a collection technology different from cyclones, which may be unfamiliar to users. According to NIOSH, cyclones operating around 4 L/min "offer a current compromise" for obtaining higher flow rates without the need to use larger personal samplers that may be difficult for workers to wear (Document ID 2177, Attachment B, p. 13; 3579, Tr. 163).". For this reason, OSHA's review of these studies focuses on the performance of the GK2.69 cyclone.

Lee et al. (2010, Document ID 3616) tested the GK2.69 against 11 sizes of monodisperse aerosol and found that, at the 4.2 L/min flow rate, the estimated bias against the ISO/CEN convention was positive for all particle size distributions (i.e., the sampler collected greater mass of particulate than would be predicted from an ideal sampler that exactly conformed to ISO/CEN), with a 10-percent efficiency for collecting 10 µm particles, compared to 1 percent for the ISO/CEN convention. The authors estimated a bias of +40 percent for a particle size distribution having a MMAD of 27.5 µm. However, adjustment of the flow rate to 4.4 L/min resulted in biases of less than 20 percent for most particle size distributions and the collection efficiency for 10 µm particles was much closer to the ISO/CEN convention (2.5% compared to 1%). The authors concluded that, at the higher flow rate, the GK2.69 cyclone met the international standard for sampler conformity to relevant particle collection conventions (European Committee for Standardization, EN 13205, cited in Lee et al., 2010, Document ID 3616), and would provide relatively unbiased measurements of respirable crystalline silica (Document ID 3616, pp. 706, 708, Figure 5(a)).

Lee et al. (2012, Document ID 3615) performed a similar evaluation of the same samplers using coal dust but included analysis of crystalline silica by both XRD and IR. The GK2.69 runs at a flow rate of 4.4 L/min collected somewhat more respirable dust and crystalline silica than would be predicted from differences in flow rates, compared to the 10-mm nylon cyclone, but nearly the same as the Higgins-Dewell cyclone. The authors found that the GK2.69 "showed non-significant difference in performance compared to the low-flow rate samplers" (Document ID 3615, p. 422), and that "the increased mass of quartz collected with high-flow rate samplers would provide precise analytical results (i.e., significantly above the limit of detection and/or the limit of quantification) compared to the mass collected with low-flow rate samplers, especially in environments with low concentrations of quartz …" (Document ID 3615, p. 413). Lee et al. concluded that "[a]ll samplers met the [EN 13205] requirements for accuracy for sampling the ISO respirable convention" (Document ID 3615, p. 424).

Stacey et al. (2013, Document ID 3618) used Arizona road dust aerosols to evaluate the performance of high-flow samplers against the Safety In Mines Personal Dust Sampler (SIMPEDS), which is the low-flow sampler used to measure respirable crystalline silica in the U.K. For the GK2.69, use of a flow rate of 4.2 L/min or 4.4 L/min made little difference in the respirable mass collected, and there was closer agreement between the GK2.69 and SIMPEDS sampler when comparing respirable crystalline silica concentration than respirable dust concentration, and the difference was not statistically significant (Document ID 3618, p. 10). According to NIOSH, the findings by Stacey et al. (2013) corroborate those of Lee et al. (2010 and 2012) that the GK2.69 meets the ISO/CEN requirements for cyclone performance and that either the 4.2 L/min or 4.4 L/min flow rate "can be used to meet the ISO convention within acceptable limits" (Document ID 2177, p. 13).

Mr. Scott testified that the high-flow samplers (including the GK2.69) studied by Lee et al., (2010 and 2012), "tended to have a substantial bias towards collecting more respirable particulates than the low-flow samplers, collecting between 12 percent and 31 percent more mass" because high-flow samplers tend to collect a higher proportion of larger particles (Document ID 3582, Tr. 1984). In his written testimony, he noted that Lee et al. (2010) reported a nearly 10-fold higher collection efficiency for 10 μm particles compared to the ISO/CEN standard. However, Mr. Scott's testimony ignores Lee et al.'s findings that the oversampling of larger particles seen at a flow rate of 4.2 L/min was not apparent at the higher 4.4 L/min flow rate and that Lee et al. (2010) concluded that agreement with the ISO/CEN convention was achieved at the higher flow rate (Document ID 3616, pp. 706, 708). In addition, oversampling of larger particles at the 4.2 L/min flow rate was not reported by Lee et al. (2012, Document 3615) or Stacey et al. (2013, Document ID 3618).

Dr. Hall expressed a similar concern as Mr. Scott. He cited Lee et al. (2010) as stating that the GK2.69 would collect significantly more aerosol mass for particle size distributions having an MMAD of more than 6 µm. He also cited Lee et al. (2010 and 2012) for the finding that the GK2.69 collects from 1.8 to 3.84 times as much aerosol mass as the Dorr-Oliver or Higgins-Dewell cyclones (Document ID 2285, p. 12). In his pre-hearing comment, Dr. Hall stated that "[f]or aerosol clouds with a [MMAD] greater than 10 µm, the expected absolute bias can range be (sic) between 20 and 60%" and "the total variability for the method SAE can be as large as 85-90%" (Document ID 2285, pp. 15-16).

OSHA notes that both Dr. Hall and Mr. Scott focus their comments regarding the performance of high-flow samplers on environments where the particle size distribution is characterized by larger particles and small variance (GSD). The findings by Lee et al (2010) show that, at a flow rate of 4.2 L/min, under this experimental system, there were large positive biases (> 20%) against the ISO/CEN convention for nearly all particle size distributions having MMAD of 5 to 10 µm (Document ID 3616, pp. 704-706, Figure 3(b)). However, when the flow rate was adjusted to 4.4 L/min, bias exceeding 20 percent was found to occur primarily with particle size distributions having GSDs under 2.0 and MMAD greater than 10 µm (Document ID 3616, p. 707, Figure 5(a)). As discussed above, it is rare to encounter particle size distributions having relatively large MMADs and small GSDs, so the high variability attributed to high-flow samplers by Dr. Hall and Mr. Scott should not be of concern for most workplace settings. Further, sampler performance is considered acceptable if the bias and accuracy over at least 80 percent of the remaining portion of the bias map are within acceptable limits, which are no more than 10 and 30 percent, respectively (Document ID 1457, pp. 49, 52). The Lee et al. studies (2010 and 2012) concluded that the high-flow samplers tested met these international requirements for accuracy for sampling the ISO/CEN convention, and the

Stacey et al. (2013) study found that their results compared favorably with those of Lee et al. (2012). Therefore, OSHA finds that the uncertainties characterized by Dr. Hall and Mr. Scott are exaggerated for most workplace situations, and that there is substantial evidence that high-flow samplers, in particular the GK2.69 cyclone, can be used to collect respirable crystalline silica air samples in most workplace settings without introducing undue bias.

Mr. Scott, testifying for the ACC, was of the opinion that, although high-flow samplers have been evaluated by Gorner et al. (2001, Document ID 1457) and Lee et al. (2010, Document ID 3616; 2012, 3615) with respect to their sampling efficiencies as compared to the ISO/CEN convention and their performance compared to low-flow samplers, none of the studies evaluated the accuracy and precision using methods recommended in NIOSH’s Guidelines for Air Sampling and Analytical Method Development and Evaluation (1995, http://www.cdc.gov/niosh/docs/95-117/) (Document ID 2308, Attachment 6, p. 18). OSHA understands Mr. Scott to contend that the sampler must be tested against a generated atmosphere of respirable crystalline silica and that the precision of the sampling and analytical method must be determined overall from these generated samples.

OSHA does not agree with the implication that, until high-flow samplers have been evaluated according to the NIOSH (1995) protocol, the findings from the studies described above are not sufficient to permit an assessment of sampler performance. The NIOSH Guidelines cited by Mr. Scott state that “[a]“n experimental design for the evaluation of sampling and analytical methods has been suggested. If these experiments are not applicable to the method under study, then a revised experimental design should be prepared which is appropriate to fully evaluate the method” (http://www.cdc.gov/niosh/docs/95-117/, p. 1). These guidelines contemplate the development of entirely new sampling and analytical methods. Because the analytical portion of the sampling and analytical method for respirable crystalline silica was already fully evaluated before the GK2.69 was developed (Kenny and Gussman, 1997, Document ID 1444), it was only necessary to evaluate the performance of the GK2.69 high-flow sampler. As described above, the studies by Lee et al. (2010, Document ID 3616; 2012,

3615) and Stacey et al. (2013, Document ID 3618) reflect a collaborative effort between NIOSH in the U.S. and HSE in the U.K. to evaluate the performance of high-flow respirable dust samplers. The Lee et al. (2010, 2012) studies were conducted by NIOSH laboratories in Morgantown, West Virginia with peer review by HSE scientists, and the Stacey et al. (2013) study was conducted by HSE at the Health and Safety Laboratory at Buxton in the U.K. Both Lee et al. (2012) and Stacey et al. (2013) concluded that high-flow samplers studied, including the GK2.69, met the EN 13205 requirements for accuracy for sampling against the ISO/CEN convention, demonstrating that results from these two national laboratories compared favorably. OSHA concludes these peer-reviewed studies, performed by NIOSH and HSE scientists, meet the highest standards for effective methods evaluation and therefore does not agree with the suggestion that additional work following NIOSH's protocol is necessary. Comments submitted by NIOSH indicate that the Lee et al. (2010, 2012) and Stacy et al. (2013) studies are sufficient to establish the GK2.69 high-flow sampler as acceptable for sampling respirable crystalline silica under the ISO/CEN convention (Document ID 2177, Attachment B; 4233, p. 4).

URS Corporation, on behalf of the ACC, commented that precision will not be improved by the use of high-flow samplers because filter loadings of interferences will increase along with the amount of crystalline silica; this would, in URS's opinion, necessitate additional sample handling procedures, such as acid washing, that erode precision. URS also argued that such samples may require analysis of multiple peaks and that overall X-ray intensity may be diminished due to increased filter load (Document ID 2307, Attachment 12, p. 3). In its post-hearing brief, the ACC stated that the use of high-volume samplers "in addition to traditional Dorr-Oliver sampler" would reduce inter-laboratory precision (i.e., the extent to which different laboratories achieve similar results for the same sample) due to the use of multiple sampler types (Document ID 4209, p. 154).

OSHA finds that these arguments are unsupported. Although the high-flow sampler will collect more dust than lower-flow samplers in the same environment, the relative proportion of any interfering materials collected to the amount of crystalline silica collected would remain unchanged. Thus, there should be no increased effect from the interfering materials relative to the silica. OSHA recognizes that, to prevent undue interference or diminished X-ray intensity, it is important to keep the dust load on the filter within reasonable limits. Both OSHA and NIOSH methods stipulate a maximum sample weight to be collected (3 mg for OSHA and 2 mg for NIOSH) (Document ID 0946, p. 5; 0901, p. 3), and in the event that excess sample is collected, the sample can be split into portions and each portion analyzed separately (Document ID 0946, p. 5). In environments where using a high-flow sampler is likely to collect more than the maximum sample size, use of a lower-flow sampler is advised. In response to the concern that permitting use of high-flow samplers will affect interlaboratory variability, OSHA observes that employers are already using a variety of commercially available samplers, such as those listed in the NIOSH Method 7500, to obtain exposure samples; not everyone uses the Dorr-Oliver sampler. Thus, for the final rule, OSHA is permitting employers to use any sampling device that has been designed and calibrated to conform to the ISO/CEN convention, including higher-flow samplers such as the GK2.69. In effect, this is a continuation of well-studied current practice, not an untested departure from it.

3.2 LABORATORY ANALYSIS OF CRYSTALLINE SILICA

Crystalline silica is analyzed in the laboratory using either X-ray diffraction (XRD) or infrared spectroscopy (IR). A third method, colorimetric spectrophotometry, is no longer used (Document ID 3579, Tr. 211; Harper et al., 2014, 3998, Attachment 8, p. 1). This section describes crystalline silica analysis by XRD and IR and responds to comments and testimony on the precision and accuracy of these methods for measuring crystalline silica concentrations in the range of the final rule's PEL and action level. As discussed below, both XRD and IR methods can detect and quantify crystalline silica in amounts collected below the final rule's 25 µg action level.

3.2.1 X-Ray Diffraction

For XRD, a dust sample that has been collected by a sampler is deposited on a silver-membrane filter and scanned by the X-ray beam, where X-rays diffract at specific angles.

A sensor detects these diffracted X-ray beams and records each diffracted beam as a diffraction peak. Unique X-ray diffraction patterns are created when the diffraction peaks are plotted against the angles at which they occur. The intensity of the diffracted X-ray beams depends on the amount of crystalline silica present in the sample, which can be quantified by comparing the areas of the diffraction peaks obtained with those obtained from scanning a series of calibration standards prepared with known quantities of an appropriate reference material. Comparing multiple diffraction peaks obtained from the sample with those obtained from the calibration standards permits both quantitative and qualitative confirmation of the amount and type of crystalline silica present in the sample (i.e., quartz or cristobalite). A major advantage of XRD compared with the other techniques used to measure crystalline silica is that X-ray diffraction is specific for crystalline materials. Neither non-crystalline silica nor the amorphous silica layer that forms on crystalline silica particles affects the analysis. The ability of this technique to quantitatively discriminate between different forms of crystalline silica and other crystalline or non-crystalline materials present in the sample makes this method least prone to interferences. Sample analysis by XRD is also non-destructive, meaning that samples can be reanalyzed if necessary (Document ID 1720, pp. IV-26 - IV-27).

The OSHA Technical Manual lists the following substances as potential interferences for the analysis of crystalline silica using XRD: aluminum phosphate, feldspars (microcline, orthoclase, plagioclase), graphite, iron carbide, lead sulfate, micas (biotite, muscovite), montmorillonite, potash, sillimanite, silver chloride, talc, and zircon (https://www.osha.gov/dts/osta/otm/ otm_ii/otm_ii_1.html, Chapter 1, III.K). The interference from other minerals usually can be recognized by scanning multiple diffraction peaks quantitatively. Diffraction peak-profiling techniques can resolve and discriminate closely spaced peaks that might interfere with each other. Sometimes interferences cannot be directly resolved using these techniques. However, many interfering materials can be chemically washed away in acids that do not dissolve the crystalline silica in the sample. Properly performed, these acid washes can dissolve and remove these interferences without appreciable loss of crystalline silica (Document ID 1720, p. IV-27).

The nationally recognized analytical methods using XRD include OSHA ID-142, NIOSH 7500, and MSHA P-2 (Document ID 0946; 0901; 1458). All are based on the XRD of a redeposited thin-layered sample with comparison to standards of known concentrations (Document ID 0946, p. 1; 0901, p. 1; 1458, p. 1). These methods, however, differ on diffraction peak confirmation strategies. The OSHA and MSHA methods require at least three diffraction peaks to be scanned (Document ID 0946, p. 5; 1458, p. 13. The NIOSH method only requires that multiple peaks be qualitatively scanned on representative bulk samples to determine the presence of crystalline silica and possible interferences, and quantitative analysis of air samples is based on a single diffraction peak for each crystalline silica polymorph analyzed (Document ID 0901, pp. 3, 5).

3.2.2 Infrared Spectroscopy

Infrared spectroscopy is based on the principle that molecules of a material will absorb specific wavelengths of infrared electromagnetic energy that match the resonance frequencies of the vibrations and rotations of the electron bonds between the atoms making up the material. The absorption of IR radiation by the sample is compared with the IR absorption of calibration standards of known concentration to determine the amount of crystalline silica in the sample. Using IR can be efficient for routine analysis of samples that are well characterized with respect to mineral content, and the technique, like XRD, is non-destructive, allowing samples to be reanalyzed if necessary. The three principle IR analytical methods for crystalline silica analyses are NIOSH 7602 (Document ID 0903), NIOSH 7603 (http://www.cdc.gov/niosh/docs/2003-154/pdfs/7603.pdf), and MSHA P-7 (Document ID 1462); NIOSH Method 7603 and MSHA P-7 were both specifically developed for the analysis of quartz in respirable coal dust. OSHA does not use IR for analysis of respirable crystalline silica.

Interferences from silicates and other minerals can affect the accuracy of IR results. The electromagnetic radiation absorbed by silica in the infrared wavelengths consists of broad bands. In theory, no two compounds have the same absorption bands; however, in actuality, the IR spectra of silicate minerals contain silica tetrahedra and have absorption bands that will overlap. If interferences enhance the baseline measurement and are not taken into account, they can have a negative effect that might underestimate the amount of silica in the sample. Compared with XRD, the ability to compensate for these interferences is limited (Document ID 1720, pp. IV-29 - IV-30).

3.2.3 Sensitivity of Sampling and Analytical Methods

The sensitivity of an analytical method or instrument refers to the smallest quantity of a substance that can be measured with a specified level of accuracy, and is expressed as either the LOD or the "Limit of Quantification" (LOQ). These two terms have different meanings. The LOD is the smallest amount of an analyte that can be detected with acceptable confidence that the instrument response is due to the presence of the analyte. The LOQ is the lowest amount of analyte that can be reliably quantified in a sample and is higher than the LOD. These values can vary from laboratory to laboratory as well as within a given laboratory between batches of samples because of variation in instrumentation, sample preparation techniques, and the sample matrix, and must be confirmed periodically by laboratories.

At a concentration of 50 $\mu g/m^3$, the final rule's PEL, the mass of crystalline silica collected on a full-shift (480 minute) air sample at a flow rate of 1.7 L/min, for a total of 816 L of air, is approximately 41 µg (see Table IV.3-A). At a concentration of 25 $\mu g/m^3$, the final rule's action level, the mass collected is about 20 µg. The LOQ for quartz for OSHA's XRD method is 10 µg (Document ID 0946; 3764, p. 4), which is below the amount of quartz that would be collected from full-shift samples at the PEL and action level. Similarly, the reported LODs for quartz for the NIOSH and MSHA XRD and IR methods are lower than that which would be collected from full-shift samples taken at the PEL and action level (NIOSH Method 7500, Document ID 0901, p. 1; MSHA Method P-2, 1458, p. 2; NIOSH Method 7602, 0903, p. 1; NIOSH Method 7603, http://www.cdc.gov/niosh/docs/2003-154/pdfs/7603.pdf, p. 1; MSHA Method P-7, 1462, p. 1).

The rule's 50 $\mu g/m^3$ PEL for crystalline silica includes quartz, cristobalite, and tridymite in any combination. For cristobalite and tridymite, the previous general industry formula PEL was approximately 50 $\mu g/m^3$, so the change in the PEL for crystalline silica does not represent a substantive change in the PEL for cristobalite or tridymite when quartz is not present. OSHA Method ID-142 (Document ID 0946) lists a 30-µg LOQ for cristobalite; however, because of technological improvements in the equipment, the current LOQ for cristobalite for OSHA's XRD method as implemented by the OSHA Salt Lake Technical Center (SLTC) is about 20 µg (Document ID 3764, p. 10).

That XRD analysis of quartz from samples prepared from reference materials can achieve LODs and LOQs between 5 and 10 µg was not disputed in the record. Of greater concern to several rulemaking participants was the effect of interfering materials potentially present in a field sample on detection limits and on the accuracy of analytical methods at low filter loads when interferences are present. Although the Chamber's witness, Robert Lieckfield of Bureau Veritas Laboratories, did not dispute that laboratories could achieve this level of sensitivity (Document ID 3576, Tr. 485-486), the ACC took issue with this characterization of method sensitivity stating that "the LOQ for real world samples containing interferences is likely to be higher than the stated LOQ's for analytical methods, which are determined using pure NIST samples with no interferences" (Document ID 4209, p. 132). Both Mr. Lieckfield and Mr. Scott testified that the presence of interferences in samples can increase the LOQ and potential error of measurement at the LOQ (Document ID 2259, p. 7; 3460, p. 5).

Mr. Scott (Document ID 2308, Attachment 6, p. 5) cited a laboratory performance study by Eller et al. (1999a, Document ID 1687), in which laboratories analyzing samples with and without interfering materials present reported a range of LOD's from 5 µg to 50 µg. Mr. Scott believed that this study provided evidence that interfering materials present in crystalline silica samples adversely affected laboratories' reported LODs. OSHA disagrees with this interpretation. The Agency reviewed this study in the PEA (Document ID 1720, p. IV-33) and believes that the variability in reported LODs reflected differences in laboratory practices with respect to instrument calibration and quality control procedures. These factors led Eller et al. (1999b, Document ID 1688, p. 24; 1720, p. IV-42) to recommend changes in such practices to improve laboratory performance. Thus, OSHA finds that the variation in reported LODs referred to by Mr. Scott cannot be attributed primarily to the presence of interfering materials on the samples.

The presence of interferences can adversely affect the sensitivity and precision of the analysis, but typically only when the interference is so severe that quantification of crystalline silica must be made from secondary and tertiary diffraction peaks (Document ID 0946, p. 6). However, OSHA finds no evidence that interferences usually present serious quantification problems. First, there are standard protocols in the OSHA, NIOSH, and MSHA methods that deal with interferences. According to OSHA Method ID-142,

> Because of these broad selection criteria and the high specificity of the method for quartz, some of the listed interferences may only present a problem when a large amount of interferent is present…. Interference effects are minimized by analyzing each sample for confirmation using at least three different diffraction peaks so as to include peaks where the quartz and cristobalite results are in good agreement and where the interferent thus causes no problem. Bulk samples or a description of the process being sampled are useful in customizing a chemical cleanup procedure for any interference found difficult to resolve by software. Even so, the presence of an interference rarely jeopardizes the analysis (Document ID 0946, p. 5).

Software developed by instrument manufacturers and techniques such as acid washing of the sample when interferences are suspected to be present are also useful in resolving interferences. The Chamber's expert witness, Mr. Lieckfield, acknowledged that it was also their practice at his lab to chemically treat samples from the start to remove interfering materials and to analyze multiple diffraction peaks to resolve interferences (Document ID 3576, Tr. 533, 542). According to OSHA's representative from the SLTC, it is "nearly always possible" to eliminate interferences and is it no more difficult to obtain precise measurements when interferences are present than when they are not (Document ID 3579, Tr. 48).

ACC also cites the results of a round-robin performance study that it commissioned, in which five laboratories were provided with crystalline silica samples with and without interfering materials (Document ID 4209, p. 132). These laboratories reported non-detectable levels of silica for 34 percent of the filters having silica loadings of 20 μg or more. However, as discussed below in the section on inter-laboratory variability (Section IV-3.2.5 – Measurement Error Between Laboratories), OSHA has determined that this study is seriously flawed and, in particular, that there was systematic bias in the results, possibly due to sample loss. This could explain the high prevalence of reported non-detectable samples by the laboratories, rather than the presence of interferences *per se*.

Furthermore, OSHA's review of the several hundred inspection reports relied on to evaluate the technological feasibility of the final rule's PEL in many industry sectors does not show that investigators have particular difficulty in measuring respirable crystalline silica concentrations below the PEL. Sections IV-4 and IV-5 of this chapter contain hundreds of exposure measurement results in a wide variety of workplace settings that were detected and reported by a laboratory as being above detectable limits but below the PEL or action level. If, as ACC suggests, interferences have a profound effect on the ability to measure concentrations in this range, many of these samples might have been reported as "less than the LOD," with the reported LOD in the range of 25 μg to 50 μg. Examination of the exposure data described in Sections IV-4 and IV-5 of this chapter shows clearly that this is not the case (see, for example, exposure profiles for Concrete Products, Section IV-4.3; Cut Stone, Section IV-4.4; Foundries (Metal Casting), Section IV-4.8; Mineral Processing, Section IV-4.12; Porcelain Enameling, Section IV-4.14; Ready Mix Concrete, Section IV-4.17; Refractories, Section IV-4.18). In addition, the United Steelworkers reported receiving exposure data from 17 employers with samples in this same range, indicating that sampling of exposures below the final PEL and action level is feasible and already being utilized by employers (Document ID 4214, pp. 12-13; Document ID 4032, Attachment 3).

Therefore, OSHA finds that the presence of interfering substances on field samples will not, most of the time, preclude being able to detect concentrations of respirable crystalline silica in the range of the PEL and action level, and that such instances where this might occur are rare. Accordingly, even when the presence of interfering substances is taken into account, worker exposure is capable of being measured with a reasonable degree of sensitivity and precision.

3.2.4 Precision of Measurement

All analytical methods have some random measurement error. The statistics that describe analytical error refer to the amount of random variation in measurements of replicate sets of samples containing the same quantity of silica. This variation is expressed as a standard deviation about the mean of the measurements. The relative standard deviation (RSD), a key statistic used to describe analytical error, is calculated by dividing the standard deviation by the mean for a data set. The RSD is also known as the coefficient of variation (CV).

When random errors are normally distributed, a 95-percent confidence interval can be calculated as $\overline{X} \pm (1.96 \times CV)$, where $\overline{X}$ is the mean. This statistic is termed the "precision" of the analytical method and represents a 2-sided confidence interval in that, for a particular measurement, there is a 95-percent chance that the "true" value, which could be higher or lower than the measurement, lies within the confidence interval. The measure of analytical precision typically also includes a term to represent error in sampler pump flow, which is conventionally taken to be 5 percent. The better the precision of an analytical method, the lower its value (i.e., a method having a precision of 17% has better precision than one with a precision of 20%).

OSHA also uses a statistic called the Sampling and Analytical Error (SAE) to assist compliance safety and health officers (CSHOs) in determining compliance with an exposure limit. The estimate of the SAE is unique for each analyte and analytical method, and must be determined by each laboratory based on its own quality control practices. At OSHA's Salt Lake Technical Center (SLTC), where analytical methods are developed and air samples taken for enforcement purposes are analyzed, the SAE is based on statistical analysis of results of internally prepared quality control samples. Sampling and analytical components are assessed separately, where CV_1 reflects analytical error that is estimated from the analysis of quality control samples, and CV_2 is the sampling error, assumed to be 5 percent due to variability in sampling pump flow rates that can affect sample air volume. Analytical error is combined with sampling pump error, and the SAE is calculated as a one-sided 95-percent confidence limit with the following formula:

$$\mathrm{SAE} = 1.645 \times \sqrt{\mathrm{CV}_1^2 + \mathrm{CV}_2^2}$$

The current SLTC SAE for crystalline silica is approximately 0.17, according to testimony from a representative of SLTC (Document ID 3579, Tr. 95). OSHA uses the SAE in its enforcement of PELs, where the PEL times the SAE is added to the PEL for a substance and compared to a sample result (see Section II, Chapter 1 of the OSHA Technical Manual, https://www.osha.gov/dts/osta/otm/otm_toc.html). A sample result is considered to have definitively exceeded the PEL if the result is greater than the sum of the PEL and the PEL times the SAE. For example, with the PEL at 50 µg/m^3 and an SAE of 17 percent, an air sample result would have to be greater than 58.5 µg/m^3 (i.e., 50 + (50 x 0.17)) to be considered to have definitively exceeded the PEL. This policy gives employers the benefit of the doubt, as it assumes that the actual exposure was below the PEL even when the result is above the PEL but below the PEL plus the SAE; the effect is that OSHA does not cite an employer for an exposure above the PEL unless the Agency has obtained a sample measurement definitively above the PEL after accounting for sampling and analytical error.

OSHA's quality control samples, which were prepared and analyzed at SLTC, demonstrate that the XRD method has acceptable precision, even at the low range of filter loads (50 µg). For the period April 2012 through April 2014, SLTC's analysis of 348 quality control samples, with a range of filter loads of about 50 to 250 µg crystalline silica, showed average recovery (i.e., the measurement result as compared to the reference mean value for the sample) of 0.98 with an RSD of 0.093 and precision of 20.8 percent (Document ID 3764, Attachment 1). Among those samples, there were 114 with a target filter load of 50 µg (range of actual filter load was 50 to 51.6 µg); these samples showed an average recovery of 1.00 with an RSD of 0.093 and precision of 20.7 percent (Document ID 3764, Attachment 1). Thus, OSHA's experience with quality control standards shows that the XRD method for quartz is as precise in the low range of method validation as it is over the full range.

The ACC raised several questions regarding OSHA's Method ID-142 and its validation. First, a paper they submitted by Sandra Wroblewski, CIH, of Computer Analytical Solutions notes that OSHA's stated Overall Analytical Error is 26 percent, higher than the 25-percent level "OSHA states is necessary to ensure that a PEL can be feasibly measured," and that the method had not been validated for cristobalite (Document ID 2307, Attachment 10, pp. 13-14). In addition, the ACC stated that OSHA's method specifies a precision and accuracy validation range of 50-160 µg quartz per sample, above the quantity that would be collected at the PEL and action level (assuming use of a Dorr-Oliver sampler at 1.7 L/min) and that the method has not been tested for validation at a range corresponding to the PEL and action level (Document ID 2307, Attachment 10, p. 14). ACC also argued that OSHA's method does not comply with the Agency's Inorganic Methods Protocol, which requires the CV_1 to be 0.07 or less and the detection limit to be less than 0.1 times the PEL (Document ID 2307, Attachment A, p. 202). The Edison Electric Institute (Document ID 2357, pp. 20-21) and Ameren Corporation (Document ID 2315, p. 2) expressed similar concerns about the detection limit.

While OSHA's published Method ID-142 reports an Overall Analytical Error of 26 percent, OSHA no longer uses this statistic (it is in the process of revising Method ID-142); the Agency provides measures of precision and SAE instead. The Overall Analytical Error, which is described in Method ID-142, published in 1996, included a bias term that is now corrected for in the data used to determine method precision, so there is no longer a need to include a bias term in the estimation of analytical error. As described above, the precision of Method ID-142 is about 21 percent based on recent quality control samples[4]. OSHA's Inorganic Methods Protocol, to which the ACC referred, has been replaced by evaluation guidelines for air sampling methods using spectroscopic or chromatographic analysis, published in 2005 (https://www.osha.gov/dts/sltc/methods/spectroguide/spectroguide.html) and 2010 (https://www.osha.gov/dts/sltc/methods/chromguide/chromguide.html), respectively. These more recent publications no longer reflect the guidance contained in the Inorganic Methods Protocol, and OSHA's Method ID-142 is consistent with these more recent guidelines. Finally, although the published method did not include validation data for filter loads below 50 µg or data for cristobalite, OSHA has conducted studies to

[4] OSHA also wishes to point out that the guideline for achieving a method precision of 25 percent was never an OSHA requirement for determining method feasibility, but is drawn from the NIOSH Accuracy Criterion (http://www.cdc.gov/niosh/docs/95-117/), which was used for the purpose of developing and evaluating analytical methods. Nevertheless, OSHA's Method ID-142 now meets that guideline.

characterize the precision that is achieved at low filter loads for quartz and cristobalite; these studies are in the rulemaking record (Document ID 1670, Attachment 1; 1847, Attachment 1; 3764, pp. 15-16) and are discussed further below.

In comments submitted on behalf of the Chamber, Mr. Lieckfield cited the NIOSH Manual of Analytical Methods, Chapter R, as stating that “current analysis methods do not have sufficient accuracy to monitor below current exposure standards” (Document ID 2259, p. 1). However, this is contradicted by NIOSH’s own post-hearing submission, which stated that, although method variability was assessed based on the exposure limits at that time (i.e., 1983, see Document ID 0901, pp. 1, 7), “it was known from an intra-laboratory study that an acceptable variability would likely be at least 20 µg on-filter, and so 20 µg was given as the lower range of the analytical method” (Document ID 4233, p. 3). Furthermore, in Chapter R of NIOSH’s Manual, NIOSH goes on to say that the GK2.69 high-flow sampler “has promise for potentially lowering the levels of silica that can be measured and still meet the required accuracy” (http://www.cdc.gov/niosh/docs/2003-154/pdfs/chapter-r.pdf, p. 265). This chapter was published in 2003, well before the studies by Lee et al. (2010, 2012) and Stacey et al. (2013), discussed above, which demonstrate that the GK2.69 sampler has acceptable performance. NIOSH concluded in its post-hearing comment that “current methods of sampling and analysis for respirable crystalline silica have variability that is acceptable to demonstrate compliance with the proposed PEL and action level” (Document ID 4233, p. 4).

At the time of the proposal, there was little data characterizing the precision of analytical methods for crystalline silica at filter loads in the range of the PEL and action level (i.e., with prepared samples of 40 µg and 20 µg crystalline silica, which are the amounts of silica that would be collected from full-shift sampling at the PEL and action level, respectively, assuming samples are collected with a Dorr-Oliver cyclone at a flow rate of 1.7 L/min). To characterize the precision of OSHA’s Method ID-142 at low filter loads, SLTC conducted studies in 2010 and again in 2013 (the latter of which was presented in the PEA; see Document ID 1720, p. IV-35). For these studies, the lab prepared 10 replicate samples each of quartz and cristobalite from NIST standard reference material and determined the precision of the analytical method; a term representing pump flow rate error was included in the precision estimate. In the 2010 test (Document ID 1670, Attachment 1), the precision for quartz loads equating to the PEL and action level was 27 and 33 percent, respectively. For cristobalite loads equating to the PEL and action level, the precision was 23 and 27 percent, respectively. The results from the 2013 test (Document ID 1847, Attachment 1; 3764, pp. 15-16; Document ID 1720, p. IV-35) showed improvement in the precision; for quartz, precision at loads equating to the PEL and action level was 17 and 19 percent, respectively, and for cristobalite, precision at loads equating to the PEL and action level was 19 and 19 percent, respectively. Both the 2010 and 2013 tests were conducted using the same NIST standards, same instrumentation, and same sample preparation method (OSHA Method ID-142) with the exception that the 2013 test used automatic pipetting rather than manual pipetting to prepare the samples (Document ID 1847). OSHA believes it likely that this change in sample preparation reduced variation in the amount of silica loaded onto the filters, which would account for at least some of the increased precision seen between 2010 and 2013 (i.e., imprecision in preparing the samples would make the analytical precision for 2010 appear worse than it actually was). Based on these studies, particularly the 2013 study, OSHA preliminarily determined that the XRD method was capable of accurately measuring crystalline silica concentrations at the PEL and action level.

The ACC believed that OSHA's reliance on the 2013 study was "misplaced" because the results were not representative of "real world" samples that contain interfering minerals that could increase analytical error, and because the studies did not account for inter-laboratory variability (Document ID 4209, pp. 135-137; 2308, Attachment 6, p. 10). The ACC also believed that variability would have been depressed in this study because the samples were analyzed in close temporal proximity by the same analyst and using the same instrument calibration, and the study involved only 10 samples at each filter load (Document ID 4209, pp. 137-138; 2308, Attachment 6, p. 10). The ACC's witness, Mr. Scott, also commented that the study failed to take into account the effect of particle sizes on the analysis of crystalline silica and believed that SLTC's evaluation could not reflect differences in precision between the XRD and IR methods (Document ID 2308, Attachment 6, p. 10).

3) FEASIBILITY OF MEASURING RESPIRABLE CRYSTALLINE SILICA EXPOSURES AT THE FINAL RULE'S PEL AND ACTION LEVEL

Despite the criticism that OSHA's investigation involved a small number of samples analyzed at the same time, the results obtained were comparable to OSHA's analysis of quality control samples at somewhat higher filter loads (between 50 and 51.6 μg) analyzed over a two-year period (Document ID 3764, Attachment 1). These results, described above, showed a precision of 20.7 percent, compared to 17 and 19 percent for quartz filter loads of 40 and 20 μg, respectively (Document ID 1847, Attachment 1; Document ID 3764). From these results, OSHA concludes that any effect on analytical error from performing a single study using the same analyst and instrument calibration is modest.

OSHA also concludes that Mr. Scott's argument that particle size effects were not taken into account is without merit. The samples prepared and analyzed in OSHA's study, like any laboratory's quality control samples, use standard materials that have a narrow range in particle size. Although large (non-respirable) size particles can result in an overestimate of crystalline silica content, in practice this is not typically a serious problem with air samples and is more of a concern with analyzing bulk samples. First, as discussed above, respirable dust samplers calibrated to conform to the ISO/CEN convention are collecting respirable particulate and excluding larger particles (Document ID 3579, Tr. 219). In analyzing field samples, OSHA uses microscopy to identify whether larger particles are present and, if they are, the results are reported as a bulk sample result so as not to be interpreted as an airborne exposure (Document ID 3579, Tr. 213). Additionally, OSHA's Method ID-142 calls for grinding and sieving bulk samples to minimize particle size effects in the analysis (Document ID 0946, p. 13). OSHA also notes that the Chamber's witness, Mr. Lieckfield, testified that his laboratory does not check for oversized particles (Document ID 3576, p. 483).

With regard to interferences, as discussed above, there are procedures that have been in place for many years to reduce the effect of interfering materials in the analysis. The presence of interferences does not typically prevent an analyst from quantifying crystalline silica in a sample with reasonable precision. As to the claim regarding XRD versus IR, a recent study of proficiency test data, in which multiple laboratories are provided comparable silica samples, both with and without interfering materials added, did not find a meaningful difference in precision between laboratories using XRD and those using IR (Harper et al., 2014, Document ID 3998, Attachment 8). In addition, as discussed above, NIOSH's and OSHA's measures of precision of the XRD method at low filter loads were comparable, despite differences in equipment and sample preparation procedures. Therefore, OSHA finds that the studies it carried out to evaluate the precision of OSHA Method ID-142 at low filter loads provide a reasonable characterization of the precision of the method for analyzing air samples taken at concentrations equal to the final PEL and action level under the respirable crystalline silica rule.

With respect to the ACC's and Mr. Scott's reference to inter-laboratory variation in silica sample results, OSHA discusses data and studies that have evaluated inter-laboratory variance in analytical results in the next section.

3.2.5 Measurement Error Between Laboratories

The sources of random and systematic error described above reflect the variation in sample measurement experienced by a single laboratory; this is termed intra-laboratory variability. Another source of error that affects the reliability of results obtained from sampling and analytical methods is inter-laboratory variability, which describes the extent to which different laboratories may obtain disparate results from analyzing the same sample. Inter-laboratory variability can be characterized by using data from proficiency testing, where laboratories analyze similarly-prepared samples and their results are compared. In practice, however, it is difficult to separate intra- and inter-laboratory variability because each laboratory participating in a proficiency test provides analytical results that reflect their own degree of intra-laboratory variability. Thus, use of proficiency test data to compare performance of laboratories in implementing an analytical method is really a measure of total laboratory variability.

The best available source of data for characterizing total variability (which includes an inter-laboratory variability component) of crystalline silica analytical methods is the AIHA Industrial Hygiene Proficiency Analytical Testing (PAT) Program. The AIHA PAT Program is a comprehensive testing program that provides an opportunity for laboratories to demonstrate competence in their ability to accurately analyze air samples through comparisons with other labs. The PAT program is designed to help consumers identify laboratories that are deemed proficient in crystalline silica analysis.

Crystalline silica (using quartz only) is one of the analytes included in the proficiency testing program. The AIHA PAT program evaluates the total variability among participating laboratories based on proficiency testing of specially prepared silica samples. The AIHA contracts the preparation of its crystalline silica PAT samples to an independent laboratory that prepares four PAT samples in the range of about 50 to 225 μg (Document ID 3586, Tr. 3279-3280) and one blank sample for each participating laboratory per round. Each set of PAT samples with the same sample number is prepared with as close to the same mass of crystalline silica deposited on the filter as possible. However, some variability occurs within each numbered PAT sample set because of small amounts of random error during sample preparation. Before the contract laboratory distributes the round, it analyzes a representative lot of each numbered set of samples to ensure that prepared samples are within ±10 percent (Document ID 3586, Tr. 3276). The samples are distributed to the participating laboratories on a quarterly basis (Document ID 1720, p. IV-36). The PAT program does not specify the particular analytical method to be used. However, the laboratory is expected to analyze the PAT samples using the methods and procedures it would use for normal operations.

The results of the PAT sample analysis are reported to the AIHA by the participating laboratories. For each PAT round, AIHA compiles the results and establishes upper and lower performance limits for each of the four sample results based on the mean and RSD of the sample results. For each of the four samples, a reference value is defined as the mean value from a selected set of reference laboratories. The RSD for each of the four samples is determined from the results reported by the reference labs after correcting for outliers (generally clear mistakes in analysis or reporting, particularly those that are order-of-magnitude errors) (Document ID 4188, p. 2). A participating laboratory receives a passing score if at least three out of the four sample results reported are within 20 percent of the reference mean for the sample (Document ID 3586, Tr. 3291). Two or more results reported by a lab in a given round that are outside the limits results in the lab receiving an unsatisfactory rating. An unsatisfactory rating in 2 of the last 3 rounds results in revocation of the lab's AIHA accreditation for the analysis of crystalline silica. Participation in the PAT program is a prerequisite for accreditation through the AIHA Industrial Hygiene Laboratory Accreditation Program (IHLAP).

In the PEA, OSHA presented PAT results from its SLTC for the period June 2005 through February 2010 (PAT Rounds 160-180) (Document ID 1720, pp. IV-40-41). The mean recovery was 99 percent, with a range of 55 to 165 percent. Eighty-one percent of the samples analyzed over this period were within ±25 percent of the reference mean and the RSD for this set of samples was 19 percent, showing reasonable agreement with the reference mean. OSHA also evaluated PAT data from all participating laboratories for the period April 2004 through June 2006 (PAT Rounds 156-165) (Document ID 1720, pp. IV-37 - IV-40). Overall, the mean lab RSD was 19.5 percent for the sample range of 49 to 165 μg. Beginning with Round 161, PAT samples were prepared by liquid deposition rather than by sampling a generated silica aerosol, in order to improve consistency and reduce errors in sample preparation. The improvement was reflected in the results, with the mean lab RSD declining from 21.5 percent to 17.2 percent after the change to liquid deposition, demonstrating the improved consistency between PAT samples.

In the time since OSHA analyzed the PAT data, Harper et al. (2014, Document ID 3998, Attachment 8) evaluated more recent data. Specifically, Harper et al. (2014, Document ID 3998, Attachment 8, p. 3) evaluated PAT test results for the period 2003-2014 (Rounds 152 through 194) and found that variation in respirable crystalline silica analysis has improved substantially since the earlier data from 1990 to 1998 was studied by Eller et al. (1999a, Document ID 1687). A total of 9,449 sample results were analyzed after removing re-test results, results where the method of analysis was not identified, and results that were more than three standard deviations from the reference mean. There was a clear improvement in overall variation in the newer data set compared with that of Eller et al. (1999a, Document ID 1687), with the mean laboratory RSD declining from about 28.7 percent to 20.9 percent (Document ID 3998, Attachment 8, Figure 1). Both the older and newer data sets showed that analytical variation increased with lower filter loadings, but the more recent data set showed a much smaller increase than did the older. At a filter load of 50 μg, the mean lab RSD of the more recent data was less than 25 percent, whereas it was almost 35 percent with the older data set (Document ID 3998, Attachment 8, Figure 1). It was also clear that the change in sample preparation procedure (i.e., from aerosol deposition to liquid deposition starting in Round 161) explained at least some of the improvement seen in the more recent PAT results, with the mean lab RSD declining from 23.6 percent for all rounds combined to 19.9 percent for Rounds 162-194.

Despite the improvement seen with the change in deposition method, it is important to understand that the observed variation in PAT results between labs still reflects some sample preparation error (limited to ±10 percent as explained above), a source of error not reflected in the analysis of field samples. Other factors identified by the investigators that account for the improved performance include the phasing out of the colorimetric method among participating labs, use of more appropriate calibration materials (i.e., NIST standard reference material), calibration to lower mass loadings, stricter adherence to published method procedures, and possible improvements in analytical equipment. There was also only a small difference (2%) in mean lab RSD between labs using XRD and those using IR (Document ID 3998, Attachment 8, p. 9). The increase in variance seen with lower filter loads was not affected either by analytical method (XRD vs. IR) or by the composition of interfering minerals added to the matrix (Document ID 3998, Attachment 8, p. 4).

OSHA finds that this study provides substantial evidence that employers will obtain reliable results from analysis of respirable crystalline silica most of the time for the purpose of evaluating compliance with the PEL. From Round 162 through 194 (after the deposition method was changed), and over the full range of PAT data, only about 7 out of the 128 (5%) lab RSD values reported were above 25 percent (Document ID 3404, Figure 2). For filter loads of 75 µg or less, only 3 lab RSD values out of about 30 reported, were above 25 percent. As stated above, the mean RSD at a filter load of 50 µg was less than 25 percent and agreement between labs improved substantially compared to earlier PAT data.

Summary data for PAT samples having a target load of less than 62.5 µg were provided by AIHA in a post-hearing comment (Document ID 4188) and compared with the findings reported by Harper et al. (2014, Document ID 3998, Attachment 8). For PAT rounds 155-193 (from 1999 to 2013), there were 15 sets of samples in the range of 41.4 to 61.8 μg distributed to participating laboratories. Lab RSDs from results reported for these samples ranged from 11.2 to 26.4 percent, with an average RSD of 17.1 percent, just slightly above the average RSD of 15.9 percent for all samples across the entire range of filter loads from those rounds. Taken together, the results of the analysis performed by Harper et al. (2014, Document ID 3998, Attachment 8) and the summary data provided by AIHA (Document ID 4188) suggest that sample results from participating labs will be within 25 percent of the crystalline silica filter load most of the time.

In its post hearing comments, the National Stone, Sand & Gravel Association (NSSGA) contended that analytical laboratories cannot provide adequately precise and accurate results of silica samples (Document ID 4232). NSSGA provided a detailed analysis of low-load samples from the same 15 PAT rounds as examined by AIHA (Document ID 4188) and concluded that "employers and employees cannot rely on today's silica sampling and analytical industry for consistently accurate sample results necessary to achieve or surpass compliance requirements" (Document ID 4232, p. 26). The NSSGA compared individual labs' sample results to the reference mean for each sample and found, from the AIHA PAT data, that 76-84 percent of the results were within 25 percent of the reference mean, and the range of results reported by laboratories included clear outliers, ranging from zero to several-fold above the target filter load (Document ID 4232, p. 8, Table 1, rows 1-6). NSSGA concluded from this that "[i]t is of little value to employers that a given lab's results meet the NIOSH Accuracy Criterion while other labs' results cannot, particularly since employers almost certainly won't know which labs fall into which category" (Document ID 4232, p. 10). NSSGA's point appears to be that the outliers in the PAT data erode an employer's ability to determine if they are receiving accurate analytical results, without which they have little ability to determine their compliance status with respect to the PEL or action level. Further, NSSGA suggests that OSHA's analysis of the PAT data, discussed above, is not adequate to demonstrate the performance of an individual laboratory that may be chosen by an employer.

3) FEASIBILITY OF MEASURING RESPIRABLE CRYSTALLINE SILICA EXPOSURES AT THE FINAL RULE'S PEL AND ACTION LEVEL

In response to NSSGA's criticism, OSHA points out that its analysis of the PAT data was part of its analysis of technological feasibility in which the Agency's legal burden is to show that employers can achieve compliance in most operations most of the time. It may be an unavoidable fact that lab results may be inaccurate some of the time, but that does not render the standard infeasible or unenforceable. OSHA contends that its analysis has satisfied that burden and nothing in the NSSGA's comments suggests otherwise.

NSSGA further suggests that employers have no means of determining, based on a laboratory's PAT proficiency rating alone, whether that individual laboratory is likely to produce erroneously high or low results. OSHA concurs that selecting a laboratory based on accreditation, price, and turnaround time, as NSSGA suggests (Document ID 4232, p. 5), is common but may be inadequate to determine whether an individual laboratory is capable of producing results of consistently high quality. Employers and their industrial hygiene consultants can, and should, ask additional questions and request additional assurances of quality from the laboratories they consider using. For example, employers can ask to review the laboratory's individual PAT results over time, focusing on and questioning any significant outliers in the laboratory's results. While NSSGA suggests that the PAT results are treated as confidential by the AIHA-PAT program (Document ID 4232, p. 6), there is nothing stopping a laboratory from sharing its PAT data or any other information related to its accreditation with their clients or prospective clients.

Further, laboratories routinely perform statistical analyses of their performance in the context of analyzing known samples they use for equipment calibration, and often perform statistical comparisons among the various technicians they employ. Review of these statistics can shed light on the laboratory's ability to provide consistent analysis. Finally, as employers conduct exposure monitoring over time, and come to understand what results are typically seen in their workplaces, clear outliers should become more identifiable; for example, if employee exposures are usually between the action level and PEL, and a sample result shows an exposure significantly above the PEL without any clear change in workplace conditions or operations, employers should question the result and ask for a reanalysis of the sample. Employers could also request gravimetric analysis for respirable dust against which to compare the silica result to confirm that the silica content of the dust is consistent with past experience. For example, if, over time, an employer's consistent results are that the silica content of respirable dust generated in its workplace is 20 percent silica, and subsequently receives a sample result that indicates a significantly higher or lower silica content, it would be appropriate for the employer to question the result and request reanalysis. Therefore, OSHA rejects the idea that employers are at the mercy of random chance and have to simply accept a high degree of uncertainty in exposure measurements; rather, there are positive steps they can take to reduce that uncertainty.

Results from the AIHA PAT program were discussed at considerable length during the rulemaking proceeding. After considering all of the analyses of PAT data presented by Eller et al. (1999a, Document ID 1687), OSHA in its PEA, and Harper et al. (2014, Document ID 3404), the ACC concluded that "PAT program results indicate that analytical variability as measured by precision is unacceptably high for silica loadings in the range of 50-250 µg" and that the PAT data "provide strong evidence that commercial laboratories will not be able to provide reliable measurements of…[respirable crystalline silica] exposures at the levels of the proposed PEL and action level" (Document ID 4209, p. 144). OSHA disagrees with this assessment. First, OSHA's experience over the last forty years in enforcing the preceding PEL that this standard supersedes is that analytical variability has not been an impediment to successful enforcement of the superseded PEL, and there have been few, if any, challenges to such enforcement actions based on variability. Nor has OSHA been made aware of concerns from employers that they have been unable to evaluate their own compliance with the former PEL or make reasonable risk management decisions to protect workers. In fact, the Chamber's expert, Mr. Lieckfield, admitted that analytical variability for asbestos, another substance that has been regulated by OSHA over the Agency's entire history, "is worse" than that for crystalline silica (Document ID 3576, Tr. 531).

To support its contention that reliably measuring silica at the final rule's PEL and action level is not possible, the ACC cited Harper et al. (2014, Document ID 3998, Attachment 8) as stating that further increases in laboratory variance below the 40-50 µg range would have "implications for the [working] range of the analytical methods," and that excessive variance might "make it difficult to address for either method" (Document ID 4209, p. 144). However, it is clear from Harper et al. (2014) that this is the basis for the authors' recommendation that the PAT program consider producing samples with filter loads as low as 20 µg to "support the analysis of lower target concentration levels" (Document ID 3404, p. 5). They also identify use of currently available higher-flow-rate sampling devices (discussed above) to increase the collected mass of silica, which would generate field samples in the filter load range currently used in the PAT program.

Finally, the ACC sponsored a performance testing study to assess inter-laboratory variability at crystalline silica filter loads at 40 and 20 µg (i.e., the amount of silica collected at final rule's PEL and action level, respectively, assuming use of a Dorr-Oliver cyclone operated at a flow rate of 1.7 L/min) as well as at 80 µg (i.e., the amount collected at the preceding PEL) (Document ID 2307, Attachment 14; 3461; 3462). The study was blinded in that participating laboratories were not aware that they were receiving prepared samples, nor were they aware that they were involved in a performance study. For this study, each of five laboratories was sent three replicate rounds of samples; each round consisted of three filters prepared with respirable crystalline silica (Min-U-Sil 5) alone, three of silica mixed with kaolin, three of silica mixed with soda-feldspar, and one blank filter. The samples were prepared by RJ Lee Group and sent by a third party to the laboratories as if they were field samples. All laboratories were accredited by AIHA and analyzed the samples by XRD.

The samples were initially prepared on 5 µm PVC filters; however, due to sample loss during preparation, RJ Lee changed to 0.8 µm PVC filters. It should be noted that the 2-propanol used to suspend the Min-U Sil sample for deposition onto the 0.8 µm filter dissolved between 50 and 100 µg of filter material, such that the amount of minerals deposited on the filter could not be verified from the post-deposition filter weights. In addition, two of the labs had difficulty dissolving these filters in tetrahydrofuran, a standard method used to dissolve PVC filters in order to redeposit the sample onto silver membrane filters for XRD analysis. These labs were replaced by two laboratories that used muffle furnaces to ash the filters before redeposition, as did the other three labs originally selected.

Results reported from the labs showed a high degree of both intra-and inter-laboratory variability as well as a systematic negative bias in measured vs. applied silica levels, with mean reported silica values more than 30 percent lower than the deposited amount. Across all laboratories, mean results reported for filter loads of 20, 40, and 80 µg were 13.36, 22.93, and 46.91 µg, respectively (Document ID 2307, Attachment 14, pp. 5-6). In addition, laboratories reported non-detectable results for about one-third of the silica samples (Document ID 2307, Attachment 14, p. 7) and two blank filters sent to the labs were reported to have silica present, in one case an amount of 52 µg (Document ID 2307, Attachment 14, pp. 9-10; 3582, Tr. 1995). Individual CVs for the labs ranged from 20 to 66 percent, up to more than 3 times higher than the CVs reported by OSHA or NIOSH for their respective methods. After examining variability in reported results, the investigators concluded that two-fold differences in filter load could not be reliably distinguished in the concentration range of 25 to 100 $\mu g/m^3$ (Document ID 2307, Attachment 14, p. 14).

OSHA identifies several deficiencies in this study; these deficiencies are sufficient to discredit the finding that high variability in silica results can be attributed to the inability of the analytical method to accurately measure crystalline silica at filter loads representative of concentrations at the action level and PEL set by this rule. Principally, the loss of filter material during deposition of the samples, combined with the lack of any verification of the actual amount of silica loaded onto the filters, makes it impossible to use the laboratory results to assess lab performance since the amount of silica on the filters analyzed by the labs cannot be known. The large negative bias in lab results compared to the target filter load implies that there was significant sample loss. In addition, the quality control employed by RJ Lee to ensure that filter loads were accurately known consisted only of an analysis of six separately prepared samples to evaluate the recovery from the 0.8 µm PVC filter and two sets of filters to evaluate recovery and test for shipping loss (Document ID 3461, Slides 8, 15, 16; 3582, Tr. 2090-2091). This is in stark contrast to the procedures used by the AIHA PAT program, which verifies its sample preparation by analyzing a statistically adequate number of samples prepared each quarter to ensure that sample variation does not exceed ±10 percent (Document ID 3586, Tr. 3276-3277). RJ Lee's use of the 0.8 µm PVC copolymer filter

(Document ID 4001, Attachment 1) is also contrary to the NIOSH Method 7500 (Document ID 0901), which specifies use of the 5 μm PVC filter, and may have introduced bias. As stated at the hearing by Mary Ann Latko of the AIHA Proficiency Analytical Testing Programs, "[a]ny variance from the NIOSH method should not be considered valid unless there's a sufficient quality control data provided to demonstrate the reliability of the modified method" (Document ID 3586, Tr. 3278).

OSHA finds that the AIHA PAT data are a far more credible measure of inter-laboratory variation in crystalline silica measurement than the ACC-sponsored RJ Lee study. Strict procedures are used to prepare and validate sample preparation in accordance with ISO requirements for conformity assessment and competence of testing in calibration laboratories (Document ID 3586, Tr. 3275) and the database includes 200 rounds of silica testing since 2004, with 55 laboratories participating in each round (Document ID 3586, Tr. 3264-3265). By comparison, the RJ Lee study consisted of three rounds of testing among five laboratories.

One of the goals of the RJ Lee study was to conduct a double-blind test so that laboratories would not know they were analyzing prepared samples for proficiency testing; according to Mr. Bailey, a laboratory's knowledge that they are participating in a performance study, such as is the case with the AIHA PAT program, "can introduce bias into the evaluation from the very beginning" (Document ID 3582, Tr. 1989; Document ID 4209, p. 147). However, OSHA doubts that such knowledge has a profound effect on laboratory performance. Accredited laboratories participating in the PAT program undergo audits to ensure that analytical procedures are applied consistently whether samples are received from the field or from the PAT program. According to testimony from Mr. Walsh:

> [S]ite assessors [for the AIHA accreditation program] are very sensitive to how PAT samples are processed in the lab. It's a specific area that's examined, and if the samples are processed in any way other than a normal sample, the laboratory is cited as a deficiency (Document ID 3586, Tr. 3299-3300).

Therefore, after considering the evidence and testimony on the RJ Lee study and AIHA PAT Program data, OSHA concludes that the AIHA PAT data are the best available data on which to evaluate inter-laboratory variability in measuring respirable crystalline silica. The data evaluated by Harper et al. (2014) showed that laboratory performance has improved in recent years resulting in greater agreement between labs; mean RSD for the period 2003-2013 was 20.9 percent (Document ID 3998, Attachment 8, Figure 1). In addition, across the range of PAT filter loadings, only about 5 percent of the samples resulted in lab RSDs above 25 percent. At lower filter loads, 75 µg or less, about 10 percent of samples resulted in RSDs above 25 percent Document ID 3998, Attachment 8, Figure 2). OSHA concludes that these findings indicate general agreement between laboratories analyzing PAT samples.

Although laboratory performance has not been broadly evaluated at filter loads below 40 µg, particularly when interferences are present, OSHA's investigations show that the XRD method is capable of measuring crystalline silica at filter loads of 40 µg or less without appreciable loss of precision. The analysis of recent PAT data by Harper et al. (2014, Document ID 3998, Attachment 8) shows that the increase seen in inter-laboratory variation with lower filter loads (e.g., about 50 and 70 µg) is modest compared to the increase in variation seen in the past from earlier PAT data, and the summary data provided by AIHA (Document ID 4188) show that the average lab RSD for samples with low filter loads is only a few percentage points above average lab RSD across the full range of filter loads used in the PAT program since 1999. OSHA finds that the studies of recent PAT data demonstrate that laboratories have improved their performance in recent years, most likely as a result of improving quality control procedures such as were first proposed by Eller et al. (1999b, Document ID 1688, pp. 23-24). Such procedures, including procedures concerning equipment calibration, use of NIST standard reference material for calibration, and strict adherence to published analytical methods, are required by Appendix A of the final rule. According to Dr. Rosa Key-Schwartz, NIOSH's expert in crystalline silica analysis, NIOSH worked closely with the AIHA laboratory accreditation program to implement a silica emphasis program for site visitors who audit accredited laboratories to ensure that these quality control procedures are being followed (Document ID 3579, Tr. 153). With such renewed emphasis being placed on tighter procedures for crystalline silica analysis, OSHA finds that exposure monitoring results being received from laboratories are more reliable than was the case in years past and thus are deserving of greater confidence from employers and workers.

3.3 CONCLUSION

Based on the record evidence reviewed in this section, OSHA finds that current methods to sample respirable dust and analyze samples for respirable crystalline silica by XRD and IR methods are capable of reliably measuring silica concentrations in the range of the final rule's PEL and action level. This finding is based on the following considerations, which were discussed in more detail above: (1) several sampling devices are available that conform to the ISO/CEN specification for particle-size selective samplers with a level of bias and accuracy deemed acceptable by international convention, and moving to the ISO/CEN convention will maintain continuity with past practice, (2) both the XRD and IR methods can measure respirable crystalline silica with acceptable precision at amounts that would be collected by samplers when airborne concentrations are at or around the PEL and action level, and (3) laboratory proficiency data demonstrate that there is reasonable agreement between laboratories analyzing comparable samples most of the time.

There are several sampling devices that can collect respirable crystalline silica in sufficient quantity to be measured by laboratory analysis; some of these include the Dorr-Oliver nylon cyclone operated at 1.7 L/min air flow rate, the Higgins-Dewell cyclones (2.2 L/min), the SKC aluminum cyclone (2.5 L/min), and the GK2.69, which is a high-flow sampler (4.2 L/min). Each of these cyclones can collect the minimum amount of silica necessary, at the PEL and action level, for laboratories to measure when operated at their respective flow rates for at least four hours. In addition, each of these devices (as well as a number of others) has been shown to conform to the ISO/CEN convention with an acceptable bias and accuracy for a wide range of particle-size distributions encountered in the workplace. OSHA used the Dorr-Oliver at a flow rate of 1.7 L/min to enforce the previous PELs for respirable crystalline silica, so specifying the use of sampling devices conforming to the ISO/CEN convention does not reflect a change in enforcement practice. The modest error that is associated with using respirable dust samplers is independent of where the PEL is set, and these samplers have been used for decades both by OSHA, to enforce the preceding silica PEL (and other respirable dust PELs), and by employers in managing silica-related risks. Therefore, OSHA finds that these samplers are capable of and remain suitable for collecting respirable dust samples for crystalline silica analysis.

Both XRD and IR analytical methods are capable of quantifying crystalline silica with acceptable precision when air samples are taken in environments where silica concentrations are around the PEL and action level. OSHA's quality control samples analyzed by XRD over the past few years show the precision to be about 20 percent over the range of filter loads tested (about one-half to twice the former PEL). OSHA conducted studies to characterize the precision of its Method ID-142 at low filter loads representing the amounts that would be captured using the Dorr-Oliver cyclone at the action level and PEL (i.e., 20 and 40 μg, respectively), and found the precision, for quartz and cristobalite, at both 20 and 40 μg to be comparable to the precision at the higher range of filter loads.

Evaluation of data from AIHA's Proficiency Analytical Testing Program shows that results from participating laboratories are in agreement (i.e., within 25%) most of the time. Performance between laboratories has improved significantly in recent years, most likely due to adoption of many of the quality control practices required by Appendix A of the final rule. Although precision declines as the amount of crystalline silica in samples declines, the rate of decline in precision with declining mass is less today than for prior years. OSHA expects that increasing emphasis on improved quality control procedures by the AIHA laboratory accreditation program (Document ID 3579, Tr. 153), the requirement in the final rule for employers to use laboratories that use XRD or IR analysis (not colorimetric) and that are accredited and conform to the quality control procedures of Appendix A of the final rule, and increased market pressure for laboratories to provide reliable results are likely to improve agreement in results obtained by laboratories in the future.

Inter-laboratory variability has not been well characterized at filter loads below 50 μg, which is slightly more than would be collected by a Dorr-Oliver cyclone sampling a silica concentration at the PEL over a full shift. However, OSHA concludes that the studies conducted by SLTC show that acceptable precision can be achieved by the XRD method for filter loads obtained by collecting samples with the Dorr-Oliver and similar devices at the action level and PEL. If employers are concerned about the accuracy that their laboratory would achieve at filter loads this low, samplers with higher flow rates could be used to collect an amount of silica that falls within the working range of the OSHA method and within the range of filter loads currently used by the PAT program (i.e., 50 μg or more). For example, either the aluminum cyclone or HD will collect at least 50 μg or more of silica where concentrations are around the PEL, and the GK2.69 will collect a sufficient quantity of crystalline silica where concentrations are at least at the action level.

Based on the information and evidence presented in this section, OSHA is confident that current sampling and analytical methods for respirable crystalline silica provide reasonable estimates of measured exposures. Employers should be able to rely on sampling results from laboratories meeting the requirements in Appendix A of the final rule to analyze their compliance with the PEL and action level under the new silica rule; employers can obtain assurances from laboratories or their industrial hygiene service providers that such requirements are met. Similarly, employees should be confident that those exposure results provide them with reasonable estimates of their exposures to respirable crystalline silica. Thus, OSHA finds that the sampling and analysis requirements under the final rule are technologically feasible.

4. TECHNOLOGICAL FEASIBILITY FOR GENERAL INDUSTRY

4.1 ASPHALT PAVING PRODUCTS

4.1.1 Description

Asphalt paving product manufacturing facilities are primarily classified in the six-digit North American Industry Classification System (NAICS) code 324121, Asphalt Paving Mixture and Block Manufacturing. Silica-containing materials are commonly used as aggregate to add bulk and durability to asphalt mixtures and blocks (unit pavers) used for pavement construction, rehabilitation, and/or maintenance. Common aggregates for asphalt paving products include sand, gravel, crushed stone, and reclaimed asphalt pavement (RAP) and account for about 95 percent of the total mixture by weight. Additionally, virgin Portland cement is sometimes added as a stabilizer (Document ID 1365, p. 19-1).

There are two types of central mix plants broadly classified as batch mix plants and drum mix (continuous) plants, depending on the process by which the raw materials are mixed. There are two commonly used types of asphalt paving mixtures that are produced at mix plants: hot mix and cold mix. In addition, some asphalt plants have begun using a warm mix asphalt technology as an alternative to hot mixes to decrease fumes and odors (Document ID 0674, p. 1). Hot mix plants require drying (heating) and screening of aggregate, presenting additional sources of silica dust not present at cold mix plants (Document ID 1365, p. 19-3).

Asphalt paving product workers can be exposed to silica-containing dusts when handling loose, dry aggregate; during crushing, drying, and screening activities; and when mixing aggregate with asphalt cement (Document ID 1365, pp. 19-2 – 19-3). The job categories with potential for exposure to silica include facility operator, front-end loader operator, and maintenance worker. Table IV.4.1-A summarizes the major activities and sources of exposure in this industry.

There is potential for further exposure in facilities with recycling activities that include crushing and screening of recovered concrete and/or RAP. These workers have job titles such as crusher operator and tender (belt picker, laborer), and their activities might involve the use of mobile rubble crushing plants, lump breakers, and screeners. For a discussion of crusher operators and tenders, refer to Section IV-5.10 – Mobile Crushing Machine Operators and Tenders.

Table IV.4.1-A
Job Categories, Major Activities, and Sources of Exposure of Workers in the Asphalt Paving Products Industry (NAICS 324121)

Job Category*	Major Activities and Sources of Exposure
Facility Operator	Controls and monitors production of asphalt paving products with an automated computer-controlled process. Operates conveyors, elevators, dryers, and mixing equipment, and dispenses product into trucks or storage silos from a control room/booth. Most control rooms are fully enclosed and ventilated with little potential for exposure to silica-containing dusts. • Dust from "manually" operating production operations (when necessary). • Dust from material handling activities and the plant yard/haul road (when control rooms are not fully enclosed).
Front-End Loader Operator	Transports raw materials using a front-end loader. Might oversee receipt of raw materials via truck or rail car. • Dust from manually transporting sacks of specialty materials (when necessary). • Dust from material handling activities (when the front-end loader is not equipped with a fully enclosed and ventilated cab). • Dust from the plant yard/haul road.
Maintenance Worker (Laborers)	Inspects, services, repairs, and adjusts equipment. Cleans up around the facility. • Dust from the plant yard/haul road, raw material storage piles, conveyors, weight scales, and process equipment (such as dust collectors).

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility.
Source: Document ID 1365, p. 19-7.

Table IV.4.1-B summarizes the available exposure information for the affected job categories. For each of the job categories listed in Table IV.4.1-B and for the asphalt paving industry as a whole, OSHA concludes that Table IV.4.1-B represents baseline conditions.

4.1.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.1-B includes 5 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for workers in the asphalt paving industry. The median is 20 μg/m^3, the mean is 27 μg/m^3, and the range is 20 μg/m^3 (limit of detection (LOD)) to 53 μg/m^3. Table IV.4.1-B shows that, of the 5 samples, 1 (20 percent) is at or above 50 μg/m^3 and none exceed 100 μg/m^3. The following sections describe the exposure profile and baseline conditions for each affected job category based on two OSHA Special Emphasis Program (SEP) inspection reports from hot mix plants (Document ID 1365, p. 19-8; 0186; 0077).[5] In the absence of information specific to cold mix plants, OSHA considers the available exposure data relevant to both hot and cold mix production. OSHA noted in its preliminary analysis that the data may overestimate the exposure of some workers at plants using cold mix techniques (Document ID 1720, p. IV-50). This is because cold mix plants might be somewhat less dusty than hot mix plants as they lack dryers and screens. OSHA received no comments regarding this conclusion.

As noted above, the available exposure data for the Asphalt Paving Products industry includes only five samples obtained from two OSHA SEP reports. Four of these samples are between 4 and 5 hours duration and are below the limits of detection [LOD] of 20 to 21 μg/m^3. The U.S. Chamber of Commerce commented that this small number of samples does not provide a representative sample of exposures at Asphalt Paving Products manufacturing facilities (Document ID 2368, p. 19). OSHA acknowledges that these data are limited; however, OSHA requested – but did not receive – additional exposure data for this industry, and therefore considers the samples to represent the best available evidence regarding exposures to respirable crystalline silica in the asphalt paving products industry.[6]

Exposure Profile and Baseline Conditions for Facility Operators

The exposure profile in Table IV.4.1-B includes 1 sample for facility operators in the asphalt paving industry, with a value of 21 μg/m^3. This single exposure result available for facility operators is from an OSHA inspection at an asphalt plant. The exposure result is below the LOD, which in this case is less than or equal to 21 μg/m^3 (290-minute sample). This value was obtained for an operator working in an air-conditioned room at a

[5]Due to the limited exposure data available for the asphalt paving industry, OSHA has considered data from four samples greater than 4 hours duration. In this case, 8-hour time-weighted averages (8-hour TWAs) were derived from samples of 4-hours or longer by assuming the exposure concentration during any unsampled portion of the shift was the same as the concentration during the period sampled.

[6] In the PEA, OSHA included as supporting information a discussion of sampling results from the Ready-Mix industry in that the processes and range of exposures are similar to the Asphalt Paving Products industry. However, OSHA has not relied on the sampling information from the Ready-Mix operations as the basis for the conclusions in the FEA because the sample results did not significantly alter the exposure profile and therefore did not impact the related conclusions.

continuous feed asphalt plant where visible dust had been greatly reduced by maintenance and adjustments to an existing ventilation system on the blending equipment and water spray in the sand/aggregate drier exhaust system (Document ID 1365, p. 19-15; 0077). The inspection report prepared by the compliance officer stated:

> High dust levels were noted during the initial walk-around, based in large part on dust being discharged from the blender overflows. When sampling could be conducted, the employees had had the opportunity to perform a large amount of maintenance work and experiment with dust control measures in the operation of the blender. The operator was successful in controlling dust overflows from the blender quite well, making the dust levels measured by sampling quite low. Dust emissions from the drier were controlled by a water spray scrubber that had been installed on the air exhaust from the drier. Bulk sample results showed silica levels of about 8%, with none being detected in the personal air monitoring samples (Document ID 0077, p. 13).

OSHA received no additional exposure data for facility operators. OSHA also reviewed the OSHA inspection data from OSHA's Information System (OIS) submitted to the rulemaking record (Document ID 3958); however, no additional data were identified for facility operators. Based on the information in the docket, OSHA considers 21 μg/m^3 to be the baseline exposure level for facility operators.

Exposure Profile and Baseline Conditions for Front-End Loader Operators

The exposure profile in Table IV.4.1-B includes 2 samples for front-end loader operators in the asphalt paving industry. The median is 37 μg/m^3, the mean is 37 μg/m^3, and the range is 20 μg/m^3 (limit of detection (LOD)) to 53 μg/m^3. Table IV.4.1-B shows that, of the 2 samples, 1 (50 percent) is at or above 50 μg/m^3 and none exceed 100 μg/m^3. These two PBZ silica samples were obtained during two inspections at asphalt plants. One sample measured an exposure below the LOD of 20 μg/m^3 during a 290-minute sampling period, and a second sample measured 53 μg/m^3 over a 435-minute sampling period (Document ID 1365, p. 19-16; 0186; 0077). At both plants, the front-end loader operators scooped sand, aggregate, and other filler materials and dumped them into hoppers (Document ID 0186, p. 63; 0077, p. 30). At the plant where the sampling result was below the LOD, the front-end loader operator worked in a ventilated cab and maintenance work on existing dust controls had substantially reduced visible dust on the sampling date (Document ID 0077, p. 13).

OSHA also reviewed the OIS sampling data submitted to the rulemaking record (Document ID 3958); however, no additional data were identified, nor were any comments received related to front-end loader operator exposure. Based on this best available (but limited) data, OSHA concludes that half of front-end loader operators are currently exposed to silica levels below 50 μg/m^3, and the median exposure is below 50 μg/m^3 (37 μg/m^3), with the highest exposure only slightly above the PEL.

Exposure Profile and Baseline Conditions for Maintenance Workers (Laborers)

The exposure profile in Table IV.4.1-B includes 2 samples for maintenance workers (laborers) in the asphalt paving industry. These maintenance workers serviced machinery, picked trash from the belt carrying aggregate to the blender, and assisted plant operators with trucks. The sample durations were 282 minutes and 297 minutes, and both samples were below the reported LOD of 20 μg/m^3 (Document ID 1365, p. 19-17; 0077).

OSHA received no additional exposure data for maintenance workers. OSHA also reviewed its inspection data recorded in OIS and submitted to the rulemaking record (Document ID 3958); however, there were no additional data for maintenance workers in the asphalt paving products sector. Based on this best available (but limited) information, OSHA considers 20 μg/m^3 to be the baseline exposure level for maintenance workers.

Table IV.4.1-B Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Asphalt Paving Products Industry (NAICS 324121)											
	Exposure Summary			Exposure Range			Exposure Profile				
Job Category	N	Mean (µg/m³)	Median (µg/m³)	Min (µg/m³)	Max (µg/m³)		<25 (µg/m³)	≥25 and ≤50 (µg/m³)	>50 and ≤100 (µg/m³)	>100 and ≤250 (µg/m³)	>250 (µg/m³)
Facility Operator	1	21	21	21	21		1 (100%)	0 (0%)	0 (0%)	0 (0%)	0 (0%)
Front-End Loader Operator	2	37	37	20	53		1 (50%)	0 (0%)	1 (50%)	0 (0%)	0 (0%)
Maintenance Worker	2	20	20	20	20		2 (100%)	0 (0%)	0 (0%)	0 (0%)	0 (0%)
Total	**5**	**27**	**20**	**20**	**53**		**4 (80%)**	**0 (0%)**	**1 (20%)**	**0 (0%)**	**0 (0%)**

Notes: All samples summarized are personal breathing zone (PBZ) results representing 8-hour time-weighted average exposures. Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility. Percentages may not add to 100 percent due to rounding.

4.1.3 Additional Controls

Additional Controls for Facility Operators

The exposure profile in Table IV.4.1-B shows that zero percent (0 out of 1 sample) of facility operators have exposures above the final PEL of 50 μg/m^3. Therefore, no additional controls are required. As noted above, based on the best available exposure data, OSHA concludes that the baseline exposure level for facility operators performing routine activities is 21 μg/m^3. In those instances where elevated exposure might occur, silica levels can be reduced through the use of fully enclosed and ventilated operator control rooms and/or by controlling adjacent sources of silica-containing dust through local exhaust ventilation (LEV) and dust suppression methods (Document ID 1365, p. 19-19).

Although few data are available regarding exposure reduction through LEV or dust suppression methods, these methods are generally effective in controlling silica dust. In a 272-minute sample, OSHA measured a PBZ concentration less than the LOD (21 μg/m^3 in this case) for a facility operator who worked in an air-conditioned booth at the previously discussed hot-mix asphalt plant where maintenance and adjustments to existing LEV (on the blender) and wet scrubber (aggregate drier exhaust) had greatly reduced visible dust (Document ID 1365, p. 19-15; 0077).

Related studies involving exposures from similar types of materials, with the use of dust suppressants suggest that a significant reduction in silica exposure can be achieved with the proper use of dust suppressants to control fugitive dust emissions associated with haul roads, and aggregate storage and handling. For example, a study by Addo and Sanders compared the performance of three dust suppressants (lignosulfonate, calcium chloride, magnesium chloride) to no treatment on an unpaved roadway over four and a half months (Document ID 0516). The dust suppressants reduced fugitive dust emissions by 50 to 70 percent when compared with the untreated section (Document ID 0516, p. 106).

OSHA received no comments questioning its conclusion that no additional exposure controls are required for this job category.

Additional Controls for Front-End Loader Operators

The exposure profile in Table IV.4.1-B shows that 50 percent (1 out of 2 samples) of front-end loader operators have exposure above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. However, since the only sample in the record above 50 μg/m^3 was a 53 μg/m^3 sample, and the other sample in the record was at the LOD of 20 μg/m^3, the median exposure level for front-end loader operators is 37 μg/m^3. Therefore, OSHA believes that approximately half of front-end loader operators will require some additional controls to achieve the PEL of 50 μg/m^3. In those instances where an exposure above the PEL would still occur, the silica exposure of front-end loader operators will be reduced through improved maintenance of existing dust control systems. Furthermore, silica levels can be reduced through the use of fully enclosed, sealed, ventilated, and maintained operator cabs, and/or by controlling adjacent sources of silica-containing dust through LEV and wet or other dust suppression methods (Document ID 1365, p. 19-21).

In its preliminary analysis, OSHA concluded that dust suppression methods are particularly beneficial for work with sand and aggregates, such as those that are handled by front-end loader operators. Simple foams provide dust control benefits similar to water spray, but offer increased dust control capacity compared with the same volume of water (Document ID 1720, pp. IV-53 –54). OSHA received no comments questioning the effectiveness of foam as a dust control method for front-end loader operators in this industry, and therefore reaffirms its conclusion here.

For facilities where elevated exposures persist, well-sealed, air-conditioned cabs maintained under positive pressure with filtered air provide an additional control option for loader operators. While cabs are available, the cabs are not consistently used as a dust control measure. Cab interiors can contain a notable amount of silica-containing dust (Document ID 0839, p. 1). Additionally, the National Institute for Occupational Safety and Health (NIOSH) and the Mine Safety and Health Administration (MSHA) report that, in general, heavy equipment cabs are poorly sealed and that original-equipment ventilation design does not necessarily provide positive pressure or appropriately filter air

(Document ID 0839, pp. 1-2; 0888, p. 1; 0822, pp. 3-4; 0824, pp. 3-4). To effectively reduce the silica exposure of loader operators, cabs may need to be modified.

Although data documenting the effectiveness of such enclosures (i.e., equipment cabs) at asphalt paving product facilities are not available, other sources suggest a 94 to 99.5 percent reduction in respirable dust (inside compared with outside the cab) with well-sealed, air-conditioned, and filtered cabs (Document ID 0719, p. 51). The precise reduction depends on dust size and the ventilation system. Operators working in heavy equipment cabs that are sealed and pressurized with filtered intake air should experience exposure reductions in this general range. Although these cabs require regular maintenance to function properly, OSHA estimates and concludes that appropriately fitted and maintained cabs would offer a similar reduction in silica exposure for front-end loader operators in the asphalt paving products industry (Document ID 1365, p. 4-20).

Additional Controls for Maintenance Workers (Laborers)

The exposure profile in Table IV.4.1-B shows that none of the (0 out of 2 samples) maintenance workers (laborers) have exposure above the final PEL of 50 μg/m^3. Therefore, additional controls are not required for this job category. As noted above, the best available information indicates that the baseline exposure level for maintenance workers is less than 20 μg/m^3, well below the final PEL of 50 μg/m^3. In those instances where elevated exposure occurs, silica levels can be reduced by: 1) controlling adjacent sources of silica-containing dust (e.g., yard dust and dust associated with aggregate storage and handling activities) through wet or other dust suppression methods (discussed above); 2) installing enclosures and exhaust ventilation; and/or 3) using wet cleaning methods and high-efficiency particulate air (HEPA)-filtered vacuuming (Document ID 1365, p. 19-22; 0717, pp. 8-11; 1413, p. 854).

NIOSH recommends vacuuming with an approved HEPA-filtered vacuum or the use of wet cleaning methods to minimize worker exposure to hazardous air contaminants such as asbestos, silica, and heavy metals during housekeeping activities (Document ID 0881, p. 8; 0883, p. 5; 0873, p. 11). For some maintenance and repair activities (e.g., servicing the inside of a dust collector/bag house), engineering controls might not be feasible. In these cases, respiratory protection might be necessary to control worker exposure to silica.

4.1.4 Feasibility Finding

Feasibility Finding for Facility Operators

Based on the exposure profile in Table IV.4.1-B and other record evidence discussed above, OSHA finds that most facility operators are likely to have silica exposures below 50 μg/m^3 because they are usually isolated from production operations in a control room or booth. Additional exposure controls are not anticipated for this job category. In instances where elevated exposures might occur, OSHA reasonably expects that silica levels can be reduced to 50 μg/m^3 or less through the use of fully enclosed and ventilated operator control rooms and/or by controlling adjacent sources of silica-containing dust through LEV.

Feasibility Finding for Front-End Loader Operators

Based on the exposure profile in Table IV.4.1-B and other record evidence discussed above, OSHA finds that the exposures for 50 percent of front-end loader operators are less than 50 μg/m^3. Where elevated exposures occur, OSHA estimates silica levels can be reduced to 50 μg/m^3 or less through the use of fully enclosed, sealed, ventilated, and maintained operator cabs and/or by controlling adjacent sources of silica-containing dust through LEV or dust suppression methods.

Feasibility Finding for Maintenance Workers (Laborers)

Based on the exposure profile in Table IV.4.1-B and other record evidence discussed above, OSHA finds that exposure levels for most maintenance workers are less than 25 μg/m^3. While the need for additional controls is not anticipated, in instances where elevated exposures might occur, OSHA estimates silica levels can be reduced to 50 μg/m^3 or less by: 1) utilizing wet or other dust suppression methods, 2) installing engineering controls such as enclosures and LEV, and 3) using wet cleaning methods and HEPA-filtered vacuuming.

Overall Feasibility Finding for Asphalt Paving Products Facilities

Based on the exposure profile in Table IV.4.1-B and other record evidence discussed above, OSHA concludes that after implementing additional controls for front-end loader operators, most asphalt paving product manufacturing facilities can achieve exposure levels of 50 $\mu g/m^3$ or less in most operations, most of the time. Accordingly, OSHA concludes that the final PEL of 50 $\mu g/m^3$ is technologically feasible for the Asphalt Paving Products industry.

4.2 ASPHALT ROOFING MATERIALS

4.2.1 Description

Manufacturers of asphalt roofing materials produce roofing products that can be classified in three broad categories: shingles, surfaced and smooth roll roofing, and asphalt-saturated felt rolls. Shingles and roll roofing are outer roof coverings, while saturated felts are used as inner roof materials or underlayment. Shingles and roll roofing consist of three basic components: 1) a base material of organic felt or fiberglass mat, 2) an asphalt coating, and 3) a surfacing of mineral granules. Saturated felts consist of dry felt saturated with asphalt. These manufacturers are classified in the six-digit North American Industry Classification System (NAICS) 324122, Asphalt Shingle and Coating Materials Manufacturing (Document ID 1365, pp. 22-1 – 22-2; 1720, p. IV-58).

The production of asphalt roofing materials is a highly automated, stationary continuous process. The principal steps begin with unwinding a roll of base material and saturating it with asphalt by passing it through a series of hot asphalt tanks, and ending with a coater unit that applies a final layer of mineral-stabilized asphalt. For shingles and roll roofing, an additional step is mineral application during which minerals are pressed into both sides of the hot, coated surface (Document ID 1365, p. 22-1). Silica-containing minerals are incorporated into asphalt coatings and used as front and back surfacing granules to increase weather and fire resistance; back surfacing agents like talc and mica (commonly known as “partying agents”) also act to prevent asphalt products from sticking to each other in the manufacturer’s packaging (Document ID 1365, pp. 22-1, 22-3, 22-18; 0889, p. 3). Minerals typically used include slate (5 to 15 percent silica), limestone (up to 67 percent silica), dolomite (0 to 3 percent silica), granite (9-60 percent silica), trap rock (up to 12 percent silica), talc (up to 5 percent silica), silica sand (75 – 98 percent silica), mica (up to 10 percent silica), and or ceramic granules. After application of the mineral surfacing, the coated sheet is rapidly cooled and air dried, and then cut and packaged (Document ID 1365, pp. 22-1 – 22-4).

Mineral stabilizer material is delivered by truck, conveyed to storage bins, heated, and then mixed with the coating asphalt. Granules and back surfacing materials are brought by rail or truck and mechanically or pneumatically conveyed to storage bins and hoppers (Document ID 1365, p. 22-4; 1720, p. IV-58).

Workers attend each step of the process, including the receiving, handling, transfer, storage, and mineral surfacing, and their exposures occur primarily when silica-containing materials are added during the process (Document ID 1365, pp. 22-1, 22-4). Workers with potential silica exposure are production operators and material (mineral) handlers. Production operators monitor production line areas, which include the coater, the press, and the cooling section. These workers' major sources of silica exposure are from dust released during drying, preheating the mineral stabilizer, and mineral surfacing, as well as from mineral storage hoppers and bins located near the coater. Material handlers are responsible for handling and monitoring the use of granules and other minerals, and loading these materials into hoppers. Major sources of silica exposure for material handlers are dust from manually loading hoppers, from the mineral transfer systems, and from mixing silica-containing materials with asphalt coating (Document ID 1365, pp. 22-4 – 22-5). The major activities and sources of exposure for these job categories are summarized below in Table IV.4.2-A.

Table IV.4.2-A
Job Categories, Major Activities, and Sources of Exposure of Workers in the Asphalt Roofing Materials Industry (NAICS 324122)

Job Category*	Major Activities and Sources of Exposure
Production Operator (coater, press, cooling section, and relief operator)	Monitoring production line operations. • Dust from drying and preheating mineral stabilizer. • Dust from mineral surfacing (pressing minerals such as mica or talc into both sides of the base material). • Dust from mineral storage hoppers and bins in close proximity to the coater.
Material Handler (slate assistant, granule assistant)	Handling and monitoring the use of granules and other minerals and loading the materials into hoppers. • Dust from manually loading materials into hoppers. • Dust from the mineral transfer system. • Dust from mixing silica-containing minerals with coating asphalt.

*Job categories are intended to represent job functions; actual job titles may differ and responsibilities may be allocated differently, depending on the facility.
Source: Document ID 1720, p. IV-59.

Table IV.4.2-B summarizes the available exposure information for the affected job categories. For each of the job categories listed in Table IV.4.2-B and for the asphalt roofing materials industry as a whole, OSHA concludes that Table IV.4.2-B represents baseline conditions.

4.2.2 Exposure Profile and Baseline Conditions

In preparing the Preliminary Economic Analysis (PEA), OSHA reviewed exposure monitoring data from 12 samples from five NIOSH health hazard evaluations (HHE) conducted during the late 1970s.[7] Due to the small numbers of available samples, two samples of less than 360 minutes duration were included in the exposure profile (these samples had durations of 300 and 312 minutes). Approximately 42 percent of samples were below the PEL of 50 μg/m^3, with a median of 59 μg/m^3, a mean of 71 μg/m^3, and a range from below the limit of detection (LOD, in this case 28 μg/m^3) to 188 μg/m^3(Document ID 1720, pp. IV-59 - IV-60).

Due to the age of the NIOSH evaluations and to provide additional insight into exposures, OSHA also reviewed sample results from inspections recorded in OSHA's Integrated Management Information System (IMIS) for the years 1983 through 2001. The majority of the highest exposure samples were collected before 1985 (Document ID 1365, p. 22-8). These IMIS data were not added to the exposure profile due to the lack of information regarding sample duration and worker activities, workplace conditions, and engineering controls during the sampling period. Over 40 percent of IMIS sample results were below the limit of detection (Document ID 1720, pp. IV-59 – IV-62 (reviewing Document ID 1698 [IMIS data])). OSHA also reviewed inspection data recorded in the OSHA Information System (OIS) and submitted to the rulemaking record but identified no additional pertinent data (Document ID 3958).

Controls typically used in this industry include process enclosures with local exhaust ventilation (LEV) to control worker exposures associated with mineral handling and storage operations, and bag-type dust collectors with LEV to control exposures during mineral surfacing in the mineral application and cooling process areas of the plant. General dilution ventilation in the cooling sections of the manufacturing line also

[7] Exposure data collected prior to 1990 was retained in this exposure profile because more recent data were not available for this sector. (see Section IV-2–Methodology within this chapter)

contributes to lower contaminant exposures, although its effectiveness may vary within the industry (Document ID 0837, pp. 23, 28).

Information That Silica Exposures Have Declined in the Industry

Information on exposure data for other air contaminants from the asphalt roofing materials industry suggests that more recent silica exposure values are likely significantly lower than those reflected in the NIOSH HHE and IMIS data. The data at 53 U.S. plants of four companies indicated that, after 1990, exposures to total particulates, benzene, and cyclohexane-soluble samples declined for three companies. It is likely that the engineering controls implemented to control these exposures, including the improved capture efficiency of exhaust hoods, and reduction of fugitive emissions in order to meet the requirements of the Clean Air Act Amendment of 1990, would also be effective in reducing silica exposures (Document ID 0837, p. 17).

In Germany, bitumen roofing products manufacturing (i.e., asphalt roofing materials manufacture) saw a marked decline in respirable quartz exposure from a mean of 150 $\mu g/m^3$ for the period from 1983 through 1989 to a mean of 40 $\mu g/m^3$ for the period from 1995 through 2004 (Document ID 0553, p. 129). Over the same periods, the median (reported as the 50th percentile) silica result was reduced from 40 $\mu g/m^3$ to 10 $\mu g/m^3$, and the 90th percentile value, representing the higher individual exposures, was cut by slightly less than 63 percent to 100 $\mu g/m^3$ (Document ID 0553, p. 129).[8] These reductions indicate that improvements in equipment, materials, control technology, and work practices have effectively reduced exposure levels in this industry.

Similarly, Anttila et al. (2009) noted a 61 percent decline in arithmetic mean silica exposures in Finland between the periods from 1975 through 1979 and from 2000 through 2005, and a 66 percent decline in geometric mean (i.e., median) exposures for the same time periods. The authors credit improvements in dust control and work methods

[8] The difference between the 1983-1989 time frame (0.27 mg/m^3) and the most recent period 1995 to 2004 (0.10 mg/m^3) is 0.27-0.10=0.17 mg/m^3. 0.17/0.27= 62.9 percent (rounds to 63 percent) difference (Document ID 0553, p. 129).

implemented in the mid-1980s for reducing average exposures (Document ID 0529, pp. 147 - 148).

Mr. John Ferraro, General Manager of the Asphalt Roofing Manufacturers Association (ARMA), provided extensive exposure data for ARMA members that included newer data from 70 plants representing 81 percent of ARMA members and approximately 31 percent of the overall industry (Document ID 2291, p. A-3). Mr. Ferraro noted that “silica exposures are well controlled in ARMA member plants (Document ID 2291, p. A-6). For routine manufacturing operations, 91 percent of samples were less than 50 µg/m^3 (Document ID 2291, p. B-4).

The ARMA data reflect median exposures substantially lower than the values in OSHA’s exposure profile (Table IV.2-B). The data provided by ARMA could not be included in the exposure profile for this industry since only summary data by job category were provided with no individual sample results or descriptions of working conditions.

Given the implementation of more efficient technology and updated work practices since the late 1970s, the U.S. trends reflected in the ARMA data, and the international experience in reducing silica levels, OSHA concludes that silica exposures in the U.S. are likely lower in the asphalt roofing materials industry than reflected by the NIOSH HHE and IMIS data.

Exposure Profile and Baseline Conditions for Production Operators

The exposure profile in Table IV.4.2-B includes 5 samples for production operators in the asphalt roofing materials industry. The median is 29 µg/m^3, the mean is 56 µg/m^3, and the range is 28 µg/m^3 (limit of detection (LOD)) to 131 µg/m^3. Table IV.4.2-B shows that, of the 5 samples, 2 (40 percent) are above 50 µg/m^3 and 1 (20 percent) exceeds 100 µg/m^3. The exposure profile for production operators is based on five PBZ silica samples obtained by NIOSH at four different asphalt roofing manufacturing facilities in the 1970s. Sixty percent of the samples were below the PEL of 50 µg/m^3.

The ARMA data referenced above, which include positions equivalent to Production Operator, reflect a median exposure of 13 µg/m^3, a mean exposure of 33 µg/m^3, and reports that 91 percent of samples were below the PEL of 50 μg/m^3 (Document ID 2291, p. B-4, Table B-2). These data, considered with the German and Finnish studies discussed above, strongly indicate that the exposure profile based on the older NIOSH HHE evaluations, as shown in Table IV.4.2-B, likely significantly overstates the exposure levels of production operators. In the PEA, OSHA estimated that "current silica exposure levels are lower by half than those reported in the NIOSH HHE reports of the 1970s" for production operators (Document ID 1720, p. IV-62). OSHA's estimate was not questioned and, indeed, was shown to be conservative by the ARMA data. Therefore, OSHA is retaining the estimate that current silica exposure levels are likely 50 percent lower than those reported in Table IV.4.2-B. Therefore, OSHA has revised the exposure profile in Table IV.4.2-C to reflect this reduction.

In addition, OSHA notes that the proportion of workers in each job category is not accurately reflected by the number of samples in each job category as presented in Table IV.4.2-B. The ARMA data reflect a greater percentage of Production Operators (86 percent) than Material Handlers (Document ID 2291, p. B-2, Table B-1). In light of this information, OSHA prepared a revised estimated exposure distribution for the workers to better reflect the industry in Table IV.4.2-C.

Therefore, Table IV.4.2-C shows the revised exposure profile, presenting an updated exposure profile reflecting the reduction in the estimate of exposures for each job category as well as a revised exposure distribution for the total workers.

Exposure Profile and Baseline Conditions for Material Handlers

The exposure profile in Table IV.4.2-B includes 7 samples for material handlers in the asphalt roofing materials industry. The median is 67 μg/m^3, the mean is 82 μg/m^3, and the range is 29 μg/m^3 (limit of detection (LOD)) to 188 μg/m^3. Table IV.4.2-B shows that, of the 7 samples, 5 (71.4 percent) are above 50 μg/m^3 and 2 (28.6 percent) exceed 100 μg/m^3. These seven PBZ silica samples were collected by NIOSH investigators during HHEs at five different roofing manufacturing facilities as shown in Table IV.4.2-B. Even in the 1970s, when these data were collected, 28.6 percent of workers sampled had exposures below 50 μg/m^3. These samples had a median of 67 μg/m^3, a mean of 82 μg/m^3, and a range from less than 29 μg/m^3 (below the sample limit of detection) to 188 μg/m^3. Three of the seven samples were below the limit of detection, with LODs of 29 μg/m^3, 39 μg/m^3, and 57 μg/m^3 (Document ID 1365, pp. 22-11 – 22-14).

The ARMA data submitted into the record provide summary statistics for a number of job categories (Document ID 2291, p. B-4, Table B-2). The job description for “Slate/Granule/Bulk Materials Attendant” matches the description “material handler” (Document ID 2291, p. B-3; 1720, p. IV-59). The 180 PBZ silica exposure samples reported by the ARMA for this job category show a mean of 51 μg/m^3, a median of 14 μg/m^3, and a third quartile of 28 μg/m^3, with 85 percent of samples below 50 μg/m^3 (Document ID 2291, p. B-4, Table B-2). These data are consistent with the conclusion that the exposure profile overestimates the baseline exposure level for material handlers.

For the reasons discussed above for production operators, OSHA has concluded that the exposure profile for material handlers generated from the NIOSH HHE evaluations likely overestimates median exposure levels for this job category. In the PEA, OSHA estimated that “the NIOSH data might overestimate the baseline exposure level for [material handlers] * * * by greater than half” (Document ID 1720, pp. IV-62 – IV-63). OSHA’s estimate was not questioned and, indeed, was shown to be conservative by the ARMA data. Therefore, OSHA is retaining the estimate and concludes that the revised exposure profile (Table IV.4.2-C) accurately reflects the distribution of exposures for workers in the asphalt roofing materials industry.

Table IV.4.2-B
Preliminary Exposure Profile
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Asphalt Roofing Materials Industry (NAICS 324122)

	Exposure Summary			Exposure Range			Exposure Profile				
Asphalt Roofing Materials Industry	**N**	**Mean (μg/m^3)**	**Median (μg/m^3)**	**Min (μg/m^3)**	**Max (μg/m^3)**		**<25 (μg/m^3)**	**≥25 and ≤50 (μg/m^3)**	**>50 and ≤100 (μg/m^3)**	**>100 and ≤250 (μg/m^3)**	**>250 (μg/m^3)**
Production Operator	5	56	29	28	131		0 (0%)	3 (60%)	1 (20%)	1 (20%)	0 (0%)

4.2.3 Additional Controls

<u>*Additional Controls for Production Operators*</u>

The preliminary exposure profile in Table IV.4.2-B shows that 40 percent (2 out of 5 samples) of production operators in the asphalt roofing materials industry have exposures above the final PEL of 50 μg/m^3. As shown in Table IV.4.2-C, revised exposure profile, OSHA estimates that only 20 percent of production operators will require additional controls.

As discussed above, OSHA estimated in the PEA that the profile likely overstated exposures "by half," that is, only 20 percent of production operators would require additional controls, as compared to the 40 percent indicated by the profile (Document ID 1720, pp. IV-62 – IV-63). OSHA's estimate was not questioned and, indeed, borne out by the ARMA data showing that only approximately eight percent of production operators would need additional controls.

In those instances where elevated exposures occur (e.g., at the coater, cooling, and press areas), as described further below, manufacturers will need to use a combination of improvements or upgrades in existing LEV systems and process enclosures, and improved housekeeping methods (e.g., HEPA vacuums) to reduce silica levels to 50 μg/m^3 or less. In addition, the use of washed sand has been shown to reduce exposure. In an analysis of respirable quartz exposures obtained at two Finnish roofing membrane plants from 1975 to 2005, worker exposure was significantly lower when washed quartz sand was used compared with unwashed quartz sand (Document ID 0529, p. 148).

Ventilation and Process Enclosures for Production Operators

In assessments of facilities manufacturing asphalt roofing materials, NIOSH investigators recommended installation of LEV over the coater and press areas, enclosure of the coating process, and/or repair and servicing of existing process enclosures and ventilation systems to eliminate leaks and poor hood capture (Document ID 0889, pp. 12-13; 0891, pp. 3, 11; 0890, p. 14; 0893, p. 12).

OSHA does not have data specifically measuring the exposure reductions achieved with adequate ventilation and enclosures in this industry. However, in OSHA inspections of similar mineral powders handling operations in the pottery industry, OSHA measured an exposure level of 29 μg/m^3 for a worker operating mixers equipped with LEV and fed by ventilated, automated conveyance equipment, and 23 μg/m^3 for a worker charging mixers using enclosed, automated equipment (Document ID 1365, p. 22-20; 1436, pp. 1, 27, 28-29; 0143, pp. 128, 130-131).[9] At a site where workers produced batches of paint by emptying 50-pound bags of quartz and cristobalite powder into hoppers, the OSHA contractor Eastern Research Group (ERG) reported exposures of less than 12 μg/m^3 and 13 μg/m^3 (the sample limits of detection) when the combined exhaust ventilation and local exhaust ventilation on bag disposal systems were working properly. These values are 95 percent lower than the result obtained during another shift at the same plant when these controls malfunctioned (Document ID 0199, p. 9). OSHA expects that these same types of controls would be effective in controlling exposures for production operators and material handlers in asphalt roofing materials manufacturing because the materials handled have similar characteristics.

Further, the levels of silica exposure control reported by the ARMA, with median exposures of 13 μg/m^3 and mean exposures of 31 μg/m^3 for process operators (excluding bulk materials attendant, which corresponds to the OSHA job function of materials handler discussed below), indicate that adequate controls can be achieved to reduce exposures to levels well below the PEL most of the time (Document ID 2291, p. B-4).[10]

[9] OSHA calculated silica exposure results using the weight of respirable dust measured by the laboratory on the sample filter, multiplied by the percent crystalline silica in the dust sample to obtain the weight of silica on the sample filter. The weight of silica was divided by the air volume sampled. For example, 460 μg of respirable dust on the filter, times 0.036 (the fractional value of 3.6 percent silica), divided by 0.706 m^3 volume of air sampled = 23 μg/m^3.

[10] OSHA estimated the revised mean for data summarized in AMRA's comments. For each row (except the group of 180 samples including the bulk materials attendants), OSHA created proxy sample results by assigning the average value for the row to the number of samples represented in the row, then recalculating the average for these 1,000 proxy sample results for workers performing production operator activities (Document ID 2291, p. B-4). OSHA's estimate of the mean for the 1,000 production worker samples is 31 μg/m^3. [Note on total number of samples: the correct total sum of the "No. of Samples" column is 1,180, including the bulk material attendants. The total is incorrectly listed as 1,320 in Table 2B of Document ID 2291. Based on the information presented in the table, OSHA finds that the number of samples associated with production operator duties is 1,180 minus the 180 Bulk Material attendant samples = 1,000 samples.]

Additional Controls for Material Handlers

The preliminary exposure profile in Table IV.4.2-B shows that 71.4 percent (5 out of 7 samples) of material handlers have exposures above the final PEL of 50 μg/m^3. As shown in Table IV.4.2-C, revised exposure profile, OSHA estimates that only 36 percent of material handlers experience exposures above 50 μg/m^3. OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

The preliminary exposure profile (Table IV.4.2-B) reflected that the exposure level for at least 28.6 percent of mineral material handlers is less than 50 μg/m^3, indicating that additional controls would be required for the remaining 71.5 percent of material handlers. As discussed above, however, more recent data reported by ARMA reflect that for more recent periods, 85 percent of material handlers had exposures below 50 μg/m^3, indicating that as few as 15 percent may require additional controls. Because the companies that submitted exposure data to ARMA represent only thirty-one percent of the industry, the actual percentage of material handlers working in plants without effective controls is likely higher. OSHA has more conservatively estimated that the exposure profile based on the NIOSH data from the 1970s overstate current exposures by 50 percent. Based on these considerations, OSHA estimates that approximately 36 percent (half of the 71.4 percent in the preliminary profile) of material handlers would require additional controls to limit their exposures to below the PEL. Controls to address exposures for these material handlers include improvements in local exhaust ventilation, preventive maintenance, and housekeeping methods such as HEPA-filtered vacuuming, which are discussed in more detail below.

Local Exhaust Ventilation for Material Handlers

Adequate exhaust ventilation and process enclosures for the manufacture of asphalt roofing materials as described above for the production operator job category are also applicable to mineral handling systems.

Material handlers in this industry work with raw material and dust collection drums, transfer equipment, hoppers, and similar points of material handling and distribution. The NIOSH reports indicate that LEV is already installed at slate and dust drums, granule and backdust applicators, transfer rolls, and the majority of mineral products hoppers, although leaks or inadequate hood capture efficiency were noted in some cases. NIOSH recommended providing LEV at all mineral transfer points, providing LEV for mineral products hoppers, and repairing leaks or improving hood capture efficiency (Document ID 0837, p. 28; 1365, p. 22-22). The highest exposures in the exposure profile (78 µg/m^3, 120 µg/m^3, and 188 µg/m^3) were associated with two facilities that either did not have LEV at slate transfer points, or had leaks in the slate transfer system (Document ID 1365, pp. 22-13 – 22-14; 0889, p. 4, 15; 0893, pp. 12, 18). The silica exposures reported by the ARMA for a bulk materials attendant, which corresponds to the job category of materials handler, indicated a median exposure of 14 µg/m^3, with 85 percent of exposed workers below 50 µg/m^3 (Document ID 2291, p. B-4). This more recent data suggest that improvements in LEV and maintenance to prevent leaks can lower silica levels significantly below the values reflected in the exposure profile.

Additional Controls for Both Production Operators and Materials Handlers

Housekeeping

NIOSH and OSHA have recommended cleaning using either vacuuming with a HEPA-filtered vacuum or wet cleaning methods in order to minimize worker exposure to silica (Document ID 0895, p. 10). In a study of Finnish construction workers, worker exposures were approximately five times lower when workers used vacuums as compared with dry sweeping (Document ID 1163, p. 217).

Although Mr. John Ferraro of the ARMA agreed that wet methods “are effective for dust suppression,” they were not always safe or feasible. He stated:

> Wet methods * * * cannot be used in many settings in asphalt roofing plants because of safety and feasibility constraints * * * The mineralization area * * * is directly adjacent to the hot asphalt coater * * * introduction of water to the coater pan * * * may result in serious burn hazard * * * [that] expose[s] workers to splashes of hot asphalt” (Document ID 2291, p. 13).

Regarding HEPA-filtered vacuuming, Mr. Ferraro stated that portable HEPA vacuums would not be feasible in many cases due to the "practical limitation * * * [that] include cumbersome hoses with often inadequate reach, limited or problematic mobility, and inadequate collection capacities." Mr. Ferraro concluded that central, HEPA-filtered vacuum systems would need to be installed at great expense (Document ID 2291, p. 13).

Mr. Ferraro further stated that:

> While ARMA members support the use of HEPA vacuuming and wet methods in all settings in which they are feasible and effective * * * the standard must recognize that compressed air, dry sweeping and dry brushing represent the only feasible methods of housekeeping in a number of important settings in asphalt roofing plants * * * Specifically * * * certain pieces of equipment on the production line require use of compressed air to clean out small compartments and crevices. We know from long experience that vacuums cannot reach many of these dust and debris accumulations, and that wet methods are also infeasible as water will foul the production process * * * In addition, experience shows that * * * during scheduled housekeeping campaigns, shoveling or sweeping of bulk material is required because there is no feasible alternative (Document ID 2291, p. 19).

Mr. Ferraro further noted that scheduled housekeeping campaigns are typically conducted during plant "down days" when few workers are present (Document ID 2291, p. 14).

As previously stated, OSHA recognizes that the complete elimination of compressed air cleaning or dry sweeping may not be feasible. The ARMA comments, however, do indicate that wet methods and HEPA vacuums can and are used in many, if not all, situations to reduce exposures.

Preventive Maintenance

Properly maintained mineral handling systems are necessary to ensure low exposures to silica-containing dusts during material transfer and other process-related operations. NIOSH investigators noted process leaks in and around enclosures and less-than-optimal LEV in a facility manufacturing roofing granules. NIOSH recommendations included: 1) implementing a preventive maintenance program, 2) designing and testing LEV systems according to recognized guidelines, and 3) replacing process enclosures that are removed for inspection or maintenance purposes as soon as the work is completed (Document ID 0889, pp. 12-13; 0890, p. 14-15; 0891, pp. 3, 11; 1377, pp. 15-16). OSHA made similar recommendations for controlling the exposure of workers performing similar duties at a facility where airborne clay dust was prevalent (Document ID 0108, pp. 7, 45, 47).

Non-routine Tasks

Comments submitted to the docket regarding the feasibility of engineering controls in the asphalt roofing materials sector related to non-routine tasks and compliance deadlines. Mr. Ferraro of the ARMA described areas of a plant where "workers are not routinely present," that are entered only occasionally for activities "such as housekeeping during extended scheduled maintenance down time * * * once or twice a year" (Document ID 2291, pp. 17-18). The Agency has acknowledged that respiratory protection is appropriately used for short-term intermittent activities such as maintenance tasks where it is not feasible to implement permanent engineering solutions.

4.2.4 Feasibility Finding

Comments on Feasibility

Except for comments on the infeasibility of using wet methods near the hot asphalt coater and HEPA-filtered vacuuming in certain areas with limited access, there were no industry comments that it was technologically infeasible to reduce exposure levels below the PEL for most operations, most of the time (Document ID 2291, pp. 13, 14, and *passim*). ARMA stated that it was infeasible to implement controls that would assure that exposures did not exceed the PEL 100 percent of the time (or with a 95 percent certainty), and that OSHA had not therefore demonstrated that the standard's requirements of engineering and administrative controls were technologically feasible (Document ID 2291, pp. 5-15, 27, and *passim*).

As reflected in Section IV-1 – Introduction: Technological Feasibility of this FEA, courts do not require OSHA to demonstrate that an employer can comply 95 percent of the time or with a 95 percent certainty to show that the requirements are feasible. Based on careful reading of the studies and inspection documents, it appears that the causes for exposures above the PEL are predictable and that there will be few to no instances where an employee will be exposed above the PEL if the employer has implemented adequate engineering and administrative controls for normal manufacturing operations, including LEV, hopper and process enclosures, general ventilation, and regular housekeeping using methods that do not re-suspend settled dust.

Nevertheless, the ARMA exposure data indicate that the PEL is feasible for routine operations in asphalt roofing manufacture because 91 percent of the sample results associated with routine operations were below 50 μg/m^3 TWA.

Ms. Peg Seminario of the AFL-CIO supported this conclusion, stating:

> [T]he exposure information provided by the ARMA shows that the mean exposure in all but one of the jobs in routine manufacturing in that industry are already below the proposed 50 μg/m^3 exposure level (Document ID 2291, p. B-4, Table B-2). The information also shows that 91 percent of the samples in these jobs were below 50 μg/m^3, with a median exposure less than 15 μg/m^3 (Document ID 4204, p. 29).

Feasibility Finding for Production Operators

Based on the exposure profiles in Tables IV.4.2-B and IV.4.2-C and other record evidence discussed above, OSHA estimates that the current exposure level for most production operators is below 50 μg/m^3. This finding is based on information presented in Table IV.4.2-B indicating that 60 percent of these workers had exposure levels of 29 μg/m^3 or below during the 1970s. In light of the German and ARMA data, OSHA estimates that approximately 20 percent of production operators may require additional controls to reduce exposures to 50 μg/m^3 or less, as shown in Table IV.4.2-C. In those instances where elevated exposure might occur, silica levels can be reduced to 50 μg/m^3 or less through the use of adequate LEV, process enclosures, and the use of low dust producing cleaning methods such as HEPA-filtered vacuuming. As discussed above, other industries with similar dust producing processes have been shown to achieve dust levels below the PEL where process equipment is enclosed and ventilated (Document ID 1436, pp. 1, 27, 28-29; 0143, pp. 128, 130-131).

Feasibility Finding for Material Handlers

Based on the exposure profiles in Tables IV.4.2-B and IV.4.2-C and other record evidence discussed above, OSHA concludes that the PEL of 50 μg/m^3 is feasible for material handlers. Approximately 28.6 percent of material handlers already had exposures below 50 μg/m^3 in the 1970s, as shown in Table IV.4.2-B. However, as shown the revised profile in Table IV.4.2-C, OSHA estimates that currently only approximately 36 percent of material handlers may require additional controls to reduce exposures to 50 μg/m^3 or less. Control options include properly enclosed, ventilated, and maintained mineral handling systems and the use of low dust-producing cleaning methods such as HEPA-filtered vacuuming. Although OSHA does not have data demonstrating the effectiveness of engineering controls in the asphalt roofing materials industry, as discussed above, other industries with similar dust producing processes, have been shown to achieve dust levels below the PEL where process equipment is enclosed and ventilated. As NIOSH has stressed and is obvious, preventive maintenance at asphalt roofing materials facilities is necessary to ensure that exposure control systems function properly and are effective (Document ID 0837, p. 26).

Overall Feasibility Finding for Asphalt Roofing Materials Manufacturers

Based on the exposure profiles in Tables IV.4.2-B and IV.4.2-C and other record evidence discussed above, OSHA believes that in the United States exposure levels in this industry have declined since the 1970s, when data used in the exposure profile were obtained by NIOSH, and therefore, the exposure profile (Table IV.4.2-B) likely overestimates current exposures in the asphalt roofing materials industry. Exposure monitoring data submitted to the record by the ARMA indicate that among the facilities that are members of their organization, 91 percent of production operators and 85 percent of material handlers already have exposures below 50 μg/m^3. In Table IV.4.2-C, OSHA presents revised estimates of the distribution of exposures in the asphalt roofing materials manufacturing sector, which lowers the preliminary exposure profile results by 50 percent. In summary, OSHA concludes that most asphalt roofing materials manufacturing facilities currently achieve exposure levels of 50 μg/m^3 or less in most operations most of the time. Accordingly, OSHA finds a PEL of 50 μg/m^3 is technologically feasible for the Asphalt Roofing Materials industry.

4.3 CONCRETE PRODUCTS

4.3.1 Description

Silica-containing materials are the main ingredients in the manufacture of concrete products, such as blocks, bricks, tanks, pipes, and dry mixes. Facilities manufacturing concrete products are classified in six-digit North American Industry Classification System (NAICS) codes 327331, Concrete Block and Brick Manufacturing; 327332, Concrete Pipe Manufacturing; 327390, Other Concrete Product Manufacturing; and 327999, All Other Miscellaneous Nonmetallic Mineral Product Manufacturing. OSHA has grouped together facilities in these industries based on the similarity of raw materials, processes, and worker activities associated with potential silica exposure. A similar industry, NAICS 327320 – Ready-Mix Concrete Manufacturing, differs from those addressed here in many of the processes and job categories associated with silica exposure, and thus OSHA has created a separate section for it (see Section IV-4.17 – Ready-Mix Concrete).

OSHA reviewed the available NIOSH studies, OSHA Special Emphasis Program (SEP) reports, hearing testimony and information submitted to the rule making record, to identify job categories in the concrete industry with the potential for exposure to crystalline silica. OSHA has determined that workers in all phases of the production of concrete products have the potential for silica exposure. Industry agrees with this determination. Robert Thomas of the National Concrete Masonry Association (NCMA) commented that "the manufacturing of concrete products inherently exposes employees to respirable crystalline silica as this material is present in all phases of the operation" (Document ID 2279, p. 3).

Concrete products are typically made by mixing cement, usually Portland cement made from calcined lime and clay, with sand, and aggregate materials (such as gravel or crushed stone) with water in varying proportions depending on the final product (NIOSH, 1984 as cited in Document ID 1365, p. 5-2). Cement does not contain silica, so the crystalline silica content of concrete will vary based on the amount of sand and aggregate mixed into the product. The mixed concrete is poured into forms or molding machines.

The formed products are then allowed to harden (cure), and the forms are removed.[11] Certain products are finished by sawing, grinding, drilling, or abrasive blasting. Dry-mixed concrete is normally produced by drying the raw materials (cement, sand, and aggregate), mixing the dried materials, and then packaging the dry mixture (Document ID 1365, p. 5-2; 0602).

The primary job categories with potential for exposure are: material handler, mixer operator, forming operator, finishing operator, and packaging operator. Certain workers regularly perform tasks associated with multiple job categories. Table IV.4.3-A presents a summary of the primary activities associated with silica exposure of workers in each job category.

Material Handler

As discussed below in Section IV-4.3.2 – Exposure Profile and Baseline Conditions, material handlers oversee the transfer of raw materials such as cement, sand, and aggregate to on-site storage locations. Facilities typically receive raw materials by railcar or bulk truck. At some facilities, material handlers operate pneumatic conveyors that transfer raw materials into storage silos. At other facilities, raw materials are dumped into outdoor piles, and material handlers use front-end loaders to transfer materials to storage silos or bins. Material handlers may also use forklifts to transport bagged raw materials. After forming and curing, material handlers use lift trucks to transport products to finishing lines, storage areas, and shipping areas. Material handlers may transfer products by manually placing them onto conveyors. At some facilities, material handlers manually stack and palletize products (Document ID 1365, p. 5-3; 0039; 0220; 0236).

Mixer Operator

Mixer operators oversee the weighing and transfer of raw materials and water (if required) to concrete mixers. Batching and mixing operations are typically automated and do not require mixer operators to handle raw materials. At some facilities, however,

[11] "Curing" is the term for the chemical reaction that causes hardening of cement-based materials, such as concrete. Within hours of casting, most concrete products become firm enough to handle without the mold, but it can take days or weeks for the concrete to reach its full strength. "Uncured" concrete has recently become firm, but has not yet completed the hardening process (Document ID 1720, p. IV-68).

mixer operators may manually weigh and transfer ingredients, such as silica sand, into mixers by shoveling or emptying bags into mixer hoppers. Mixer operators typically operate mixers using control panels adjacent to the mixer or in isolated control booths. Mixer operators also clean mixers daily. Typically, they are cleaned immediately following each production run while the concrete residue is still wet. Mixer operators spray mixer interiors with high-pressure water hoses, rotate the mixers with the wash water inside, and then pour the water out. However, sometimes the operator has to enter the mixers to manually hammer or chip away dried concrete deposits (Concrete Product Industry Representative A, 2000, as cited in Document ID 1365, pp. 5-3 – 5-4).

Forming Operator

Forming line operators transfer the mixed concrete into forms or automatic molding machines that shape the mixture. Depending on the facility, forming line operators pour wet concrete into forms manually or by operating computer-controlled equipment. At some facilities, forming line operators use trowels or other hand tools to ensure that the concrete has completely filled the forms. After products have set sufficiently, forming line operators remove the forms. Forms are typically removed manually. Depending on the facility and product, forming line operators remove forms while products are still wet or after they have cured. After removing forms, forming line operators clean the forms by removing any concrete residue. Sometimes, forming line operators might be required to manually hammer or chip away deposits of dried concrete. More typically, workers clean forms by scraping off the concrete residue while still wet and then spraying with water (Concrete Product Industry Representative A, 2000, as cited in Document ID 1365, p. 5-4).

Finishing Operator

After forming, finishing operators perform various processes such as grinding, patching, coring, drilling, sanding, blasting, and sawing of concrete products. Finishing operators perform these tasks to enhance product appearance, to cut or drill products to required specifications, and to repair defects. Finishing activities are most frequently associated with architectural product facilities (Concrete Products Industry Representative A, 2000 as cited in Document ID 1365, p. 5-4). However, OSHA SEP, NIOSH reports, and industry contacts indicate that at least some finishing processes (grinding, chipping, and coring) are performed at approximately two-thirds of the facilities making concrete blocks and bricks (NAICS 327331), but at only a few establishments in the other concrete industries (NAICS 327332, 327390, and 327999). Although finishing operators typically work on cured products, an increasing number of facilities have altered their processes so finishing operators are working on uncured (still wet) products. Finishing operators usually use manually-operated dry tools, such as handheld grinders. Automated equipment, such as enclosed grinding machines, is sometimes used for repetitive finishing tasks, such as finishing the faces of blocks. Finishing work with automated equipment often uses wet processes or LEV (Document ID 1365, p. 5-5; 0039; 0603; 0606). For patching products, finishing operators manually mix small batches of concrete in buckets and apply concrete by hand. Finishing operators may also perform abrasive blasting, typically outdoors (Document ID 1365, p. 5-5; 0055; 0898). The increasing popularity of retarders (which slow curing and allow the outer layer of concrete to be removed by brushing or pressure washing) is rapidly reducing the need for abrasive blasting in this industry (Concrete Products Industry Representative A, 2000, as cited in Document ID 1365, p. 5-5). While abrasive blasting is normally an activity performed by the finishing operator, OSHA is handling this activity separately to more accurately describe the exposure profile and additional controls.

Packaging Operator

Packaging operators transfer dry, powdered concrete mix into bags or boxes at facilities producing dry-mixed concrete products. At some facilities, packaging operators might operate bagging equipment requiring them to manually position empty bags against fill nozzles that dispense dry concrete mix in the bags, which the machine then seals. Some bagging machines automatically discharge filled bags to a conveyor, but others require manual removal of filled bags. To package dry-mixed concrete in super sacks, packaging operators may use forklifts to hold the super sacks in place while being filled. Packaging operators may also handle filled bags during manual stacking or palletizing tasks (Document ID 1365, p. 5-5; 0602; 0604).

Table IV.4.3-A Job Categories, Major Activities, and Sources of Exposure of Workers in the Concrete Products Industry (NAICS 327331, 327332, 327390, 327999)	
Job Category*	**Major Activities and Sources of Exposure**
Material Handler	Transferring silica-containing raw materials from storage silos to weigh hoppers via front-end loader; transferring product via fork lift or travel lift; manually stacking and palletizing product. • Dust generated during transfer and dumping of raw material. • Dust resuspended by heavy equipment operations. • Dust from adjacent operations.
Mixer Operator	Weighing and transferring silica-containing raw materials into mixing machines; operating and cleaning mixing machines. • Dust generated during manual weighing and ingredient transfer. • Dust generated during manual cleaning of mixers, especially dried concrete deposits.
Forming Operator	Transferring concrete into forms or molding machines manually or automatically; removing formed products; preparing and cleaning forms. • Dust generated while removing forms from cast product and during cleaning of forms, especially dried concrete deposits. • Dust from adjacent operations.
Finishing Operator: Abrasive Blasting	Abrasive blasting on cured products. • Dust from silica abrasive blasting media and concrete surface being abrasively blasted.
Finishing Operator (Other than Abrasive blasting)	Grinding, chipping, coring, sawing, patching, or sanding on formed products. • Dust generated during finishing activities on cured products.
Packaging Operator	Packaging dry, powdered concrete mixture. • Dust released at bag nozzle. • Dust in air displaced during filling or expelled when the bag is released from filling nozzle and drops to conveyor. • Dust from bags breaking.
*Job categories are intended to represent job functions; actual job titles might differ and responsibilities might be allocated differently, depending on the facility. Source: Document ID 1365, pp. 5-2 – 5-17.	

Table IV.4.3-B summarizes the available exposure information for the affected job categories. For each of the job categories listed in Table IV.4.3-B and included in the exposure profile and for the concrete products industry as a whole, OSHA concludes that Table IV.4.3-B represents baseline conditions.

4.3.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.3-B includes 219 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for workers in concrete products industry. The median is 15 μg/m^3, the mean is 219 μg/m^3, and the range is 10 μg/m^3 (limit of detection (LOD)) to 26,826 μg/m^3. Table IV.4.3-B shows that, of the 219 samples, 57 are above 50 μg/m^3 and 36 exceed 100 μg/m^3. To assess current exposure levels and develop the exposure profile for workers in concrete product manufacturing facilities, OSHA reviewed exposure monitoring data from 17 OSHA SEP inspection reports, five NIOSH case studies of concrete manufacturing, one contractor site visit, and two articles in the published literature. The facilities covered by these inspections, case studies, and articles produced a wide variety of concrete products ranging from precast concrete wall cladding and decorative concrete architectural elements, to water pipes and sacks of dry concrete and mortar mixes. OSHA restricted its analysis to observations obtained for workers performing single, well-defined tasks during the sampling period, thereby permitting a better characterization of the exposures associated with each job category. Based on a comprehensive review of the available information, OSHA identified a total of 144 TWA exposures measurements covering six job categories that were presented in the PEA.

Following the publication of the PEA, OSHA reviewed the compliance monitoring data from its OIS system for air sampling data. An additional 90 measurements taken in the concrete products industry between 2011 and 2014 were identified, but 15 were not included in the exposure profile due to insufficient information.[12] The remaining 75 measurements were added to the exposure profile, increasing the number of exposure measurements available for the exposure profile to a total of 219. These measurement results are summarized by job title in Table IV.4.3-B.

Exposure Profile and Baseline Conditions for Material Handlers

The exposure profile in Table IV.4.3-B includes 46 sample results for material handlers in the concrete products industry. The median is 21 μg/m^3, the mean is 62 μg/m^3, and the range is 11 μg/m^3 (limit of detection (LOD)) to 620 μg/m^3. Table IV.4.3-B shows that, of the 46 samples, 12 (26 percent) are above 50 μg/m^3 and 6 (13 percent) exceed 100 μg/m^3.

All of the sample readings for material handlers exceeding 50 μg/m^3 were obtained in facilities where the majority of exposure readings for workers in all job categories also

[12] The 15 sample results that were excluded: Document ID 3958, Rows 426, 427, 429, 430, 432, 436, 438, 477, 479, 495, 596, 597, 598, 605, and 606.

exceeded 50 μg/m^3, suggesting poor dust control throughout these facilities. For example, OSHA obtained a sample of 116 μg/m^3 for a material handler who operated a forklift to transport cast concrete products between various surface finishing stations at a facility that manufactured precast concrete siding. The report indicated that dust generated by various other processes in the facility was a contributing factor (Document ID 1365, p. 5-9; 0039). This conclusion was supported by the fact that 9 of the 10 samples collected for workers in four job categories at the facility also exceeded 100 μg/m^3. The OSHA inspector noted that there were leaks in the silo bin chute as well as some controls were not being fully utilized. These circumstances suggest that material handlers at some facilities experience elevated silica exposure simply from passing through or working in areas where other workers' activities generate high concentrations of silica. If dust from these activities is permitted to accumulate, silica particles resuspended in the air by passing forklifts can exacerbate the situation. The exposures for this industry also suggest that when dust is controlled for all job categories, material handler exposure levels are also reduced. In fact, most of the concrete products industry material handler exposure readings below 50 μg/m^3 were obtained in facilities where the majority of exposure values for workers in all job categories also were less than 50 μg/m^3.

At another concrete products facility, four samples for two material handlers evaluated on two consecutive days resulted in values of 48 μg/m^3, 54 μg/m^3, 57 μg/m^3, and 73 μg/m^3. The workers inspected and prepared to palletize concrete blocks exiting an automated de-hacking machine used to unload blocks from a curing kiln and also performed a variety of other tasks, which included dry sweeping (Document ID 0220, p. 6). During the evaluation, NIOSH noted that "most of the facility has 1/8-inch dust on the floor." The investigators concluded that the dry sweeping might have had a notable effect on worker exposure and that as an alternative the facility could eliminate dry sweeping by switching to either a centralized or portable High-Efficiency Particulate Air (HEPA)-filtered vacuum system.

Although the exposure of many material handlers appears to have been influenced by the activities of other job categories, in a few cases material handlers were performing tasks that generated substantial dust. The two highest sample results available to OSHA for this job category, 610 μg/m^3 and 620 μg/m^3, were obtained in a packaging area with ineffective ventilation where one material handler palletized sacks of dry concrete mix and the other used a front-end loader to transfer sand to a hopper feeding the dry mix blending equipment (Document ID 0013, pp. 95, 97). Exposures of 60 μg/m^3 (palletizing job) and 193 μg/m^3 (loader operator moving sand and gravel) were observed in the same part of the plant the previous year (the report provides no explanation for the difference in exposure levels from one year to the next). OSHA did note that forced-air jets, intended to slightly levitate 80-pound sacks of dry mix concrete as the worker slid the sacks off the conveyor, blew dust (emitted from the bags during the transfer) into the workers' breathing zone. These samples comprise three of the four values above 100 μg/m^3 (among a total of 45 results for this job category), indicating that most material handlers at other concrete product facilities work under less extreme conditions. Brian Ogle with Nation Shale commented that "[i]n the packaging end, the finished product, we don't have any problem. The local exhaust ventilation normally suffices" (Document ID 3586, Tr. 3450). In this facility, however, both material handlers and packaging operators contributed to the substantial airborne silica in the area, where the material handlers were usually the most highly exposed workers (Document ID 0013, pp. 7, 36-60).[13]

For material handlers operating in outdoor work areas and product storage yards, thirteen results (42 percent) are associated with some variety of yard maintenance to control dust (not necessarily effectively), including the use of water spray, dust suppressants, crushed aggregate ground cover, or regular power-sweeping of paved surface. These results range from 11 μg/m^3 to 110 μg/m^3 and have a median of 24 μg/m^3 and a mean of 34 μg/m^3. The highest of these outdoor readings, 110 μg/m^3, is associated with a yard that had been previously watered but let dry. Other watered yards (presumably not dried) and yards using a dust suppressant are associated with very low exposure readings, including five

[13] The packaging operator working in the same area also had elevated exposures (370 μg/m^3 and 142 μg/m^3 in the two respective years) (Document ID 0013).

readings at or below the LOD and one reading of 21 µg/m^3.[14] (Document ID 0087, p. 258; 0220, p. 7-8; 0234, pp. 5-6; 0236, p. 7-9; 0898, p. 7-8).

OSHA has determined that the baseline conditions are best represented by the range of working conditions associated with the use of some engineering controls (e.g., LEV or wetting) that may not be operating optimally. The results are summarized in Table IV.4.3-B. Therefore, OSHA concludes that the median value for all material handlers (21 µg/m^3), shown in Table IV.4.3-B, is also the median baseline value.

Exposure Profile and Baseline Conditions for Mixer Operators

The exposure profile in Table IV.4.3-B includes 35 sample results for mixer operators in the concrete products industry. The median is 12 µg/m^3, the mean is 40 µg/m^3, and the range is 10 µg/m^3 (limit of detection (LOD)) to 281 µg/m^3. Table IV.4.3-B shows that, of the 35 samples, 7 (20 percent) are above 50 µg/m^3 and 6 (17.2 percent) exceed 100 µg/m^3. Two of the highest readings, 281 µg/m^3 and 122 µg/m^3, were obtained for mixer operators who cleaned the interior of a concrete mixer using handheld jackhammers to chip dried concrete residue (Document ID 0067, pp. 159-160). Other elevated readings – 134 µg/m^3, 108 µg/m^3, and 107 µg/m^3 – were obtained for operators manually dumping bags of silica-containing materials at hoppers equipped with ineffective LEV systems (Document ID 1365, pp. 5-10 – 5-11; 0039).

Several low sample readings were taken on operators controlling enclosed mixers from ventilated control rooms. One low exposure result, 24 µg/m^3, is for an operator who used a pneumatic chipping hammer and a compressed air wand to remove dried concrete from the interior of the mixer (Document ID 0898, pp. 12, 15). This result, along with the two high exposure levels described in the previous paragraph, indicates a wide variability in exposure for operators removing concrete from mixing drums, possibly due to variations

[14] Exposures reported as “none detected” are assigned a value equal to the LOD. The LOD is determined individually for each sample based on the volume of air sampled and the method used to analyze the sample, therefore, the limit of detection varies between samples. See Section IV-2–Methodology.

in work practices, the amount of concrete being removed, and the amount of time spent on the task (a function of how frequently cleaning is performed).

Information from industry contacts suggests that common controls for mixer operators include enclosed mixers, automated weighing and charging or loading of raw materials into the mixing equipment, and wet methods to clean mixing equipment. Facilities in this industry commonly use at least one of these controls, but no single control is consistently used throughout the industry (i.e., the baseline condition includes use of any one of several controls). Examples of exposures associated with these conditions include 12 μg/m^3, 24 μg/m^3, and 25 μg/m^3 (Document ID 0236, p. 11; 0898, p. 15). Mixer operators at some facilities, however, continue to manually charge mixers and clean mixing equipment using dry methods, yielding higher exposure levels (Document ID 1365, p. 5-16; 0039; 0067; 0898).

OSHA has determined that the baseline conditions for this job category are best represented by the wide range of exposure situations under which exposures summarized in Table IV.4.3-B were obtained. Thus, the median value for mixer operators in the Table IV.4.3-B exposure profile (12 μg/m^3) represents the median value for this job category under baseline conditions.

Exposure Profile and Baseline Conditions for Forming Operators

The exposure profile in Table IV.4.3-B includes 65 sample results for forming operators in the concrete products industry. The median is 13 μg/m^3, the mean is 20 μg/m^3, and the range is 11 μg/m^3 (limit of detection (LOD)) to 107 μg/m^3. Table IV.4.3-B shows that, of the 65 samples, 5 (7.7 percent) are above 50 μg/m^3 and 1 (1.5 percent) exceeds 100 μg/m^3.

The highest sample reading, 107 μg/m^3, was associated with a forming operator removing concrete siding from forms and palletizing it at an unventilated workstation. At this facility, 9 of 10 respirable silica readings for workers in four job categories exceeded 100 μg/m^3, indicating poor control of silica throughout (Document ID 1365, p. 5-11; 0039). This was confirmed by the OSHA inspector, who noted that there were leaks in the silo bin chute as well as some controls were not being fully utilized. OSHA notes that secondary exposure from activities of other workers most likely contributed to the silica exposure of this forming operator.

Other samples in excess of 50 μg/m^3 were associated with similar, widespread dust control problems (Document ID 0220, pp. 6, 10). Two such samples were obtained at a facility for a worker controlling a concrete block-making machine. The worker stood near activities which generated high volumes of dust, including a block making machine that generated dust and dry sweeping activities. Additionally, this worker was 20 feet from a mixing machine, which emitted dust during hopper loading (Document ID 1365, p. 5-12; 0220, p. 8).

In contrast, facilities that properly implemented dust controls had lower exposures. Among the lowest exposure results are six readings, ranging from less than or equal to 12 μg/m^3 (LOD) to less than or equal to 14 μg/m^3 (LOD), which were obtained for four operators at a facility visited by NIOSH. Three of the operators formed concrete products using computer-controlled molding machines. The operators used water spray, shovels, and mold vibrators to evenly distribute the wet concrete in the molds. The fourth operator manually assembled forms and then cleaned them by brushing and grinding (Document ID 1365, p. 5-12; 0234).

Based on OSHA SEP and NIOSH reports and discussions with concrete product manufacturers, OSHA finds that current or baseline conditions for forming operators involve the same range of working conditions represented by the results for this job category summarized in Table IV.4.3-B, all of which were below the detectible limit.

Exposure Profile and Baseline Conditions for Finishing Operators (Abrasive Blasting)

The exposure profile in Table IV.4.3-B includes 17 sample results for finishing operators (Abrasive Blasting) in the concrete products industry. The median is 126 μg/m^3, the mean is 2,227 μg/m^3, and the range is 10 μg/m^3 limit of detection (LOD) to 26,826 μg/m^3. Table IV.4.3-B shows that, of the 17 samples, 14 (82.3 percent) are above 50 μg/m^3 and 10 (58.8 percent) exceed 100 μg/m^3.

These values, much higher than other job categories, are based on 17 samples for abrasive blasters in this concrete products industry reported by OSHA, NIOSH, and the OSHA contractor ERG (Document ID 0011, p. 40; 0012, pp. 145-147; 0053, pp. 128, 130; 0055, pp. 128, 144, 155; 0204, p. 18; 0733, p. 26; 0898, p. 15; 3958, Rows 306, 366). 82.3 percent of the abrasive blaster results exceed 50 μg/m^3. These samples are in the same range as other similar abrasive blasting operations (see Section IV-5.1 – Abrasive Blasting).

The three highest sample readings (26,826 μg/m^3, 6,482 μg/m^3, and 2,303 μg/m^3) were obtained at two facilities, where operators performed abrasive blasting of concrete panels in unenclosed, outdoor workstations.[15] The operators at both facilities used silica sand blast media containing 87 percent to 99.9 percent quartz, according to the media manufacturer's material safety data sheets (Document ID 1365, p. 5-13; 0012; 0053). Among the workers performing abrasive blasting, some of the lowest samples were associated with outdoor blasting on concrete panels using coal slag blast media[16] (20 μg/m^3, 30 μg/m^3, and 54 μg/m^3), although values as high as 473 μg/m^3 were also reported (Document ID 1365, p. 5-14; 0011; 0055; 0204, p. 18). Results of 10 μg/m^3 and 154 μg/m^3 were obtained at a facility using silica sand blasting media with a dust suppressant additive (Document ID 1365, p. 5-14; 0898). A study described by Heitbrink (2007) used silica sand media with less than 3 percent fines[17] by weight (screened with 100-mesh) in conjunction with a water induction nozzle using water at a rate of 13 pounds per minute (approximately 1.5 gallons per minute). The wet abrasive blasting was performed outdoors and exposed the underlying aggregate of precast concrete building

[15] OSHA's requirements for respirators and exhaust ventilation for abrasive blasting are codified at 29 CFR §§ 1910.94 – Ventilation for general industry and 1910.134 – Respiratory Protection. During abrasive blasting, airline helmet-style respirators would be required under 29 CFR § 1910.94.

[16] Coal slag is a low-silica abrasive blasting media, but may contain other toxic materials such as toxic metals.

[17] "Fines" is a general term referring to very small particles in a mixture of varying sizes. A 100-mesh screen is defined as having 100 openings per linear inch, meaning that the screen openings are 149 microns in size and will separate out particles of smaller size (Document ID 1720, p. IV-75).

panels. Under these working conditions, the investigator obtained two full-shift silica exposures of 75 μg/m^3 and 124 μg/m^3 (Document ID 0733, p. 26).

Manual abrasive blasting of concrete products is most often conducted outdoors as a dry process; however, as indicated previously in this section, some concrete product manufacturers are attempting alternate methods such as retarders, which slow the rate of curing and therefore minimize the need for abrasive blasting altogether. OSHA has determined that there are a variety of working conditions ranging from no or minimum controls to the use of alternate media and/or engineering controls such as wet methods or dust suppressants. OSHA finds that the samples summarized for finishing operators (abrasive blasting) in Table IV.4.3-B best describe the baseline conditions for all abrasive blasting operators in this industry. Thus, the median value for this job category shown in Table IV.4.3-B (126 μg/m^3) also represents the median baseline silica exposure level for abrasive blasting operators.

Exposure Profile and Baseline Conditions for Finishing Operators (Other Than Abrasive Blasting)

The exposure profile in Table IV.4.3-B includes 50 sample results for finishing operators (Other than Abrasive Blasting) in the concrete products industry. The median is 19 μg/m^3, the mean is 78 μg/m^3, and the range is 11 μg/m^3 limit of detection (LOD) to 660 μg/m^3. Table IV.4.3-B shows that, of the 50 samples, 15 (30 percent) are above 50 μg/m^3 and 11 (22 percent) exceed 100 μg/m^3.

Elevated exposures for workers performing finishing activities other than abrasive blasting are associated with workers using poorly controlled processes or general dust control issues. For example, at one facility, surfacing machines were associated with results of 210 μg/m^3, 240 μg/m^3, 281 μg/m^3, and 318 μg/m^3, and a punch press operator experienced an exposure of 96 μg/m^3 (Document ID 1365, p. 5-14; 0039, pp. 80, 86, 93, 99, 155).[18] Even though the punch press and surfacing machines were all equipped with LEV, the OSHA inspector attributed the elevated sample results to inadequate LEV on

[18] The surfacing machine action is not specified but presumably involves automated grinding to level the surface or modify texture based on the job description of feeding and removing boards (Document ID 0110, p. 24).

the surface grinders and to dust which entered the punch press workstation through holes in the floor (Document ID 0039, pp. 151-153). Ninety percent of the exposure readings taken were above 100 μg/m^3 indicating a general problem with dust control throughout the facility (Document ID 0039, pp. 23-26). High exposures were also experienced at another facility where workers using handheld power tools to grind concrete panels had results of 308 μg/m^3 and 69 μg/m^3 and an exposure level of 347 μg/m^3 was recorded for a finishing operator performing patching of finished panels in the sandblasting area (Document ID 1365, p. 5-14; 0067, pp. 119, 129, 135). OSHA noted during the inspection that abrasive blasting had occurred on the day the sample was taken (Document ID 1365, p. 5-14; 0067, pp. 119, 129, 135).

Some of the lowest exposures for hand tool workers include two exposure readings of less than or equal to 12 μg/m^3 (LOD) for finishing operators who cut or scored uncured precast concrete products. This cutting was performed using non-powered hand tools while the "zero-slump" concrete was still wet, thus eliminating the need for power tools, which are required after the concrete has dried (Document ID 1365, p. 5-14; 0234). Zero-slump concrete lacks any fluidity and retains its shape prior to curing, thus enabling finishing operations to be performed on still-damp concrete. At this site, none of the 17 results for three of the other job categories exceeded 21 μg/m^3, indicating that dust was well controlled throughout the facility (Document ID 0234).

Activities and associated conditions vary greatly for finishing operators. Based on a review of OSHA SEP and NIOSH reports, OSHA has determined that baseline conditions for manual finishing operations involve outdoor, dry work performed on cured concrete, while automated finishing operations are typically conducted indoors with some form of control such as wet methods or LEV. Nevertheless, OSHA has determined that together the various working conditions represented by data summarized for finishing operators in Table IV.4.3-B best describe the baseline conditions for all finishing operators in this industry. Thus, the median value for this job category shown in Table IV.4.3-B (19 μg/m^3) represents baseline silica exposures level for finishing operators.

Exposure Profile and Baseline Conditions for Packaging Operators

The exposure profile in Table IV.4.3-B includes 6 sample results for packaging operators in the concrete products industry. The median is 84 µg/m^3, the mean is 117 µg/m^3, and the range is 11 µg/m^3 (limit of detection (LOD)) to 370 µg/m^3. Table IV.4.3-B shows that, of the 6 samples, 4 (66.7 percent) are above 50 µg/m^3 and 2 (33.4 percent) exceed 100 µg/m^3.

These six readings for packaging operators were obtained from four OSHA SEP inspection reports for facilities where workers used bag-packing machines to fill sacks with dry concrete mix (Document ID 1365, p. 5-15; 0013; 0073; 0126; 0158).

The two highest sample readings were obtained for packaging operators at a facility inspected by OSHA. OSHA obtained a sample reading of 142 µg/m^3 for a worker who used a bag-filling machine to load 80-pound bags of dry-mix concrete, with general exhaust ventilation fans located near the workstation. After the inspection, the facility installed an LEV system for the packaging operation, but an industrial hygiene consultant later obtained a reading of 370 µg/m^3 for the packaging operator even with the new ventilation system in place. The consultant found that the system did not effectively remove dust generated by the packaging operation, but offered no explanation (Document ID 1365, p. 5-15; 0013).[19]

The lowest sample reading for this job category, less than or equal to 11 µg/m^3 (the reported LOD), was obtained for a packaging operator at a facility that had upgraded its dust controls following an OSHA SEP inspection. The facility had improved the LEV system for the packaging operation by relocating hoods closer to the operator's position while filling bags. The facility also had rebuilt the LEV system to generate greater airflow and installed a new filter bag. In addition, daily housekeeping for the workstation had been implemented after the inspection (Document ID 1365, p. 5-15; 0126, p. 10).

[19] The inspection report associates the exposure readings with cement packaging. OSHA, however, described the facility as a concrete packaging plant, and the percentage of quartz (6 percent) found in the sample suggests that the reading is associated with concrete packaging.

Based on the available reports, typical conditions for packaging operators include manual insertion of empty bags into bag-filling machines equipped with LEV; however, the exhaust ventilation systems often are poorly maintained or function inefficiently. Dust is generated when filled bags expel product as they are released from bag-filling machines and when filled bags covered with spilled product are dropped onto conveyors (Document ID 1365, pp. 5-17 – 5-18; 0013; 0073; 0126). OSHA finds that the samples summarized for packaging in Table IV.4.3-B best describe the baseline conditions for all packing operators in this industry. Thus, the median value for this job category shown in Table IV.4.3-B (84 μg/m^3) also represents the median baseline silica exposure level for packaging operators.

Table IV.4.3-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Concrete Products Industry (NAICS 327331, 327332, 327390, 327999)

	Exposure Summary			Exposure Range			Exposure Profile				
Concrete Products Industry	**N**	**Mean ($\mu g/m^3$)**	**Median ($\mu g/m^3$)**	**Min ($\mu g/m^3$)**	**Max ($\mu g/m^3$)**		**< 25 ($\mu g/m^3$)**	**≥ 25 and ≤ 50 ($\mu g/m^3$)**	**> 50 and ≤ 100 ($\mu g/m^3$)**	**> 100 and ≤ 250 ($\mu g/m^3$)**	**> 250 ($\mu g/m^3$)**
Material Handlers	46	62	21	11	620		26 (56.5%)	8 (17.4%)	6 (13%)	4 (8.7%)	2 (4.3%)
Mixer Operators	35	40	12	10	281		26 (74.3%)	2 (5.7%)	1 (2.9%)	5 (14.3%)	1 (2.9%)
Forming Operators	65	20	13	11	107		56 (86.2%)	4 (6.2%)	4 (6.2%)	1 (1.5%)	0 (0%)

4.3.3 Additional Controls

There are many commonly used control methods and work practices that can significantly reduce exposures in this application group. According to Robert Whitmore from the National Precast Concrete Association (NPCA), ongoing efforts to reduce dust at concrete manufacturing plants include:

> wet sawing; water sprays and misting before sweeping concrete dust; dust collectors on tools; and enclosed cabs on equipment. In addition, the [NPCA] SHE Committee supports continuing education among plant personnel on the proper use of respirators and other personal protective equipment (Document ID 2067, p. 2).

Several commenters argued that there have been significant trends in the concrete products industry to reduce exposures to respirable silica including LEV. These systems were initially installed to control the dust associated with charging the mixer with dry cement. However, even with investing in the use of LEV, there can still be significant exposures for some operations (Document ID 2114; 2384; 2388; 3300). In the discussion below, OSHA emphasizes that when reducing worker exposures, the employer must minimize exposures from all sources and in many cases will need a combination of controls including LEV, wet methods, and improved housekeeping.

Additional Controls for Material Handlers

The exposure profile in Table IV.4.3-B shows that 26 percent (12 out of 46 samples) of material handlers have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Appropriate control measures include adding or improving LEV at raw material receiving hoppers (particularly in the dry bagged concrete mixing area), making changes to the area where material handlers transfer finished sacks from conveyors onto pallets, suppressing dust in storage yards, and using enclosed cabs on front-end loaders when transferring raw materials where exposures continue to be elevated. Adjacent operations also need to be controlled in order to reduce most material handler exposures. Specifically, changes described later under additional controls for packaging operators (e.g., improved LEV for bag-filling machines and switching to bags designed to emit less dust) will also help reduce the exposure of material handlers who work in the area or eventually handle the same bags.

Local Exhaust Ventilation (LEV)

LEV should be installed to provide appropriate air flow. The American Conference of Governmental Industrial Hygienists (ACGIH) provides design recommendations for ventilated hoppers receiving dusty materials (Document ID 0515). The designs will vary depending on the method the facility uses for loading the hopper. ACGIH recommends a minimum air flow of 150 feet per minute (fpm) across bin and hopper openings for manual loading operations. However, for other loading methods that cause material to enter the hopper in a manner different than manual loading (e.g., using a front-end loader, or during high-speed automated loading operations), ACGIH recommends an air rate of one-and-a-half to two times that minimum air flow rate of 150 fpm. The recommended velocity depends on the material flow rate (a front-end loader adds materials at a much greater material flow rate than manual transfers), dustiness (the material at this site was apparently very dusty), and the height the material falls (influenced by either hopper design or by material handler work practices). Furthermore, ACGIH also recommends that the enclosure be "*large enough to accommodate the 'splash' effect*" that occurs when a load is dumped into the hopper (Document ID 0515, p. 13-78) (italics in original).

Exposure to material handlers who operate front end loaders can be reduced by using a redesigned hopper enclosure of adequate size to accommodate the loader scoop and resulting "splash" effect. Air must be exhausted from the enclosure at a rate commensurate with the material flow rate and dustiness (potentially up to two times the minimum recommended rate of 150 fpm, equal to a rate of 300 fpm across the enclosure opening). Information from the pottery industry indicates that, when material transfer stations have functional LEV, worker exposures are markedly lower (median exposure level 27 $\mu g/m^3$) than when material transfer stations operations are associated with LEV that is clearly inadequate or missing (median exposure level 530 $\mu g/m^3$). Based on the similarity of hoppers, conveyors, and mixing equipment used to blend the similar mineral powders used by both industries, OSHA expects that LEV at material transfer stations in pottery operations would also be effective in the concrete product industry.

Yard Dust Management

Facilities that implemented yard dust management controls show that exposure levels at or below 50 µg/m^3 are achieved in almost all cases (85 percent of the samples). These observations include four readings of less than 21 µg/m^3 for facilities using dust suppressants, two readings of less than 19 µg/m^3 for those that consistently wetted yard dust, a reading of less than 40 µg/m^3 for a facility using an aggregate bed, and four readings of less than 57 µg/m^3 for facilities using power sweeping of a paved yard (Document ID 1365, p. 5-18; 0220; 0234). In contrast, exposures greater than 110 µg/m^3 were observed at a facility where wetted yards were allowed to dry (Document ID 1365, p. 5-18; 0087). Additional support for the application of dust suppressants includes a study by Addo and Sanders (1995) that examined three chemical dust suppressants (lignosulfate, calcium chloride, and magnesium chloride) applied to an unpaved roadway for four and a half months. The study found that compared to an untreated roadway, the suppressants reduced fugitive dust emissions by 50 to 70 percent (Document ID 1720, p. IV-78; 0516, p. 106).

Wet dust suppression methods can also be used to minimize exposure during raw materials transfer. One industry contact reported use of dampened aggregate to minimize dust release as materials are dumped into hoppers (Document ID 1365, p. 5-18; 0605). Although the effectiveness of this control has not been quantified for use in loading operations, other operations in this application group have shown that wetting the material effectively prevents fine particles mixed with the aggregate from becoming airborne (see the discussions below in this section, under the headings Additional Controls for Mixer Operators and Additional Controls for Finishing Operators).

Control of yard dust offers the best results when used in conjunction with other efforts to control silica dust. One facility, for example, controlled exposures through the use of worker training and regularly applied dust suppressants, enclosed equipment, wet methods, and rigorous housekeeping as elements of a comprehensive dust control program. The three exposure readings for the material handlers at this facility were all less than 13 µg/m^3 (Document ID 1365, p. 5-18; 0234).

Improved Housekeeping

Poor housekeeping contributes substantially to worker exposure levels in material handling areas. A thorough initial cleaning to remove dust that has accumulated in combination with improved dust controls and daily housekeeping procedures to maintain cleanliness can reduce exposures in areas where dust has been allowed to accumulate. Exposure levels ranged from 48 to 73 μg/m^3 for concrete product material handlers who performed dry sweeping during their shifts where "most of the facility has 1/8-inch of dust on the floor," which NIOSH indicated could have been a significant source of their exposure (Document ID 0220, pp. 9-10).

In the structural clay industry, another application group with similar material handling requirements, thorough, professional-quality cleaning of a brick manufacturing facility dramatically reduced exposure levels (by 90 percent or more in some cases) for workers in areas where raw materials were transported or handled (raw material storage, near grinding equipment and conveyors, during bag dumping, and at raw material hoppers) (see Section IV-4.21–Structural Clay) (Document ID 1365, p. 3-20; 0571).

Enclosed Operator Cabs

Enclosed operator cabs offer another option for reducing the exposure of material handlers. In the PEA, OSHA estimated that only a quarter of concrete product manufacturing facilities use well-enclosed cabs equipped with air filtration and air conditioning to effectively control exposures of material handlers operating mobile equipment in dusty areas (Document ID 1365, p. 5-18). While there were no specific comments on the percentage of companies using enclosed cabs, several commenters indicated that the use of enclosed cabs was difficult due to communication issues (Document ID 4217, PDF p. 93) while others indicated that they have solved this problem by using mobile devices (Document ID 2262, p. 28). An exposure level of 21 μg/m^3 was obtained at a precast concrete facility for a material handler who used a front-end loader with an air-conditioned cab enclosure to transport raw materials across a water and dust suppressant-treated yard (Document ID 1365, p. 5-19; 0898).

NIOSH recommends several cab design features (enclosed positive-pressured cabs with air conditioning and filtered air supply) and emphasizes the importance of maintenance and cleanliness (Document ID 0839, p. 2). Cabs employing several of these recommended features regularly achieve exposure reductions (inside versus outside the cab) exceeding 90 percent[20] (Document ID 0590, p. 59; 0844, p. 2).

Multiple silica exposure control strategies (e.g., enclosed cab, plus dust suppressant on the ground as described in the example above) can be used simultaneously if a single method is inadequate to reduce the exposure levels.

Additional Controls for Mixer Operators

The exposure profile in Table IV.4.3-B shows that 20.1 percent (7 out of 35 samples) of mixer operators have exposures above the final PEL of 50 µg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for overexposed workers. Operators in the group requiring additional controls experience elevated exposure while performing two activities: chipping residual concrete from mixing barrels and emptying bags of raw materials into the mixer during manual mixer charging.

In the concrete products industry, the chipping activity is usually performed once daily (and at least weekly), typically for brief periods. While these operations may only last for brief periods of time, worker exposure is generally substantial and warrants control. Controls include wet methods for cleaning mixing equipment before residual concrete has dried, as well as use of wet methods and LEV when chipping is required.

Other control measures are necessary when mixer operators are exposed to elevated levels of silica during manual mixer charging and raw material mixing. Use of ventilated bag dumping stations or automated mixer charging, and operator isolation in a control room or booth, can reduce mixer operators' silica exposures to levels below 50 µg/m^3 for these operations.

[20] The Cecala study (Document ID 0590, p. 59) reported reductions in levels of respirable dust between 97.8 to 98.7 percent.

Controls for Chipping Operations

As previously discussed, mixer operators must clean the mixing drum daily. OSHA has determined that the best control for reducing silica dust exposures when cleaning drums is to clean the mixer while the concrete residue is still wet (Document ID 1365, pp. 5-3 – 5-4).

Lynn Burchfield from Acme Brick commented on mixer cleaning. Cleaning normally involves the uses of compressed air and chipping hammers to break free hardened material. This activity generally takes 30 minutes or less. Ms. Burchfield has identified some difficulties associated with recommended controls, such as using water to clean mixers which can create sludge or color contamination on future batches. She also indicated that ventilation and dust collection systems have proven to be problematic. Ms. Burchfield indicated that the peak levels of exposure typically ranged from 25 to 125 $\mu g/m^3$ (Document ID 2023, pp. 3-4). OSHA appreciates the difficulty in implementing controls; however, as discussed below, these difficulties have been overcome in other industries with similar activities with the use of a combination of controls.

OSHA has determined that the chipping activity to clean hardened concrete from in-plant mixing drums is essentially the same task that workers perform to remove hardened concrete from ready-mixed concrete truck drums. As described in Section IV-4.17 – Ready-Mix Concrete, this activity occurs in a more challenging (more enclosed) environment, takes longer (several hours compared to several minutes), and usually involves a notably heavier concrete buildup on the mixer drum walls because, according to the National Ready Mixed Concrete Association, truck drums are typically only cleaned twice per year compared with the daily or weekly cleaning schedule for in-plant mixer barrels (Document ID 0922, p. 9). Therefore, OSHA has determined that work on truck drums represents the worst-case scenario. Based on the similarities between the two processes, OSHA concludes that exposure controls for ready-mixed concrete truck drum cleaning will be at least as effective for cleaning in-plant mixer barrels.

Investigators have found that the following control methods used for ready-mixed concrete truck drum cleaning offer exposure reductions of at least 70 percent compared with uncontrolled levels (typically up to approximately 1,000 μg/m^3).[21] For a more detailed discussion on the engineering controls for controlling worker exposure during ready-mixed truck drum cleaning please see Section IV-4.17 – Ready-Mix Concrete in this technological feasibility analysis.

- *LEV-equipped chipping tool plus general exhaust ventilation:* Silica levels reduced to a mean of 220 μg/m^3 (Document ID 1365, p. 13-22; 0245, p. 12).
- *Water misting device and push/pull ventilation system:* Silica levels reduced to 128 μg/m^3 (Document ID 1157, p. D123).[22]
- *Periodic spraying of the interior surface of the drum and directing continuous water spray at the chisel point during chipping:* Silica levels reduced to "less than the PEL" (100 μg/m^3 or somewhat less, calculated using OSHA's general industry standard for respirable dust containing silica) (Document ID 3732, Attachment 3, pp. 14-16).

In the exposure profile for mixer operators, the two highest sample results are 281 μg/m^3 and 122 μg/m^3 are associated with barrel cleaning. A 70 percent reduction would lower the second highest result to a level of 37 μg/m^3 and reduce all the other results in the mixer operator exposure profile summarized in Table IV.4.3-B to levels less than 37 μg/m^3; only the highest value of 281 μg/m^3 would not be reduced to below the 50 μg/m^3 PEL. OSHA's exposure profile is consistent with industries' experience of typical exposures for mixer cleaning ranging from 25 to 125 μg/m^3 (Document ID 2023, p. 4). OSHA also notes, as discussed above, that it is often a combination of controls including work practices, minimizing the amount of time an employee may spend in a drum, and engineering controls, which could include both LEV and wet methods, that is needed to adequately control exposures (Document ID 1157, p. D123; 3732, Attachment 3, pp. 9-20). However, OSHA also notes that there may be some circumstances where the use of respirators may be necessary for cleaning in-plant mixer barrels.

[21] The exposure levels shown in the bulleted list are for workers who spent at least half of the sampling period (and usually the entire period) chipping concrete from inside truck mixing drums (the worst-case scenario).

[22] The respirable crystalline silica levels were calculated by multiplying the respirable dust concentration (1.69) mg/m^3 by the percent of silica in the sample (7.6 percent): 1.69 mg/m^3 x 0.076 = 128 μg/m^3.

Controls for Mixer Charging

Manual mixer charging is another source of mixer operator exposure in non-automated plants. Control options include ventilated bag dumping stations, automatic mixer charging systems, and operator control booths.

Bag Dumping Stations

Bag dumping stations can potentially control dust generated by bag emptying and disposal. While data from concrete product facilities using ventilated bag dumping stations are not available, a bag dumping station with fully functioning LEV was found to reduce silica exposure by at least 95 percent in a paint manufacturing facility where workers emptied 50-pound bags of silica-containing materials (Document ID 1365, pp. 5-20 – 5-21; 0199). The stations consist of hoppers topped with grates enclosed by LEV hoods. After each bag is emptied, the worker releases it and suction automatically pulls the bag into the ventilation system and transfers it to an enclosed storage area. Ventilated bag dumping and disposal stations are readily available from commercial sources (Document ID 0581; 0594; 0680; 1212; 1224).

Automatic Mixer Charging

Automatic mixer charging equipment reduces operator exposure by allowing the worker to stand at a distance from the mixer while controlling the flow of raw materials into the mixer. Automated systems are widely used in many industries and are readily available from commercial sources (Document ID 0680; 1212; 1224). Exposures of less than or equal to 12 μg/m^3 (the LOD) were reported for a mixer operator using an automated charging system at a precast concrete architectural panel facility (Document ID 1365, p. 5-21; 0204, p. 10-11). An 86 percent reduction in respirable silica exposure readings occurred at a structural clay product facility after a manual bag dumping station was replaced with an enclosed, automated sand transfer system (Document ID 1365, p. 5-21; 0161). Like mixer operators in the concrete products industry, workers in the structural clay industry handle silica-containing dry ingredients (clay, sand, and other ground minerals), which they mix with water to create wet clay to form into products. OSHA expects at least similar reductions in exposures if not greater in this application group, since the structural clay industry workers use a wider range of silica-containing materials, potentially milled to smaller particle sizes. OSHA therefore concludes that control measures that are effective in controlling dust in the structural clay application group will also be effective in the concrete products industry.

Operator Control Booths

When exposures continue to be elevated during automated mixer charging, the charging system controls can be placed in an enclosed operator booth. To effectively control silica exposure, the operator booth must be maintained to exclude dust through tight seals at doors and windows and must provide clean air that keeps the booth under slight positive pressure to help exclude dust. At a structural clay facility visited twice by OSHA, an area sample collected inside a poorly sealed ventilated control room resulted in an average silica concentration of 111 μg/m^3. Before OSHA's next visit, the facility sealed gaps around the main entrance door to the control room. This modification reduced airborne silica levels inside the room to 11 μg/m^3, a 90 percent reduction compared to the earlier sample (Document ID 1365, pp. 3-17 – 3-18; 0161). OSHA notes that low silica levels inside the control room suggest that the room provides a substantial level of protection for any worker inside.

Additional Controls for Forming Operators

The exposure profile in Table IV.4.3-B shows that 7.7 percent (5 out of 65 samples) of forming operators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for overexposed workers. The data summarized in Table IV.4.3-B show that 86 percent of forming operators' exposures are 25 μg/m^3 or less, and 92 percent have exposures of 50 μg/m^3 or less, indicating that routine activities of forming operators do not normally generate silica concentrations that exceed 50 μg/m^3. Controlling adjacent sources of silica dust (e.g., chipping in mixer barrels, finishing processes that are performed near the forming area) will reduce the exposure levels of those few forming operators (10 percent) that have elevated exposures. As noted previously, the highest result (107 μg/m^3) was associated with a worker who emptied and palletized forms at a facility where 9 out of 10 silica results in four job categories exceeded 100 µg/m^3.

In the event that additional controls are needed after adjacent sources of exposure have been controlled, concrete product facilities can improve housekeeping and add LEV to work stations, particularly those stations associated with automated processes. Two of the results between 50 µg/m^3 and 100 µg/m^3 were associated with adjacent sources of exposure and a nearby block making machine that emitted dust (Document ID 1365, pp. 5-11 – 5-12; 0220).

Forming operators can also use cleaning techniques that limit dust released when they clean forms and work areas. HEPA-filtered vacuums used in place of dry brushing or sweeping will minimize worker exposure to silica during these activities. A thorough initial cleaning in conjunction with regularly scheduled housekeeping will help reduce exposure from settled dust that might have accumulated in the work area. Disturbed dust is another likely contributor to the silica exposure for all three of the workers with results above 50 µg/m^3 discussed in the previous paragraphs.

Additional Controls for Finishing Operators (Abrasive Blasting)

The exposure profile in Table IV.4.3-B shows that 82.3 percent (14 out of 17) samples of finishing operators (Abrasive Blasting) have exposures above the final PEL 50 µg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. One alternative to abrasive blasting, surface retarding, can eliminate exposure to silica, while exposing aggregate on concrete surfaces (a primary objective of some abrasive blasting tasks). Other exposure control methods do not reduce silica exposure to the same extent but do provide some benefit. Wet abrasive blasting can suppress dust considerably, provided sufficient water is added to the abrasive media. Additionally, compared to abrasive blasting with silica sand, use of low-silica abrasive blasting media that are less toxic than quartz sand also reduce worker silica exposure. The concrete surfaces that workers abrasively blast contribute to the silica dust released during abrasive blasting, so some exposure can occur even if the media contains no silica (Concrete Product Industry Representative A, 2000; APA, 2000; Master Builders, 2000, as cited in Document ID 1365, pp. 5-23 – 5-24). For a more in-depth discussion of alternatives to abrasive blasting, see Section IV-5.1 – Abrasive Blasters in this technological feasibility analysis, which covers abrasive blasting in the construction industry.

Alternatives to Abrasive Blasting – Surface Retarding

Operators creating certain product finishes can use a surface retarder to inhibit curing and allow an outer layer of concrete to be washed or brushed away as an alternative to abrasive blasting. The chemical retarder applied to the mold for concrete panels allow finishing operators to remove the outer layer of concrete by pressure-washing the surface with water. Use of the retarder reduces the need for abrasive blasting by as much as 40 percent (Document ID 1365, p. 5-23; 0898, p. 9). An industry representative indicated that use of retarders is rapidly becoming the preferred method of finishing concrete (Concrete Products Industry Representative A, 2000, as cited in Document ID 1365, p. 5-5). A wide range of finishes can be achieved using different surface retarder and acid wash products, ranging from the look of exposed aggregate to the appearance of a smooth sand-blasted surface (Concrete Product Industry Representative A, 2000; APA, 2000; Master Builders, 2000, as cited in Document ID 1365, pp. 5-23 – 5-24).

Wet Methods

Wet abrasive blasting and hydro-blasting are effective controls in some situations. During outdoor abrasive blasting of a parking garage to remove the outer layer of cured concrete (e.g., to expose the aggregate), workers using a mix of 80 percent dry sand and 20 percent water had a geometric mean (a mathematical representation of the median) silica exposure of 200 $\mu g/m^3$ (Document ID 0795, pp. D26 – D28). Another facility that produced precast concrete used a water induction nozzle to control silica exposure (Document ID 0733). The nozzle combines water with the abrasive-media-and-air mixture so that atomized liquid droplets are added to the abrasive blasting stream. Operators performed three different activities outdoors: light blasting of wall units to even the color, light blasting of fire stairs to roughen the texture, and heavier blasting of building panels to expose the aggregate. The geometric mean for 10 samples of personal silica exposure was 62 μg/m^3, with a range of 20 μg/m^3 to 130 μg/m^3 (Document ID 0733, pp. 14-15). OSHA notes that in addition to the water nozzle, this facility also used pre-screened silica sand media from which most of the fines had been removed (rendering the new abrasive media less dusty). The author of the study found that restricting the fines content of the sand in combination with wet blasting was effective in reducing silica exposures but the effect of the pre-screened media could not be separated from the effect of the water induction nozzle in this study. Although many exposures reported in Mazzuckelli et al. (2004) and Heitbrink (2007) still exceed the proposed PEL of 50 μg/m^3, they are much lower than the highest exposures reported in the exposure profile for uncontrolled, outdoor abrasive blasting with sand in this industry (e.g., 26,826 μg/m^3, 6,482 μg/m^3, and 2,303 μg/m^3) (Document ID 0012, p. 146; 0053, pp. 128, 130).

While wet methods can substantially reduce worker exposures to silica, they need to be appropriately applied. An OSHA contractor-provided study evaluated wet abrasive blasting at the precast concrete architectural panel manufacturing facility that used coal slag abrasive blasting media (Document ID 0204).[23] Water flow rate measurements showed that the rate of water application (one-half fluid ounce per minute) was less than 2 percent of the amount recommended by the water-fed abrasive blasting nozzle manufacturer (24 ounces to 192 ounces per minute) (Document ID 0204, p. 12).[24] Split-shift results for dry and wet abrasive blasting showed that this low-moisture wet method did not consistently provide lower silica exposure results compared to the same worker performing dry abrasive blasting with the same media, indicating that wet methods were not adequately implemented to reduce exposures.

Another alternative is hydroblasting, which uses high-pressure water without added abrasive media. After reviewing other published and unpublished work, Lahiri et al. (2005) estimated that silica exposure associated with sand blasting can be eliminated by using hydroblasting, even when the surface being hydroblasted contains silica, such as

[23] Results are provided in the paragraphs that follow in the discussion on alternate abrasive blasting media.

[24] The nozzle is fitted with a water hose that provides low pressure tap water. The compressed air and media stream creates negative pressure at the nozzle, which causes water from the hose to be sucked into and distributed through the blast media stream (Document ID 0204, p. 8).

with concrete (Document ID 0776, pp. 505-506). OSHA recognizes, however, that this method cannot replace the use of silica media in abrasive blasting under all circumstances.

Alternate Abrasive Blast Media

Using alternate types of abrasives that are low in silica or silica-free will reduce abrasive blasting operator silica exposure levels but not eliminate exposure when blasting is performed on silica-containing substrates, such as concrete. Outdoor abrasive blasting at two concrete product facilities using silica sand media was associated with exposure readings of 26,826 $\mu g/m^3$, 6,482 $\mu g/m^3$, 2,303 $\mu g/m^3$, 371 $\mu g/m^3$, and 56 $\mu g/m^3$ (Document ID 1365, p. 5-24; 0012; 0053). By contrast, outdoor abrasive blasting at a concrete product facility using coal slag blast grit (a low-silica media mixed with a small amount of water) was associated with exposure readings of 54 $\mu g/m^3$ and 30 $\mu g/m^3$ (Document ID 1365, p. 5-24; 0055). Outdoor abrasive blasting with coal slag media in a strong wind at another facility was associated with a reading of 20 $\mu g/m^3$ (Document ID 1365, p. 5-24; 0011).

At a third facility that produced concrete architectural panels, silica levels of 133 $\mu g/m^3$ (a less-than full-shift sample of 319 minutes), 149 $\mu g/m^3$ and 473 $\mu g/m^3$ were measured during a combination of wet and dry abrasive blasting using coal slag blasting media (Document ID 1365, p. 5-14; 0204, pp. 10, 12-14, 18, and 27). Company exposure data indicated that prior to switching to coal slag media, silica exposure levels during dry abrasive blasting ranged from 430 $\mu g/m^3$ to 5,400 $\mu g/m^3$ with three of four silica results above 2,000 $\mu g/m^3$ (Document ID 0204, pp. 24-25).[25]

Use of a ventilated booth for abrasive blasting of granite monuments (another silica-containing substrate) using alternate low-silica media was associated with a median exposure reading of 51 $\mu g/m^3$ (Document ID 1365, p. 5-24; 0218). Employers will need to consider the possible hazards of abrasive media substitutes when switching from silica to an alternate blast media. For example, depending on the abrasive, alternative media can result in elevated levels of other hazardous air contaminants such as metals

[25] The less-than-full-shift and company-reported results are not included in the exposure profile.

(Document ID 0773, p. 91). For further discussion on abrasive blasting in the construction industry, see Section IV-5.1 – Abrasive Blasters.

Enclosure and Local Exhaust Ventilation

Complete isolation of the operator from the blasting operation (i.e., use of a glove box-type ventilated blasting cabinet) can reduce silica exposure during abrasive blasting of smaller pieces. For example, ventilated blasting cabinets used by three operators in granite sheds (using either silica sand or an alternate media) generated exposure results of 15 µg/m^3 to 77 µg/m^3 with a mean of 41 µg/m^3 (Document ID 1225, pp. 427 - 428). OSHA estimates that exposure levels associated with blasting cabinets can be reduced to levels consistently below 50 µg/m^3 by using silica-free blast media that is less toxic than sand and a combination of other engineering and work practice controls. These controls include enclosed and ventilated media recycling systems, interlocks to prevent operators from opening doors before the cabinet has been exhausted, and use of HEPA-filtered vacuums instead of dry sweeping or compressed air to clean in and around the cabinet. Ventilated abrasive blasting enclosures (booths) also are effective in limiting the exposure of adjacent workers where blasting must be performed. Large, glove box-style cabinets for abrasive blasting oversize or awkwardly shaped objects are available commercially (Document ID 0953; 1693). For example, one manufacturer produces ventilated cabinets that have reportedly been used for abrasive blasting of granite tombstones (Document ID 0953; 1693). This size box is interlocked, to prevent operation unless the unit is sealed, and ventilated at 840 cubic feet per minute (cfm). In addition, the boxes are fitted with a dust collector for high efficiency filtering and a completely enclosed, ventilated media reclamation system. A larger ventilation system will be needed when two or more of these cabinets are linked together to provide a larger internal workspace (Document ID 0953).

Large items that cannot fit in a blast cabinet might be better controlled by another commercially available option: a gauntlet glove panel and window that can be inserted into the wall of a walk-in sized sealed and ventilated abrasive blast booth (Document ID 0954).

Combination of Controls

As noted previously, workers used a combination of wet and dry abrasive blasting methods outdoors with coal slag abrasive blasting media at a facility that produced precast concrete architectural panels. The wet methods, however, used a fraction of the water flow rate recommended by the wet abrasive blasting nozzle manufacturer. Under these conditions, silica levels of 133 μg/m^3 (less-than full-shift sample of 319 minutes), 149 μg/m^3, and 473 μg/m^3 were measured during a combination of wet and dry abrasive blasting using coal slag blasting media (Document ID 1365, p. 5-14; 0204, pp. 10, 12-14, 18, and 27). Based on results reported by Heitbrink (2007), described in the discussion of the exposure profile, OSHA concludes that using a greater flow rate would have resulted in somewhat lower silica levels (Document ID 0733).

Similar results were realized at German concrete products and precast component manufacturing plants where abrasive blasting operator exposures were reduced through a combination of abrasive blasting in enclosed, recirculating systems with dust collection and using conditioned abrasive blasting media. Exposure levels were approximately 100 μg/m^3 using these methods (Document ID 0553, p. 73).

Additional Controls for Finishing Operators (Other Than Abrasive Blasting)

The exposure profile in Table IV.4.3-B shows that 30 percent (15 out of 50 samples) of finishing operators (Other Than Abrasive Blasting) have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Available controls include the use of wet finishing methods, LEV, non-silica blast media, and changes in work practices to perform more finishing operations on uncured concrete. Workers can use a combination of control measures for most activities.

Robert Thomas, President of the National Concrete Masonry Association, indicated that finishing operations presented significant challenges with regard to dust control and that it would be difficult if not impossible to comply with a PEL of 50 μg/m^3 for these finishing operations (Document ID 3585, Tr. 2894-2895). Conversely, Bayou Concrete, LLC acknowledged that dust can be controlled to the previous PEL when engineering controls and work practices are strictly adhered to, stating that “OSHA has underestimated the feasibility, achievability and economics associated with the proposed rule.” (Document ID 2075, p. 3). OSHA acknowledges that some circumstances may prove more challenging to control than others; however, through implementation of the controls described below, compliance with the PEL can be achieved.

Wet Methods

A number of finishing tools use wet methods to help control dust, including water-fed drilling, grinding, cutting, and chipping equipment and automated wet process finishing equipment (Concrete Product Industry Representative A, 2000, as cited in Document ID 1365, p. 5-23; 0898; 1146). For example, at a facility that manufactured precast concrete structural and utility products, workers used a horizontal coring machine (for holes 2 to 31 inches in diameter) with a water-fed bit. The measured silica exposures of these workers were less than or equal to 12 μg/m^3 (LOD) and 31 μg/m^3 (Document ID 0898, pp. 6, 15).

In one experiment at an indoor field laboratory, the use of a wet grinder (a water hose attached to the grinder providing water at 3 liters per minute [L/min]) reduced the geometric mean silica exposure by 98.2 percent during brief periods of intensive concrete surface grinding compared to uncontrolled grinding (Document ID 0522, pp. 770, 774, and 778). During this test, however, the mean silica exposure during wet grinding was still extremely high: 896 μg/m^3. An additional study examined the exposures associated with the use of a handheld abrasive cutter to make cuts through concrete blocks (Document ID 0868, pp. v, 11-12, and 17-18). The use of a water spray attachment (providing water at 1.4 L/min) reduced silica exposures by an average of 90 percent compared to uncontrolled cutting. Again, however, silica exposures were still extremely high, ranging from 1,000 μg/m^3 to 2,400 μg/m^3. In both of these studies, test periods were extremely brief (4 to 11 minutes), during which intensive grinding took place without the normal frequent pauses to change the work angle, change concrete blocks, take measurements, or reposition materials (Document ID 0868, pp. 4, 17). The conditions in this environment are much different from those during typical grinding operations. Samples collected during these conditions typically produce higher exposures. They are valuable for evaluating control methods, but do not represent 8-hour TWA exposure levels.

Lahiri et al. (2005) described unpublished data reporting reductions of 81 and 82 percent during chipping and sawing concrete using wet methods (Document ID 0776, p. 506). The exact details on the wet method used and data collected are not available, however. OSHA notes that many electric grinder housings might not be sufficiently sealed to permit safe use in wet environments. To minimize the hazard of electric shock, the stone and stone products industry uses pneumatic handheld grinding tools to grind high-silica stone such as granite (Document ID 1146, pp. 579-581).

While using wet methods can effectively reduce worker exposures, this method may not be appropriate for all applications. It is important to note that wet grinding can create safety hazards, such as slippage and electrocution, and might be unsuitable for indoor or freezing environments. In addition, wet methods can cause aesthetic problems (e.g., water marks) if appearance is an important component of the final product (e.g., architectural elements) (Document ID 1365, p. 5-23; 4029, p. 3).

Local Exhaust Ventilation

LEV or ventilated enclosures might be necessary for facilities finishing architectural concrete products particularly where wet methods are infeasible for surface finishing. Handheld grinders equipped with LEV are widely available and can help control operator and bystander exposures. While no data are available quantifying the effectiveness of LEV or ventilated enclosures for reducing exposures associated with finishing operations in the concrete products application group, studies of concrete finishers in the construction industry provide substantial data on analogous activities. The use of vacuum dust collection systems for concrete grinders reduced workers' silica exposures by 74 to 93 percent (Document ID 1365, p. 5-23; 0521; 0613, p. 5; 1385, pp. 4-8). Another comparative study evaluating an abrasive cutter (on concrete) found an average reduction in silica of 95 percent with an LEV shroud and vacuum cleaner (Document ID 0868, p. 10). Finally, the use of four different hood-vacuum combinations on a hammer-drill being used to drill concrete reduced silica concentrations from 308 $\mu g/m^3$ (no LEV) to between

6 µg/m^3 and 28 µg/m^3 (overall reduction of 94 percent) (Document ID 1142, pp. 42, 46). Even when substantial exposure reductions are reported with LEV shrouds and vacuum attachments, however, worker exposure levels often still exceed 100 µg/m^3 and are sometimes several times higher (Document ID 0522; 0632; 0681; 0868). These levels can result from inadequate air flow rates.

Although investigators in the cited studies considered vacuum capacity when matching suction equipment to grinding shrouds, OSHA estimates that actual vacuum cleaner air flows were likely less than the published, nominal air flows (specified with zero static pressure at the air inlet) due to pressure losses attributed to the hood, hose, bends in the hose, vacuum cleaner body, vacuum cleaner filters, and debris accumulation on filters. Echt and Sieber (2002) reported that 36 pounds of debris were collected in a vacuum cleaner during one day of concrete grinding (Document ID 0632, p. 460). In addition, the vacuum cleaners used for dust control during concrete grinding and cutting might have been undersized. In Akbar-Khanzadeh et al. (2007), the grinder used with LEV had a diameter of 6 inches (Document ID 0522, p. 772). The vacuum cleaner model used in Akbar-Khanzadeh et al. (2007) had a free air flow rating of only 106 cfm (Document ID 0522, p. 776). [26] Considering system pressure losses, the actual air flow was likely substantially lower for the reasons discussed previously. To optimize performance, a vacuum system should include cyclonic pre-separation, large (2-inch) diameter hoses, a gauge indicating filter pressure, a high-efficiency filter with a large surface area, and a powerful motor (sufficient to move the required air flow even as filter loading begins to occur) (Document ID 0600, pp. 884-886; 0731, pp. 382-384). For additional discussion of issues surrounding air flow rates and vacuums, see Section IV-4.11 – Tuckpointers and Grinders.

Finishing Uncured Concrete

Silica exposures can be reduced if operators perform finishing operations on uncured concrete. Some facilities in the concrete products industry currently use a retarder to slow

[26] "Free air flow" is air flow without accounting for various pressure losses including debris accumulation on the filters, resistance in the vacuum hose, and static pressure losses throughout the vacuum (Document ID 1720, p. IV-86).

the rate at which concrete cures (Concrete Product Industry Representative A, 2000, as cited in Document ID 1365, p. 5-5). Workers cutting, scoring, and adjusting the finish on uncured concrete products eliminated the need for power-grinding and air-hammering (which typically produce large quantities of dust). This work on uncured concrete was associated with two silica readings of less than or equal to 12 μg/m^3 (LOD) (Document ID 1365, p. 5-24; 0234).

Combination of Controls

OSHA notes that, in Germany's concrete products industries, finishing operator's respirable dust and silica exposure levels have decreased as the facilities have implemented targeted controls, often in combination (Document ID 0553). Examples include:

- Abrasive blasting in enclosed, recirculating systems with dust collection and conditioned abrasive blasting media (exposure levels around 100 μg/m^3).
- Wet grinding.
- Dry grinding with dust collection (exposure levels around 50 μg/m^3).
- Sawing wet or dry with LEV (which reduces exposure levels by at least 50 percent below wet sawing alone).
- Using clean water for wet sawing to minimize silica aerosols generated by dust bearing recirculated water.

Although these German facilities encounter exposures above 150 μg/m^3 during certain tasks, the median silica value obtained during finishing and treating of concrete products was 20 μg/m^3 (Document ID 0553).

Additional Controls for Packaging Operators

The exposure profile in Table IV.4.3-B shows that 67 percent (4 out of 6 samples) of packaging operators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

Dust is generated during several parts of the packaging process: when bags are filled, when filled bags drop from the filling equipment onto the conveyor, and when workers use compressed air for cleaning (Document ID 1365, p. 5-25; 1689). Control options include installing or adding effective ventilation systems, improving existing ventilation equipment, and using alternate bag and bag valve designs to minimize dust release.

Local Exhaust Ventilation

OSHA SEP inspection report exposure results illustrate the effectiveness of well-designed LEV for concrete packaging tasks. At one facility, installing a more powerful fan motor and new filter bag for the bag-filling machine LEV and moving the hoods closer to the packaging operator's position reduced respirable dust exposure by 92 percent.[27] After these improvements, a concrete packaging operator had a full-shift silica exposure below the LOD (in this case, 11 µg/m^3) (Document ID 0126, pp. 7-8). Similar exposures were observed (12 µg/m^3, the LOD) at another facility that also had installed dust collection equipment on the concrete bagging equipment (Document ID 0073, pp. 109-111). Another type of ventilation for bag-filling operations, an overhead air supply island system (OASIS) (Document ID 1365, p. 5-26; 1326), has been shown to reduce respirable dust exposure by 98 percent and 82 percent for packaging operators at two mineral processing facilities. OSHA finds that OASIS would be similarly effective at reducing silica exposures of packaging operators in the concrete products industry because dry concrete is a form of mineral dust.

A dual concentric nozzle system for bag-filling machines also can reduce exposures for packaging operators. This system consists of an inner-fill nozzle (to load the bag with material) surrounded by an outer nozzle (to depressurize the filled bag and remove dust from bag valve, thereby preventing dust release). A study conducted by Cecala et al. (2000) at a mineral processing facility (described in more detail in the OSHA contractor

[27] Total respirable dust was reduced by 92 percent from an initial level of 15,500 µg/m^3 to 1,150 µg/m^3 after these modifications (Document ID 0126, pp. 7-8). Silica was only evaluated after the modifications were made, at which point the worker exposure level was 11 µg/m^3.

report (ERG-G, 2008)) found that this type of system reduced respirable dust levels by 83 percent compared to unvented nozzles (Document ID 1365, p. 5-26; 1326).

Bag Design and Quality

The use of bags with valves that seal effectively and prevent product leakage from filled bags is another way to control exposure. In addition to studying nozzles, Cecala et al. (2000) found that the use of 6-inch extended polyethylene valves reduced respirable dust exposures by more than 60 percent compared with standard paper valves, and the use of 4-inch foam valves reduced exposures by more than 45 percent (Document ID 1326, pp. 759, 764). Because the concrete products industry, like the mineral processing industry, packs mineral powders, OSHA expects that a dual-nozzle system and effective bag valves can be easily adopted and will be as effective in the concrete products industry as these studies have shown it is in the mineral processing industry.

Alternate bag designs that minimize breakage, spillage, and leaks reduce levels of airborne silica in the workplace. Bags that break during filling can be a notable source of silica dust and can contribute to operator exposures in the 200 to 300 $\mu g/m^3$ range (Document ID 0587, p. 1). On a busy production line, improperly handled or low-quality bags might break frequently, 10 to 20 times per two hours, releasing dust in the air as the contents spill and while workers clean up spilled material (Document ID 1365, p. 5-27; 0587, p. 2). Another major source of exposure is during leakage from bags that do not fully contain the product during filling. Additionally, workers should be trained on proper techniques for filling and handling bags and subsequent handling requirements that together minimize dust release (Document ID 1365, p. 5-27; 0587, p. 2). One dry concrete bagging facility reduced worker respirable dust and silica exposure levels by changing product packaging from a three-ply bag perforated throughout, to a two-ply bag perforated only on the inner layer. This change alone reduced respirable dust by 83 percent and caused silica levels to fall from 180 $\mu g/m^3$ to 83 $\mu g/m^3$ (Document ID 0766, pp. 1-2).[28] A subsequent adjustment to the ventilation system (temporarily repositioning the ductwork directly over the filling area) further reduced respirable dust by an additional 48 percent. Worker silica exposures associated with the last two changes ranged from 10 µg/m^3 to 23 µg/m^3, representing an 87 to 94 percent reduction compared to the original silica level of 180 µg/m^3. The samples for which durations are available were obtained over 4-hour periods (morning, afternoon) before and after modifications (midday) and so are not of sufficient duration to include in the exposure profile (Document ID 0766). However, this study demonstrates that these controls and work practices can significantly reduce worker exposure.

Combination of Controls

If the exposures of all packaging operators with currently elevated exposures were reduced by 83 percent (achieved by changing the type of bag being filled), then the percentage of packaging operators with results above 50 µg/m^3 in Table IV.4.3-B would be reduced from 66 percent to 17 percent. If the highest result for a packaging operator from Table IV.4.3-B (370 µg/m^3) were reduced by 87 to 94 percent by modifying bags and improving LEV, this worker's silica exposure level would be reduced to a value between 22 µg/m^3 and 48 µg/m^3.

4.3.4 Feasibility Findings

Feasibility Finding for Material Handlers

Based on the exposure profile in Table IV.4.3-B and other record evidence discussed above, OSHA has determined that it is feasible for most material handlers to achieve exposure levels of 50 µg/m^3 most of the time. Exposures for the vast majority of material handlers are already well below 50 µg/m^3. Exposures presented in Table IV.4.3-B, show that 73.9 percent of the material handlers in this industry currently experience silica exposures of 50 µg/m^3 or less. OSHA has determined that exposure levels of 50 µg/m^3 or

[28] Dusty displaced air from the filling process was released from points all over the sack through the perforations in the three-ply bags. In contrast, only the inner layer of the two-ply bags was perforated and displaced air passed inside the solid outer layer to a single relief point at the sack opening (i.e., nozzle entry point). Dusty air exiting from between layers at the relief point was captured by LEV associated with the filling nozzle.

less can be achieved for most of the remaining workers in this job category by using appropriately designed, well-maintained ventilation systems, implementing more consistent housekeeping and yard dust management programs, and reducing the exposures of workers in other job categories to levels of 50 µg/m^3 or less. All of these control measures may be necessary for the most highly exposed workers.

Exposures above 100 µg/m^3 were associated with material handlers for whom adjacent operations contributed to worker exposure. Additionally, most of these exposures were dramatically affected by ineffective LEV. Exposures for material handlers were drastically reduced in the pottery industry when workers had access to functional LEV (median exposure level 27 µg/m^3) versus when workers used material transfer stations where LEV was clearly inadequate or missing (median exposure level 530 µg/m^3). Based on the similarity of front-end loaders, hoppers, and mixing equipment used to blend mineral powders in both industries, OSHA has determined that LEV at material transfer stations will be as effective in the concrete product industry as in pottery operations. Therefore, OSHA concludes that installing or upgrading LEV to meet ACGIH (2010) recommendations, particularly at blender hoppers charged by material handlers operating front-end loaders, will reduce even the highest exposures reported for material handlers in the concrete products industry to levels in the range of 100 µg/m^3.[29]

OSHA projects, however, that controlling adjacent operations to levels of 50 µg/m^3, in addition to upgrading the LEV, could reduce exposure levels to even lower levels (e.g., the median of 27 µg/m^3 calculated for the pottery industry), providing that yards and floors do not contribute airborne silica. Therefore, in order to further reduce exposures and achieve levels of 50 µg/m^3 or less for all material handlers, silica emissions from yard dust and poor housekeeping practices (e.g., dry sweeping and disturbing dust settled in the plant) also need to be controlled. Exposures at facilities that implemented yard dust management controls include four readings of less than 21 µg/m^3 for facilities using dust suppressants and two readings of less than 19 µg/m^3 for those that consistently wetted

[29] This conclusion is based on the apparent prevalence of secondary exposure for this job category noted above (improved ventilation will reduce exposure levels, but will continue to be elevated until adjacent sources of exposure are also controlled).

yard dust (see discussion under the heading Yard Dust Management, later in this subsection). In contrast, a material handler result of 110 μg/m^3 was associated with a yard that had been previously watered, but allowed to get dry. Furthermore, material handler exposure levels ranged from 48 to 73 for material handlers who performed dry sweeping during their shifts where "[m]ost of the facility has 1/8-inch of dust on the floor" (Document ID 0220, p. 6). In the structural clay industry, another industry with similar material handling requirements, professional-quality, thorough cleaning of a brick manufacturing facility dramatically reduced exposure levels (by 90 percent or more in some cases). In material handling areas where such cleaning was performed, most worker exposures were reduced to less than 50 μg/m^3 without other abatement efforts (Document ID 1365, p. 3-20; 0571). Where dust does accumulate, facilities should switch from brooms to HEPA-filtered vacuums to eliminate dry sweeping as a source of exposure.

Where material handlers continue to experience elevated exposure, other control options are also available, such as enclosed, sealed, filtered and air-conditioned cabs, which can reduce the driver's exposure level by more than 90 percent when this control is combined with the benefits of LEV, dust suppressing yard maintenance, and reduced exposures from controlling job categories causing silica dust in adjacent areas. For example, NIOSH measured an exposure of 21 μg/m^3 for an operator who used a front-end loader with an air-conditioned cab to transport raw materials across a water and dust suppressant-treated yard (Document ID 1365, p. 5-19; 0898). Therefore, based on the information presented above, OSHA has determined that an exposure level of 50 μg/m^3 can be achieved for material handlers, with few exceptions.

Feasibility Finding for Mixer Operators

Based on the exposure profile in Table IV.4.3-B and other record evidence discussed above, OSHA has determined that it is feasible for mixer operators in all operations to achieve exposure levels of 50 μg/m^3 or less through a combination of controls, with few exceptions. Exposures for the vast majority of mixer operators are already 50 μg/m^3 or less. Exposures presented in Table IV.4.3-B, show that 80 percent of all mixer operators currently have exposures of 50 μg/m^3 or less, with 74.3 percent having exposures less than 25 μg/m^3. To achieve that level, the remaining 20 percent of operators will need additional controls during mixer drum chipping and manual bag dumping. Appropriate controls include frequent and conscientious rinsing of mixing equipment before residual concrete hardens on the barrel and using wet methods with chipping equipment when it becomes necessary to remove hardened concrete. During mixing activity, exposures can be controlled through ventilated bag dumping stations or automated mixer charging. In the event that results remain elevated, ventilated control rooms or booths can offer additional protection.

In the few instances where mixer operators must perform chipping operations, based on the similar activities in the ready-mix industry (see discussion under the heading Combination of Controls, above in Section IV-4.3.3 – Additional Controls for Finishing Operators), the use of a combination of controls has shown to significantly reduce worker exposures. Investigators have found that the following combinations of control methods offer exposure reductions of *at least* 70 percent compared with uncontrolled levels typically.

- LEV-equipped chipping tool plus general exhaust ventilation (Document ID 1365, p. 13-22; 0245, p. 12); or
- Water misting device and push/pull ventilation system (Document ID 1157, p. D123); or
- Periodic spraying of the interior surface of the drum and directing continuous water spray at the chisel point during chipping (Document ID 3732, Attachment 3, pp. 14-16).

A 70 percent reduction would have the effect of reducing exposures for most mixer operators who are currently above 50 µg/m^3 to below the PEL.[30] In chipping operations where mixer operators would experience higher than normal exposures due to the duration of the job or the amount of material built up prior to cleaning, supplemental use of respirators may be necessary.

[30] OSHA multiplied 70 percent by the second highest result available to OSHA for this job category (as identified in the discussion of the exposure profile for mixer operators performing barrel chipping in this industry), reducing exposures from 122 µg/m^3 (the second highest exposure value) to a level of 37 µg/m^3.

OSHA has also determined that mixer operators can achieve an exposure level of 50 μg/m^3 or less when charging the mixing vessel. For those mixer operators who experience elevated exposure while manually charging mixers, OSHA concludes that ventilated bag dumping stations will reduce even the highest exposures associated with manual mixer charging to levels of 50 μg/m^3 or less. OSHA bases this conclusion on the effectiveness of controls used in analogous operations at a paint manufacturer, which also charged mixers with high-silica powdered mineral products that used a bag dumping station with fully functioning LEV, leading to a reduction in silica exposure of at least 95 percent (Document ID 1365, pp. 5-20 – 5-21; 0199).

Exposures can be further reduced by the use of automated mixer charging. An exposure of less than or equal to 12 μg/m^3 (LOD) was reported for a mixer operator using an automated charging system at a precast concrete panel facility (Document ID 1365, p. 5-21; 0204). In the event that mixer operators continue to experience elevated exposures during automated mixer charging, ventilated control rooms are also effective in maintaining a low exposure. For example, exposure of 23 μg/m^3 was achieved for a worker who operated a computer-controlled mixer and charging equipment from an enclosed booth (Document ID 1365, p. 5-21; 0161).

Therefore, based on the information presented above, OSHA has determined that an exposure level of 50 μg/m^3 can be achieved for mixer operators with few exceptions (e.g., long duration of chipping operations or a high build-up of dried concrete).

Feasibility Finding for Forming Operators

Based on the exposure profile in Table IV.4.3-B and other record evidence discussed above, OSHA has determined that, through a combination of controls, it is feasible for forming operators to achieve exposure levels of 50 μg/m^3 or less, with few exceptions. As shown in Table IV.4.3-B, 92.4 percent of exposures for forming operators are 50 μg/m^3 or less. OSHA has determined that this is accomplished primarily by minimizing forming operators' exposure to silica produced by adjacent workers.

OSHA bases this conclusion on information that the forming operators with silica values exceeding 50 μg/m^3 were subject to silica dust from adjacent sources and from the activities of other workers who had exposure levels above 100 μg/m^3 (Document ID 1365, pp. 5-11 – 5-12; 0220, pp. 6, 8, 10). A forming operator with exposures exceeding 50 μg/m^3 on two consecutive days controlled a concrete block-forming machine that emitted dust. That forming operator's location was near the mixing area, from which dust was emitted during mixer charging. Another worker performed dry sweeping nearby (Document ID 1365, pp. 5-11 – 5-12; 0220). Additionally, the highest sample in Table IV.4.3-B for this job category (107 μg/m^3) was obtained at a facility at which 9 of 10 exposures exceeded 100 μg/m^3 and the inspector noted there were leaks in the material handling system, as well as some not-fully-used controls (Document ID 1365, p. 5-11; 0039). Therefore, OSHA concludes that controlling these sources of exposure will reduce forming operators' overall exposure.

In the event that additional controls are necessary for forming operators where exposures remain above 50 μg/m^3 (after the exposures of other job categories are controlled to levels of 50 μg/m^3 or less), other measures are available to reduce exposures. These measures include adding LEV to forming operator workstations, particularly those with automated processes, and improving housekeeping, starting with a one-time thorough cleaning to remove accumulated dust and continuing with the benefit of HEPA-filtered vacuums to clean forms and the facility. These control measures have effectively reduced exposures for workers in this job category.

Therefore, based on the information presented above, OSHA has determined that an exposure level of 50 μg/m^3 can be achieved for most forming operators, most of the time.

<u>*Feasibility Finding for Finishing Operators (Abrasive Blasting)*</u>

Based on the exposure profile in Table IV.4.3-B and other record evidence discussed above, the majority of the workers in this job category (approximately 82 percent) experience exposure levels that exceed 100 μg/m^3, and many exposures are extremely high. Therefore, OSHA has determined that additional controls or alternate production processes will be necessary to reduce exposures. Abrasive blasting has historically been associated with very high silica levels. OSHA has determined that these exposure levels can be reduced (although not eliminated) by using alternative abrasive blasting media that is less toxic than silica or by switching to wet abrasive blasting (or a combination of both). While exposures can be significantly reduced, if facilities cannot substitute a process that avoids abrasive blasting then respirator use may be necessary, particularly for abrasive blasting outdoors where isolation of the blasting operation is less common (Document ID 0553; 0733). The primary method for reducing the exposure of those abrasive blasters with the highest exposures is using retarders and water sprays to wash away incompletely-cured concrete and to expose aggregate. This completely eliminates the need for abrasive blasting. Where abrasive blasting must be performed, wet methods used outdoors or in a ventilated environment will substantially reduce silica exposure levels. Restricting the fines content of the sand in combination with wet blasting is also effective in reducing silica exposures. However, the use of appropriate respiratory protection and proper ventilation, especially within enclosures, will still be needed to protect workers from hazardous levels of contaminants that can be generated during abrasive blasting from the abrasive, the substrate, or both. To ensure protection, ventilation and respiratory protection must meet the requirements of 29 Code of Federal Regulations (CFR) 1910.94 and 1910.134, respectively (Document ID 1351).

As an alternative exposure reduction method, low-silica abrasive blast media that is less toxic than silica sand can also reduce exposure levels for abrasive blasting operators in this industry. Although concrete surfaces remain a source of silica dust during abrasive blasting even when low- or non-silica media are used, these levels are often notably lower than silica concentrations measured during abrasive blasting with quartz sand. For example, three readings, 54 $\mu g/m^3$, 30 $\mu g/m^3$, and 20 $\mu g/m^3$, were obtained from two facilities at which finishing operators performed abrasive blasting of concrete products outdoors with coal slag media (Document ID 1365, p. 5-14; 0011, p. 40; 0055, pp. 144, 155). Employers must consider the possible hazards of substitutes if switching from silica sand. For example, depending on the abrasive, alternative media can result in elevated levels of other hazardous air contaminants such as toxic metals (Document ID 0772; 0773; 0774). Furthermore, total and respirable dust levels will continue to be a concern even with alternate abrasive blasting media because of the silica content in the substrate.

OSHA has reviewed the information contained in the rulemaking record for abrasive blasting operators in this industry and in the related abrasive blasting in the construction industry (Section IV-5.1 – Abrasive Blasters). Based on this information, OSHA has determined that for those instances where abrasive blasting cannot be completely eliminated by the use of alternate processes, such as retarders, the use of wet methods or alternative abrasive blasting media can reduce the exposures of abrasive blasting operators working outdoors to levels consistently below 50 μg/m^3 (Document ID 1365, p. 5-14; 0011; 0055). However, when blasting indoors, in enclosed spaces, or in cases where wet methods cannot be implemented, respirator use may still be necessary for abrasive blasting operations.

Feasibility Finding for Finishing Operators (Other Than Abrasive Blasting)

Based on the exposure profile in Table IV.4.3-B and other record evidence discussed above, OSHA has determined that, through a combination of controls, it is feasible with few exceptions to achieve exposure levels of 50 μg/m^3 or less for finishing operations, other than abrasive blasting, which is treated here as a separate job category. As shown in Table IV.4.3-B, 70 percent of finishing operators have exposure levels at or below 50 μg/m^3. The exposure levels of the remaining 30 percent of finishing operators can be brought below 50 μg/m^3 most of the time by using controls or work practices that are commonly used in this application group, including the use of water-fed equipment, LEV, and modified work practices (e.g., finishing of uncured products). This finding is based on exposure levels ranging from less than or equal to 12 μg/m^3 (LOD) to 31 μg/m^3 obtained for finishing operators who were either working on uncured concrete products or using water-fed hand tools. Exposures obtained for finishing operators who used hand and power tools to work on uncured concrete products, were less than or equal to 12 μg/m^3 (LOD) (Document ID 1365, p. 5-24; 0234), while finishing operators who used a water-fed coring machine to drill concrete products had exposures at or below 31 μg/m^3 (Document ID 1365, p. 5-24; 0898). Therefore, OSHA has determined that finishing operators can obtain exposure at 50 μg/m^3 or less with the use of either alternate manufacturing processes or engineering controls.

Feasibility Finding for Packaging Operators

Based on the exposure profile in Table IV.4.3-B and other record evidence discussed above, Exposures for packaging operators can be controlled to 50 μg/m^3 or less through a variety of controls, either separately or in combination. By switching to package (bag) designs that release less dust and by improving or adding adequate workstation ventilation, exposure levels can be reduced to at or below 12 μg/m^3 (LOD) (Document ID 1365, p. 5-25; 0073). Additionally, a packaging operator who loaded bags of dry-mixed concrete using a bag-filling machine equipped with effective LEV experienced an exposure below the LOD (11 μg/m^3) (Document ID 1365, p. 5-25; 0126). A third concrete products facility reduced silica exposure levels from an initial reading of 180 μg/m^3 to multiple readings below 25 μg/m^3 (10 μg/m^3 and 23 μg/m^3) by changing the bag design (to reduce dust emissions) and improving LEV to capture residual dust (Document ID 0766). Therefore, OSHA has determined that, by improving LEV and bag quality and design, it is feasible to achieve exposure levels of 50 μg/m^3 or less for packaging operators.

Overall Feasibility Finding

Based on the exposure profile in Table IV.4.3-B and other record evidence discussed above, OSHA concludes that most workers at concrete products facilities are currently exposed to silica levels below 50 μg/m^3. For workers who are currently exposed above 50 μg/m^3, the engineering and work practice controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or less in most operations, most of the time, with exceptions in some cases for mixer operators during tank cleaning and workers performing abrasive blasting operations. These workers may need to continue to use supplemental respiratory protection in compliance with the existing respirator standard to achieve the PEL. Accordingly, OSHA concludes that the final PEL of 50 μg/m^3 is technologically feasible for the Concrete Products industry.

4.4 CUT STONE AND STONE PRODUCTS

4.4.1 Description

Fabricating facilities that produce cut stone and stone products are classified in the six-digit North American Industry Classification System (NAICS) as 327991, Cut Stone and Stone Products Manufacturing. The manufacture of man-made stone (engineered stone) is classified separately as NAICS 327999, All Other Miscellaneous Nonmetallic Mineral Product Manufacturing, and is discussed in Section IV-4.7 – Engineered Stone Products, in this technological feasibility analysis. Once manufactured, however, these engineered stones are cut to shape and finished by the stone and cut stone products industry. Similar processes involving the cutting, grinding, and polishing of stone products occurs infrequently in other industries. Although OSHA anticipates that these types of activities are limited in occurrence, exposure controls used in the Cut Stone industry could also be applied to reduce any potential for exposure to respirable crystalline silica in these industries.[31]

Silica exposures in this application group occur when slabs of silica-containing stones are cut, shaped, and often polished to form a diverse range of products including floor tile, countertops, roofing slates, building cladding, and funeral monuments. The most commonly used dimension stones with the highest percentage of free quartz are granite (up to 45 percent quartz), sandstone (42 to 95 percent quartz), high-silica limestone (9 to 67 percent quartz), and slate (31 to 45 percent quartz) (Document ID 1365, p. 11-1). In 2003, the U.S. Geological Survey reported that granite comprised 41 percent of the dimension stone used in the United States; sandstone contributed another 9 percent; slate comprised 6 percent (Document ID 1365, p. 11-1). Although many other stones contain silica, most have less desirable physical characteristics and are not cut for commercial purposes. Two of the other most commonly used dimension stones, marble and low-silica

[31] Samples from four NAICS codes other than 327991-Cut Stone have been included in the exposure profile for this application group. Samples from the following NAICS codes were included where OSHA determined that, at the time of sampling, the workers were performing tasks that were very similar to the tasks performed in the cut stone industry. OSHA also included samples from NAICS codes: 423320 - Brick, Stone, and Related Construction Material Merchant Wholesalers, 444110 - Home Centers 337110 - Wood Kitchen Cabinet and Countertop Manufacturing 238340 - Tile and Terrazzo Contractors (Document ID 3958).

limestone, occasionally contain low levels of silica as impurities, but do not contribute significantly to worker exposure (Document ID 1365, p. 11-1; 0098; 0154).

The process begins with the delivery from the mine of either natural or engineered stone as blocks that workers cut into slabs or, more frequently, stone is delivered as slabs precut to the approximate thickness of the ultimate product. Sawyers cut the blocks or slabs to appropriate dimensions for the product. Fabricators change the contours and finish and assemble the pieces. Additional specialized steps can include manual chipping or splitting, mechanical trimming or milling, and abrasive blasting (Document ID 1365, p. 11-1).

4.4.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.4-B includes 240 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for workers in the cut stone and stone products industry. The median is 41 μg/m^3, the mean is 165 μg/m^3, and the range is 12 μg/m^3 (the limit of detection (LOD)) to 7,439 μg/m^3. Of the 240 samples, 113 (47 percent) exceed 50 μg/m^3.

Stone industry workers can be exposed to silica when they saw large blocks and slabs of stone; grind or chip the stone; finish the pieces by smoothing, polishing, or abrasive blasting the surface; handle or transport stone; and during housekeeping activities (Document ID 1365, p. 11-1). Workers who work with cut-stone and adjacent to the above activities risk significant silica exposure at each step in the process. Exposures depend on the silica content of the stone, the work practices, and the equipment used. Table IV.4.4-A identifies and describes the five job categories with sources of exposure for workers in the cut stone industry.

Table IV.4.4-A Job Categories, Major Activities, and Sources of Exposure of Workers in the Cut Stone Industry (NAICS 327991)	
Job Category*	**Major Activities and Sources of Exposure**
Sawyer	Operates large water-fed stationary bridge or gantry-type saws. • Dust from wet-sawing stone. • Dust disturbed from stone and work surfaces. • Dust from housekeeping and adjacent activities.
Fabricator	Produces finished stone products from slabs. • Dust from dry grinding, edging, milling, contouring, and polishing stone. • Dust disturbed from stone and work surfaces. • Dust from housekeeping and adjacent activities.
Splitter/Chipper (Splitter, Stone Cutter, Sculptor)	Uses handheld equipment to change the shape of the stone. • Dust from dry chipping, splitting, and cleaving stone using hammer and chisel. • Dust generated while operating power tools for drilling and chipping. • Dust disturbed from stone and work surfaces. • Dust from housekeeping and adjacent activities.
Machine Operator (Trimmer, Gouger, Puncher, Planer)	Operates trimming, punching, gauging, or planing machines. • Dust emitted from unventilated, unenclosed trimming, punching, gauging, or planning machines. • Dust disturbed from stone and work surfaces. • Dust from housekeeping and adjacent activities.
Abrasive Blasting Operator	Operates blasting equipment. • Dust generated during blasting with silica sand or alternative media on silica-containing stone. • Dust from using compressed air for cleaning stone. • Dust disturbed from stone and work surfaces.
*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility. Source: Document ID 1365, p. 11-3.	

The following sections describe the exposure data and baseline conditions for each affected job category based on more than one dozen OSHA Special Emphasis Program (SEP) inspection reports and several NIOSH reports, previously described in ERG-G (Document ID 1365). In addition, for this analysis, OSHA identified exposure data collected by OSHA during compliance inspections that were entered into the OSHA Information System (OIS) from 2011 through April 17, 2014 (Document ID 3958).

For each of the job categories listed in Table IV.4.4-B and included in the exposure profile and for the cut stone and stone products paving industry as a whole, OSHA concludes that Table IV.4.4-B represents baseline conditions.

Exposure Profile and Baseline Conditions for Sawyers

The exposure profile in Table IV.4.4-B includes 48 sample results for sawyers in the cut stone and stone products industry. The median is 49 µg/m^3, the mean is 93 µg/m^3, and the range is 12 µg/m^3 (LOD) to 843 µg/m^3. Table IV.4.4-B shows that, of the 48 samples, 24 (50 percent) are above 50 µg/m^3 and 13 (27 percent) exceed 100 µg/m^3. Sawyers typically operate large, powerful stationary bridge or gantry-type saws, with single or multiple heads (Document ID 1365, p. 11-3). All of the results included in the exposure profile are associated with water-fed saws of these general varieties. OSHA reviewed 48 personal breathing zone (PBZ) results for sawyers from 10 OSHA SEP Inspection reports, one NIOSH report, and OIS data (Document ID 0042; 0180; 0187; 0157; 0240; 0178; 0046; 0176; 0061; 0153; 0240; 3958). The highest results were associated with cutting granite with respirable samples containing greater than 35 percent silica.

A local survey conducted by Phillips and Johnson (2012) found that 91 percent of area granite countertop fabrication shops surveyed always performed initial granite cutting using wet methods, with an additional 6 percent reporting that the task was usually performed using such wet methods (Document ID 3957, pp. 3-4).

OSHA inspection reports indicate that sawyers generally cut stone from 30 minutes to 4 hours per day, but might work at the task up to 8 hours per day. A typical shop will employ approximately 25 percent of the production work force as saw operators, although the percentage might be higher in mass production shops, such as floor tile or slate roof manufacturing facilities (Document ID 1365, p. 11-4; 0153; 0046; 0180).

An extremely high-pressure water jet, often containing abrasives, can also be used to cut stone. A small but growing number of facilities are using water jet equipment to cut specialty shapes (e.g., sink openings in countertops) in smaller pieces of stone (Document ID 1365, p. 11-4). The operator programs the automated equipment and positions the stone inside an enclosed space, and a fine, high-pressure water spray (computer controlled) is directed along the cutting line (Document ID 1365, p. 11-4). OSHA expects exposures to sawyers would be lower with this automated process since this process isolates a worker from the dust generated inside. This determination is based on similar controls used for abrasive blasters in this application group which showed significant reductions in exposures (see discussion later in this section under the heading Exposure Profile and Baseline Conditions for Abrasive Blasting Operators). Additionally, no silica was detected in two OIS samples collected on operators using computer numerical control (CNC) saws (Document ID 3958).

Exposure Profile and Baseline Conditions for Fabricators

The exposure profile in Table IV.4.4-B includes 135 sample results for fabricators in the cut stone and stone products industry. The median is 28 $\mu g/m^3$, the mean is 216 $\mu g/m^3$, and the range is 12 $\mu g/m^3$ (LOD) to 7,439 $\mu g/m^3$. Table IV.4.4-B shows that, of the 135 samples, 52 (38.6 percent) are above 50 $\mu g/m^3$ and 36 (26.7 percent) exceed 100 $\mu g/m^3$. These results were obtained from seven OSHA SEP inspection reports, two NIOSH reports, and OIS data (Document ID 0098; 0153; 0156; 0061; 0046; 0063; 1826; 0240; 0856; 3958). Fabricators produce finished stone products from the sawn slabs or shapes (Document ID 1365, p. 11-4). Fabricators use both electric and pneumatic tools, including handheld dry circular saws and angle-grinders, handheld or hand-guided grinders and routers, and higher speed polishing tools (Document ID 1365, p. 11-4).

Grinding and polishing can be performed as a wet or dry process (Document ID 1365, p. 11-4). A study conducted in the state of Washington found that fabricators in one-third of the facilities evaluated were primarily using wet methods at the time of the initial visit (Document ID 1146, pp. 578-579). A study conducted in Oklahoma on granite countertop fabricators found that 21 percent of shops surveyed reported performing all fabrication steps wet, while only one shop reported performing all fabrication steps dry. The remainder of the shops reported using a combination of wet and dry methods some or all of the time when completing various steps (Document ID 3957, p. 4).

Sixty to 100 percent of production workers in typical custom architectural component (e.g., kitchen countertop) manufacturing facilities are classified as fabricators (Document ID 1365, p. 11-5). Workers typically grind stone 20 minutes to 4 hours per day, and spend the balance of the day polishing, filling defects, waxing, inspecting work, and performing housekeeping activities (Document ID 1365, p. 11-5; 0061; 0063; 0153; 1826).

Exposure Profile Baseline Conditions for Splitters/Chippers

The exposure profile in Table IV.4.4-B includes 29 sample results for splitters/chippers in the cut stone and stone products industry. The median is 98 μg/m^3, the mean is 90 μg/m^3, and the range is 13 μg/m^3 (LOD) to 208 μg/m^3. Table IV.4.4-B shows that, of the 29 samples, 20 (69 percent) are above 50 μg/m^3 and 14 (48.3 percent) exceed 100 μg/m^3. Splitters/chippers typically use handheld hammers and chisels, working within arm's length of their breathing zones, to change the shape of stone. These results are obtained from eight OSHA SEP inspection reports, two NIOSH reports, and OIS data (Document ID 0042; 0180; 0115; 0046; 0176; 0157; 0187; 0178; 0240; 0856; 1365; 3958). Four of the highest results, ranging from 134 μg/m^3 to 181 μg/m^3, are associated with dry splitting of slate (a high silica stone, therefore a worst case condition). No dust controls or in some cases poorly implemented dust controls were typical of the slate-splitting work areas inspected by OSHA. Splitters/chippers typically work at this task for the full shift but might rotate to other tasks if the need arises. Typical slate tile manufacturing facilities employ approximately 30 percent of their production force as splitters (Document ID 1365, p. 11-5; 0046; 0178; 0157).

Exposure Profile and Baseline Conditions for Machine Operators

The exposure profile in Table IV.4.4-B includes 18 sample results for machine operators in the cut stone and stone products industry. The median is 69 μg/m^3, the mean is 118 μg/m^3, and the range is 12 μg/m^3 (LOD) to 314 μg/m^3. Table IV.4.4-B shows that, of the 18 samples, 12 (67 percent) are above 50 μg/m^3 and 8 (44 percent) exceed 100 μg/m^3. Machine operators are typically employed in facilities that mass produce large quantities of identical stone products (e.g., tiles). They operate stationary equipment. The stone is conveyed through the machine, processed, and conveyed out the back or side of the machine to be manually or automatically stacked on a pallet (Document ID 1365, p. 11-6; 0042). Typical machine functions include trimming, gouging, punching, and planing.

These results for machine operators were obtained from six OSHA SEP inspection reports, one NIOSH report, and OIS data (Document ID 0042; 0187; 0178; 0157; 0176, 0180; 0240; 3958). Three of the highest results were collected from two slate trimming machine operators and a punching machine operator where controls (e.g., ventilation) were absent or ineffective or equipment was malfunctioning. These higher results (and the associated controls) are representative of those typically seen in facilities prior to abatement efforts instigated by an OSHA inspection (Document ID 1365, p. 11-13). At facilities described in OSHA inspection reports, these processes were performed dry without any local exhaust ventilation. In these facilities, machine operators make up 20 to 30 percent of the production workforce and work at their tasks approximately 8 hours per day (Document ID 1365, p. 11-6).

Exposure Profile and Baseline Conditions for Abrasive Blasting Operators

The exposure profile in Table IV.4.4-B includes 10 sample results for abrasive blasting workers in the cut stone and stone products industry. The median is 51 μg/m^3, the mean is 115 μg/m^3, and the range is 12 μg/m^3 (LOD) to 309 μg/m^3. Table IV.4.4-B shows that, of the 10 samples, 5 (50 percent) are above 50 μg/m^3 and 4 (40 percent) exceed 100 μg/m^3. Abrasive blasting operators in this application group typically use traditional dry abrasive blasting methods to etch patterns, such as lettering or decorations, into stone (Document ID 1365, p. 11-6). These results were obtained from one OSHA SEP Inspection Report, three NIOSH reports, and OIS data (Document ID 0115; 0218; 0240; 0856; 3958).

At all six facilities considered in the exposure profile, the abrasive blasting media consisted of various grit sizes of aluminum oxide or bauxite. Aluminum oxide contains little or no silica, and bauxite can contain 2 to 9 percent quartz. Some operators also use silica sand to finish or “whiten” the blasted surface (Document ID 1365, pp. 11-6-11-7; 0218; 0240; 0856; 0115).

Abrasive blasting operators might spend 1 to 7 hours per 8-hour shift operating blasting equipment. In addition to blasting, operators normally spend substantial amounts of time applying masking materials to protect portions of the stone from the effects of blasting. Operators’ other activities include cleaning dust from stone, usually with compressed air, and removing spent media and stone dust from the blasting area using shovels and brooms. In memorial production facilities, 10 to 30 percent of production workers are abrasive blasting operators (Document ID 1365, p. 11-7).

NIOSH evaluated blasting booths at two of the three establishments it visited and found that the ventilation rate measured less than half of the face velocity rate recommended by the American Conference of Industrial Hygienists (ACGIH): 100 cubic feet per minute per square foot (cfm/ft^2) (Document ID 0240; 0218; 0515, p. 10-119). TWA respirable silica exposures for the abrasive blasters at one facility ranged from <12 to 309 μg/m^3, with a mean of 190 μg/m^3 (Document ID 0240, p. 5), and at the other facility ranged from 22 to 25 μg/m^3, with a mean of 51 μg/m^3 (Document ID 0218, p. 4).

OSHA also reviewed the results of four less than full-shift PBZ samples collected by NIOSH for abrasive blasting operators at a stone monument manufacturer. Although these data are less than full shift and thus are not included in Table IV.4.4-B, they provide additional insight on the effectiveness of the controls used by these workers. The sample times range from 4 to nearly 6 hours, and all sample results are below 50 μg/m^3 for the periods sampled (mean of 29 μg/m^3). Three of the operators performed automated blasting in ventilated abrasive blasting booths, and one used both the ventilated blasting booth and a manual blasting cabinet contained within an enclosure with a rubber curtain that acted as a barrier for dust. Although the type of media used was not reported, the percent of silica in total respirable dust for these samples ranged from 14 percent to 33 percent. The measured face velocity at the screen was 160 feet per minute (fpm) for the automated blasting operation, and 100 fpm at the curtain for the manual blasting operation (Document ID 1361, p. 4).

Table IV.4.4-B Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Cut Stone Industry (NAICS 327122, 327991, 337110, 423320, 444110)

4.4.3 Additional Controls

Throughout this application group, workers exposures have seen significant reductions over the last 40 years. Yassin et al. (2005) analyzed OSHA's Integrated Management Information System (IMIS) data for the period 1988 – 2003 and found a downward trend in exposure levels for cut stone and stone products workers compared with earlier IMIS data (Document ID 1236, pp. 255, 258-259). This industry had geometric mean silica exposure levels approximately 10 times higher in 1979 – 1987 than in 1988 – 2003 (619 micrograms per cubic meter [$\mu g/m^3$] compared to 63 $\mu g/m^3$, respectively), suggesting modern equipment and work practices have reduced exposures substantially (Document ID 1236, p. 258).

Attfield and Costello (2004) evaluated older data for Vermont granite workers and found average measured personal and area silica levels were lower after 1950 compared with earlier years for several job categories applicable to the stone and stone products industry (Document ID 0285, p. 131). This could have been due to either improved dust control (including increased automation) or increased use of lower silica stone (e.g., marble).

Additional Controls for Sawyers

The exposure profile in Table IV.4.4-B shows that 50 percent (24 out of 48 samples) of sawyers have exposures above the final PEL of 50 $\mu g/m^3$. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. These controls include wet methods, LEV, and thorough housekeeping to prevent the accumulation of dried slurry and other settled dust that can be re-entrained into the air. Increased water flow to the saw and saw or operator enclosures with remote control saws might be required in some facilities.

OSHA SEP inspection reports suggest that a combination of housekeeping and other measures can reduce silica levels. For example, the median full-shift PBZ silica exposure level was 30 $\mu g/m^3$ for eight sawyers at four facilities that implemented housekeeping in combination with other control measures, such as enclosing the saw in a booth with a fan, pre-wetting stone, managing slurry, increasing water flow for wet processes, and controlling dust from adjacent processes (Document ID 1365, p. 11-17; 0046; 0176;

0180; 0157). This level is more than 40 percent lower than the median result for all sawyers reported in the exposure profile (49 µg/m^3), which includes exposures for well-controlled as well as uncontrolled processes. It is also lower than the median of 100 µg/m^3 for sawyers in three facilities using some form of additional controls, but where rigorous housekeeping was not reported (Document ID 1365, p. 11-17; 0042; 0178; 0157).

Housekeeping activities at the four low-exposure facilities included steps that minimized dust accumulation on surfaces and kept floors damp. In the event that recirculating water for saws is becoming laden with stone dust, changing the water more frequently could also reduce the amount of silica in mist and dried slurry. Comments received from Linda Stelmaszyk, on behalf of a small fabrication business, indicated that recent installation of a water filtration system, which cleaned the water that was recirculated onto the blade, was beneficial in controlling dust exposures when using wet methods. She stated her belief that many shops in the cut stone industry continue to cut dry and have not invested in dust controls: “Regarding silica dust, we operate a wet cutting shop with a brand new state of the art water filtration system which puts us well below current OSHA requirements” (Document ID 1775, p. 1). The OSHA SEP inspections reports indicated that the median exposure for workers that used both engineering controls and housekeeping were significantly lower than exposures for workers at facilities that only used engineering controls (30 µg/m^3 versus 100 µg/m^3, respectively) (Document ID 1365, p. 11-17; 0046; 0176; 0180; 0157; 0042; 0178). For example, housekeeping, in combination with any other control measures, such as enclosing the saw in a booth with a fan, pre-washing stone, managing slurry, and controlling dust from adjacent processes reduced the PBZ respirable silica level for eight sawyers (Document ID 0046; 0176; 0180; 0157; 0042; 0178).

The value of combining LEV with whole-shop exposure control efforts is illustrated by exposure monitoring data obtained by OSHA at a facility where efforts to augment housekeeping, enclose the saw, and control other sources of silica dust in the shop had already reduced the sawyers’ median exposure from 84 µg/m^3 to 49 µg/m^3 (Document ID 1365, pp. 11-17; 0180). After modification of the ventilation to exhaust directly from the top of the saw, the silica median exposure for sawyers was further reduced to 22 μg/m^3 (Document ID 1365, pp. 11-18; 0180).

Stand-alone fan-powered dust collectors are a feasible method to lower dust levels in small dimension stone processing shops. Air cleaning units, however, must be properly sized to clean dust loads and keep acceptable dust levels low. Chekan et al. (2008) demonstrate that a 2.24 kilowatt (kW) motor cleaning unit cleaned 19 percent more air and captured 32 percent more respirable dust than the 0.56 kW unit (Document ID 0593, p. 5). The study also discussed cost-effective retrofit options. Although dust collectors are practical means to reduce respirable dust, reliable data do not exist to determine their effectiveness (Document ID 0593).

Additional Controls for Fabricators

The exposure profile in Table IV.4.4-B shows that 39 percent (52 out of 135 samples) of fabricators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

The primary controls for fabricators include both wet methods and LEV when polishing and grinding stone and rigorous housekeeping in work areas where dust accumulates.

The exposure level for fabricators can be reduced substantially by converting to water-fed equipment and switching to wet methods. According to Simcox et al. (1999), exposures of fabricators at granite handling facilities were reduced from a mean of 490 μg/m^3 to 60 μg/m^3 (88 percent) when all dry grinding tools used on granite were either replaced or modified to be water fed. The same study reported similar reductions in exposure at other fabricating facilities when wet grinding, polishing, and cutting methods were adopted (Document ID 1365, p. 11-20; 1146, p. 3). Phillips and Johnson (2012) surveyed granite countertop fabrication shops of various sizes throughout Oklahoma and concluded, “The self-reported use by some shops of exclusively wet methods indicated that this means of exposure control is feasible” (Document ID 1365, p. 11-20; 3957, p. 7).

Results obtained from NIOSH and OSHA SEP inspection reports showed a substantial reduction in fabricator exposure levels associated with wet methods. All 7 full-shift PBZ silica results for fabricators using water-fed equipment exclusively were 51 μg/m^3 or less (Document ID 1365, p. 11-20; 0061; 1826; 0156; 0240; 0856). In six of these instances of wet-method use, the fabricator was polishing granite; in one case, the fabricator was working with marble in a facility that also handled granite (Document ID 1365, p. 11-20).

Rigorous control of dust-laden water from wet processes prevents dust from depositing on surfaces where, after evaporation of the water, the dry dust can be disturbed and become airborne. The following methods, combined with water-fed equipment, are associated with reduced exposure levels for fabricators: frequent replacement or filtration of recirculated water for milling machines, adequate collection of used water from handheld equipment, and frequent washing of floors and surfaces where dust-laden water might evaporate or dust might accumulate (Document ID 1365, p. 11-21).

Stand-alone fan-powered dust collectors, discussed previously as an additional control for sawyers, also are a feasible method to lower dust levels in small-dimension stone processing shops (Document ID 0593, p. 6).

Additional Controls for Splitters/Chippers

The exposure profile in Table IV.4.4-B shows that 69 percent (20 out of 29 samples) of splitters/chippers have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

Available controls include LEV at workstations, rigorous housekeeping, and wet methods. Based on the similarity of tools and exposures, OSHA anticipates that splitters and chippers benefit similarly from the controls discussed under sawyers, fabricators, and abrasive blasters in this section.

OSHA has only limited data to quantify the reductions in exposure that can be anticipated through the use of LEV and water-fed tool attachments in the stone products industry. However, there is evidence that demonstrates that a combination of LEV, wet methods, and other efforts can be very effective in reducing exposures. For example, at a facility visited by OSHA, workers also used a combination of housekeeping, LEV, and wet methods to control splitter/chipper exposure. In this case, workers washed stone with a constant stream of water (rather than a spray). The single full-shift PBZ splitter/chipper exposure result was 31 µg/m^3. Previous silica results for chippers/splitters at the facility had been 132 µg/m^3, 124 µg/m^3, and less than 13 µg/m^3 (no quartz detected in the 13 µg/m^3 sample) (Document ID 1365, p. 11-22; 0187).

At another facility OSHA visited, the workers wet stone with a hose before and between each operation, washed floors daily with a fire hose and kept them damp at all times, and controlled dust from the saws by modifying ventilation to exhaust directly from the top of the saws. Additionally, the facility retrofitted splitting stations with LEV (Document ID 1365, p. 11-22; 0180**)**. Under these conditions, the full-shift respirable silica exposures for splitters were reduced from 104 µg/m^3, 109 µg/m^3, and 137 µg/m^3 (a mean of 117 µg/m^3) to levels of 17 and 19 µg/m^3 (a mean of 18 µg/m^3), a 66 percent reduction rate (Document ID 1365, p. 11-22; 0180). A combination of controls to reduce all source of potential exposure was needed to adequately reduce exposures. At these facilities, individual exposure reduction efforts (e.g., LEV alone) failed to maintain exposures below 100 µg/m^3, but were successful when used in combination (e.g., wet methods and LEV) (Document ID 1365, p. 11-22).

Other dust control options for power chipping tools include LEV fitted directly to the chipping bit and water feeds that spray mist at the chipping point. In short-duration tests, both LEV and water-fed attachments reduced the silica exposure of workers removing hardened concrete from the interior of concrete-mixer drums. For example, NIOSH reported a 69 percent reduction in worker exposure levels when the LEV fitting was used with jack hammers. During controlled, short-duration tests, the geometric mean PBZ silica concentration was 300 µg/m^3 with the LEV, compared with 970 µg/m^3 when no controls were used (Document ID 0245, pp. 10-11). Silica levels decreased further when general exhaust ventilation was used in addition to LEV. The combined controls provided a net reduction of 78 percent (from 970 µg/m^3 to 213 µg/m^3). Although neither control is commercially available, shop-made versions have been assembled from materials available at hardware stores (Document ID 0741).

Sampling results submitted to the docket by NIOSH showed wet suppression when using jackhammers to split or chip stone can produce respirable dust reductions of 81-95 percent and silica reductions of 86-98 percent resulting in silica exposure levels of 48-65 μg/m^3 (Document ID 2177, Attachment D, p. 19).

Stand-alone fan-powered dust collectors, discussed previously as an additional control for sawyers, also are a feasible method to lower dust levels in small dimension stone processing shops (Document ID 0593).

Additional Controls for Machine Operators

The exposure profile in Table IV.4.4-B shows that 67 percent (12 out of 18 samples) of machine operators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

Appropriate controls include converting to water-fed equipment, enclosing machines, adding exhaust ventilation close to the point where dust is generated, employing rigorous housekeeping, and frequently washing stone and floors (Document ID 1365, p. 11-24).

The respirable silica exposures of machine operators can be reduced significantly by the use of wet process rather than dry process machines and by manufacturer-designed, adequately exhausted machine housing (Document 1365, p. 11-25). Stone Working Equipment Distributor A (2000) indicated that most new machines sold to high-volume production facilities come with LEV dust collectors and/or enclosures as standard equipment (Document ID 1156).

Facilities that use a combination of these controls can reduce machine operator exposure substantially. For example, a slate-working establishment exhausted the machine at the point where dust was generated, pre-wet the stone, installed spray mister nozzles to keep the stone wet, and took steps to reduce dust released from the adjacent saws. Under these conditions, the operator exposure level dropped from 220 μg/m^3 to 26 μg/m^3 (Document ID 1365, p. 11-25; 0178). At another facility, OSHA reported 2 full-shift PBZ silica results of 44 μg/m^3 and 314 μg/m^3 around the time of the initial compliance inspection.

The facility implemented procedures to pre-wash stone, controlled dust from other operations, and enclosed trimmers in exhausted plastic housing. After the modifications, full-shift silica results for operators were more consistent, at 60 $\mu g/m^3$ and 69 $\mu g/m^3$ (Document ID 1365, p. 11-25; 0187). Although these results are more consistent and have a much lower average (65 $\mu g/m^3$ vs. 179 $\mu g/m^3$) than those collected before the modifications, they are still above 50 $\mu g/m^3$ (Document ID 1365, p. 11-25). Machine operators with exposures currently greater than 100 $\mu g/m^3$ will require the entire range of controls described previously to increase the likelihood of maintaining exposure values below 50 $\mu g/m^3$. There is one example from an OSHA inspection report of a machine operator whose exposure dropped from 220 $\mu g/m^3$ to 26 $\mu g/m^3$ after a combination of controls were implemented However, the available data are not sufficient to demonstrate that exposures to all machine operators can be reduced below 50 $\mu g/m^3$ with any subset of the controls (Document ID 0178, pp. 61, 185).

Additional Controls for Abrasive Blasting Operators

The exposure profile in Table IV.4.4-B shows that 50 percent (5 out of 10 samples) of abrasive blasting operators have exposures above the final PEL of 50 $\mu g/m^3$. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

Additional controls for those over-exposed workers include improved maintenance of blasting cabinets, adequate ventilation, and alternative low-silica or silica-free blasting media that is less toxic than silica sand.

Isolation of the operator from the blasting operation can reduce silica exposure during abrasive blasting as demonstrated in a study of silica exposure in granite sheds (Document ID 1225, p. 428). In this study, ventilated blasting cabinets used by three operators in the granite sheds (using either silica sand or an alternate media) generated exposure results of 15 $\mu g/m^3$ to 77 $\mu g/m^3$ with a mean of 41 $\mu g/m^3$ (Document ID 1225, p. 428). These data provide evidence that silica exposure levels associated with granite work in blasting cabinets can be reduced to levels consistently below 50 $\mu g/m^3$ by using silica-free blast media and a combination of other engineering and work practice controls.

These controls include enclosed and ventilated media recycling systems, interlocks to prevent operators from opening doors before the cabinet has been exhausted, and use of high-efficiency particulate air (HEPA)-filtered vacuums instead of dry sweeping or compressed air to clean in and around the cabinet. A well-sealed blast cabinet (a type of containment) isolates a worker from the dust generated inside and the interlock and ventilation systems ensure that the cabinet is free of airborne dust before the operator opens it. Large, glovebox style cabinets for abrasive blasting oversized or awkward shaped objects are available commercially (Document ID 0801, p. 12). Glove boxes/cabinets are enclosed compartments with long, usually elbow-length gloves attached to them, which allow the user to reach inside and manipulate the contents while remaining outside of the sealed cabinet. One manufacturer produces ventilated cabinets that have reportedly been used for abrasive blasting of granite tombstones (Document ID 1693; 0953, p. 1). This size box is interlocked, to prevent operation unless the unit is sealed, and ventilated at 840 cfm. In addition, the boxes are fitted with a dust collector (99.9 percent filter efficiency for 0.3 micron particles available for some models) and a completely enclosed, ventilated media reclamation system. A larger ventilation system is required when two or more of these cabinets are linked together to provide a larger internal workspace (Document ID 0953, p. 3).

For large items that cannot fit in a blast cabinet, improving ventilation to at least the ACGIH-recommended air flow rate of 100 cfm per square foot of face area (equivalent to 5,000 cfm for a 7-by-7-foot booth) have been shown to decrease the exposure to blasting operators to less than 50 μg/m^3 (Document ID 1361, p. 5). Alternatively, using an abrasive blasting booth that includes a partition to separate the operator from the blasting activity (for example roll-up doors with an access slot and window) may provide an additional level of protection, if negative pressure is maintained in the blasting enclosures. For example, ventilated blasting booths used by three operators at a stone monument manufacturer resulted in exposures of less than 50 μg/m^3 (mean of 29 μg/m^3) for all three workers. Silica content ranged from 14 percent to 20 percent. Although the 4- to 6-hour sample times for these exposures are less than full shift, these durations are typical of the industry (Document ID 1361, pp. 3, 5).

In addition, this type of equipment (abrasive blasting booth that includes a partition) was used by two of the three granite working facilities in which NIOSH conducted control technology assessments (Document ID 0218, p. 3; 0240, p. 4). Exposure monitoring data associated with these partitions at one of the sites, however, showed mixed results, with full-shift PBZ exposures of 22 μg/m^3 and 252 μg/m^3 (Document ID 0218, pp. 4, 8). Although investigators indicated that the ventilation system was not operating for part of the sampling period, the available documentation is inadequate to correlate worker exposure and properly operating equipment. This is because the partitions were not evaluated at the other site. Moreover, air pressure and turbulence introduced during blasting might limit the reliability of this control option. Also, the intermittent elevated exposure evident with this style of enclosure (access slot in door) might be better controlled by another commercially available option: a gauntlet glove panel and window that can be inserted into the wall of a walk-in size sealed and ventilated abrasive blast booth (Document ID 0954).

More extensive use of silica-free blast media also might reduce operator exposures. Bauxite can contain up to 10 percent silica and might contribute to worker exposure (Document ID 1365, p. 11-27; 0207, p. 403). Aluminum oxide and steel shot, which also are used as blast media, contain little to no silica (Document ID 3747, p. 14; 2212, p. 4).

Wet abrasive blasting methods are widely available and work well on all structural and most decorative concrete surfaces (Document ID 0733, p. 22). OSHA concludes that wet abrasive blasting is an effective method of controlling dust during abrasive blasting operations. This conclusion is based on a NIOSH study and an OSHA SEP inspection that show a marked decrease in dust levels when compared to uncontrolled, dry abrasive blasting (Document ID 0230; 0497). Wet abrasive blasting would be similarly effective on stone (stone aggregate is a major component of concrete). Abrasive blasters in this application group can use wet methods as an alternative to ventilated process enclosures that separate workers from the abrasive blasting area.

Although the silica exposure levels for abrasive blasting operators performing open-air blasting can exceed OSHA's final permissible exposure limit (PEL), OSHA has existing requirements for abrasive blasting under the Ventilation standard for General Industry (1910.94). The standard requires abrasive blasting operators to wear abrasive blasting respirators approved by NIOSH for protection from dusts produced during abrasive blasting operations. The standard also includes specifications for blast-cleaning enclosures, exhaust ventilation systems, air supply and air compressors, and operational procedures.

4.4.4 Feasibility Finding

Feasibility Finding for Sawyers

Based on the exposure profile in Table IV.4.4-B and other record evidence discussed above, OSHA concludes that the respirable silica exposures of most sawyers can be controlled to levels of 50 μg/m^3 or less most of the time by implementing a combination of engineering and work practice controls. For example, the median full-shift PBZ silica exposure level for sawyers was 30 μg/m^3 at facilities that implemented housekeeping as well as other control measures (enclosing the saw, pre-washing stone, managing slurry, and controlling dust from adjacent processes) (Document ID 1365, p. 11-18; 0042; 0178; 0157). Although these examples are from slate product manufacturers, OSHA concludes that the same controls would be similarly effective in facilities that process granite and other stone since the silica percentage content is similar.

Feasibility Finding for Fabricators

Based on the exposure profile in Table IV.4.4-B and other record evidence discussed above, OSHA concludes that the exposure of most fabricators can be reduced below 50 μg/m^3 most of the time since 61 percent of the fabricators exposures are already below 50 μg/m^3. Silica exposures below 50 μg/m^3 are associated with the use of wet processes and rigorous housekeeping, such as washing or HEPA vacuuming rather than dry sweeping and work surfaces (Document ID 1365, p. 11-21). The sample results for fabricators using water-fed equipment exclusively ranged from less than or equal to 12 to 51 μg/m^3 with a median of 16 μg/m^3 (Document ID 1365, p. 11-20; 0061; 1826; 0156; 0240; 0856). OSHA expects that improved housekeeping will reduce exposures to levels below 50 μg/m^3 since resettled dust contributes significantly to worker exposures in this application group. The most successful exposure reductions have all originated from efforts to complement engineering controls with housekeeping measures, as discussed above (Document ID 1365, p. 11-17; 0046; 0176; 0180; 0157). Controlling water from wet processes prevents dust left by evaporated water from being disturbed and becoming airborne. Managing dust from adjacent operations also helps maintain exposures of fabricators below 50 µg/m^3.

Feasibility Finding for Splitters/Chippers

Based on the exposure profile in Table IV.4.4-B and other record evidence discussed above, OSHA concludes that the silica exposure of most splitters/chippers can be controlled to levels below 50 µg/m^3 most of the time by implementing a combination of engineering and work practice controls similar to those used for sawyers. The combination of rigorous housekeeping, daily floor washing, wetting of the stone before and between operations, and controlling dust from adjacent operations has been shown to be effective for splitters (note the full shift mean respirable silica reduction from 137 µg/m^3 to 19 µg/m^3 at a facility visited by OSHA (Document ID 1365, p. 11-22; 0180, p. 13).

More rigorous controls will also be necessary for some workers, including the 48 percent of splitters/chippers who are currently exposed at levels exceeding 100 µg/m^3. These workers are typically employed at slate facilities and some facilities manufacturing memorials, which will need to install LEV at splitter/chipper stations. A facility using a combination of housekeeping, LEV, and wet methods (constant water flow) to control splitter/chipper exposures reduced the splitter/chipper exposure level to 31 µg/m^3 (Document ID 1365, p. 11-22; 0187). Facilities also might need to improve drainage to allow frequent washing of stone and floors (Document ID 1365, p. 11-24).

Exposure results for splitters/chippers suggest that memorial manufacturers might require supplemental flexible exhaust trunks to ensure that LEV is readily accessible to all points around large three-dimensional products (Document ID 1365, pp. 11-23 - 11-24). Furthermore, those establishments where chipper/splitters use power tools (e.g., pneumatic chipping equipment) will need to implement task-specific controls. Options include tool-mounted water-fed or tool-mounted LEV devices as described by NIOSH

(Document ID 0838, p. 2; 0865, pp. 2-4). These controls are discussed in more detail in Section IV-5.5 – Jackhammers and Other Powered Handheld Chipping Tools in this technological feasibility analysis.

Feasibility Finding for Machine Operators

Based on the exposure profile in Table IV.4.4-B and other record evidence discussed above, OSHA concludes that stone product facilities can achieve silica exposure levels of 50 μg/m^3 or less for most machine operators in this application group most of the time. Thirty percent of machine operators already experience exposures below this level. OSHA finds that by using a combination of controls the exposures for the remaining 70 percent of workers in this job category can also be reduced to 50 μg/m^3 or less (Document ID 1365, p. 11-17; 0042; 0178; 0157). Appropriate controls include enclosing machines, adding exhaust ventilation close to the point where dust is generated, converting to water-fed equipment, and rigorous housekeeping, as well as frequently washing stone and floors (Document ID 1365, p. 11-25).

Incremental improvements will reduce exposures sufficiently for some workers; however, to consistently achieve levels of 50 μg/m^3 or less, OSHA anticipates that a facility may have to employ the full extent of available controls. For example, a facility visited by OSHA implemented procedures to pre-wash stone, controlled dust from other operations, and enclosed trimmers in exhausted plastic housing. After the modifications, exposures were reduced from a mean of 179 μg/m^3 to 65 μg/m^3. The facility did not modify the equipment to include a water delivery system, and the Agency has determined that exposures could have been further reduced if dust originating from the machine was suppressed by water. This determination is based on the exposure reduction obtained at a slate-working establishment, which exhausted the machine at the point where dust was generated, pre-wet the stone, installed spray mister nozzles to keep the stone wet, and took steps to reduce dust released from the adjacent saws. Under these conditions, the operator exposure level dropped from 220 μg/m^3 to 26 μg/m^3 (Document ID 1365, p. 11-25; 0178; 0187). OSHA expects that similar reductions in exposures to machine operators can be replicated in other stone product facilities if similar combinations of controls are also used.

Feasibility Finding for Abrasive Blasting Operators

Based on the exposure profile in Table IV.4.4-B and other record evidence discussed above, OSHA concludes that the exposure of most abrasive blasting operators can be controlled to levels of 50 μg/m^3 or less most of the time through the use of HEPA-filtered vacuum cleaning and sealed, ventilated, and interlocked blasting cabinets. These controls are appropriate for small to medium-size stone objects, including all modestly sized memorials. Properly maintained blast cabinets can offer complete isolation from exposures and are commonly used for this purpose. For example, ventilated blasting cabinets used by three operators in granite sheds (using either silica sand or an alternate media) generated a mean exposure result of 41 μg/m^3 (Document ID 1365, p. 11-26; 1225, p. 428). Although a high result of 77 μg/m^3 was recorded by these investigators, OSHA expects that exposure levels associated with blasting cabinets can be reduced to levels consistently below 50 μg/m^3 by using silica-free blast media that is less toxic than silica sand or a combination of other engineering and work practice controls. These controls include enclosed and ventilated media recycling systems, interlocks to prevent operators from opening doors before the cabinet has been exhausted once blasting is complete, and use of HEPA-filtered vacuums instead of dry sweeping or compressed air to clean in and around the blasting cabinet (Document ID 1365, pp. 11-26 - 11-27).

For larger stone objects, OSHA believes that ventilated blasting booths (with partitions) might be used to control exposures to levels of 50 μg/m^3 and below. For example, ventilated blasting booths used by three operators at a stone monument manufacturer resulted in exposures of less than 50 μg/m^3 (mean of 29 μg/m^3) for all three workers. Although the 4- to 6-hour sample times for these exposures are less than full shift, these durations are typical of the time spent performing abrasive blasting in this application group (Document ID 1361, pp. 5-6). Although the silica exposure levels for abrasive blasting operators performing open-air blasting can exceed OSHA's new PEL, OSHA's has existing requirements for abrasive blasting under the Ventilation standard for General Industry (1910.94). The standard requires abrasive blasting operators to wear abrasive blasting respirators approved by NIOSH for protection from dusts produced during abrasive blasting operations. The standard also includes specifications for blast-cleaning enclosures, exhaust ventilation systems, air supply and air compressors, and operational procedures.

Overall Feasibility Finding

Based on the best available information in the record, including submitted comments, testimony, and exposure data, OSHA concludes that most cut stone product manufacturers can achieve exposure levels of 50 μg/m^3 or less for most operations, most of the time, using the engineering controls and improved housekeeping methods described in this section. Where exposure currently exceeds 50 μg/m^3, additional controls include wet methods, including water delivery systems at the point of operation along with slurry management, LEV, enclosures, and rigorous housekeeping. In sum, OSHA concludes that the final PEL of 50 μg/m^3 is technologically feasible for the Cut Stone and Stone Products industry.

4.5 DENTAL EQUIPMENT AND SUPPLIES

4.5.1 Description

Some manufacturers of dental equipment and supplies produce silica-containing restorative materials, porcelains, plasters, and refractory investment (ceramic molding) materials[32] for use by dentists or dental labs. These materials can contain up to 100 percent silica in the form of quartz, cristobalite, or both. Some dental supply manufacturers also operate small sand casting foundries, using silica sand to produce ingots of dental metal alloys (Document ID 1365, pp. 17-1 – 17-2). Producers of supplies and equipment for dental offices and laboratories are classified in the six-digit North American Industry Classification System (NAICS) code 339114, Dental Equipment and Supplies Manufacturing.

Workers at dental equipment and supply manufacturers (production operators) receive, blend, and package silica-containing restorative materials, porcelains, plasters, and refractory investment materials. Dry, powdered quartz or cristobalite is typically received in bulk (50-pound bags up to tanker trucks), ready for blending. Large scale operations use automated processes such as pneumatic materials transfer systems, while workers in low-volume operations manually empty sacks of materials into hoppers or use handheld scoops to transfer materials from bags to weighing equipment. Production operators add silica-containing ingredients and other dry, viscous, or liquid ingredients from hoppers or weighing equipment to mixing tanks where the products are blended. Once blended, the materials move to filling and packaging operations, where worker activities vary from monitoring fully automated, mostly enclosed machinery to manual dispensing. Manual dispensing involves placing buckets under spouts or putting bags on filling nozzles, with workers standing within arm’s length of the packaging equipment (Document ID 1720, p. IV-114).

[32] Investment molding material are used in investment casting which is a form of metal casting that involves enclosing a three-dimensional pattern in a heat-resistant ceramic mold called investment material. Lost-wax casting is an example of a type of investment casting commonly used in the dental laboratory industry (Document ID 0201).

4.5) Dental Equipment and Supplies

Production operators may be exposed to silica at different points in the manufacturing process, including when dust is released during the transfer of raw materials from delivery vehicles to storage areas or from storage to mixing areas, and during the weighing or metering of raw materials into mixers. Silica exposures may also occur when dust escapes during operation of mixing and filling equipment and when powdered product is compacted into containers. Housekeeping activities, such as dry sweeping and vacuuming of silica-containing materials, can also generate exposures to silica (Document ID 1365, pp. 17-3-17-4).

Workers in dental equipment facilities that produce metal alloys might encounter silica if they use sand molds to cast ingots as part of a small foundry operation. Although the extent of foundry work in the dental equipment and supply industry is unknown, it is likely insignificant (Document ID 1365, pp. 17-2-17-3). For a complete discussion of sand casting foundries, see Section IV-4.8 – Foundries (Metal Casting).

Table IV.4.5-A summarizes the major activities and primary sources of silica exposure for this industry.

Table IV.4.5-A
Job Categories, Major Activities, and Sources of Exposure of Workers in the Dental Equipment and Supplies Manufacturing Industry (NAICS 339114)

Job Category*	Major Activities and Sources of Exposure
Production Operator (blender, compounder, packaging operator)	Preparing and packaging batches of silica-containing restorative materials, porcelains, plasters, and refractory investment materials. • Dust released during transfer of raw materials from delivery vehicles to storage areas and from storage to mixing areas. • Dust released during weighing or metering of raw materials into mixers (from hoppers, by dumping bags, or pouring by hand). Operating mixing and filling equipment, including manual placement of containers on filling equipment. • Dust escaping from mixing/blending equipment. • Dust escaping from packaging equipment used to fill product containers (envelopes, bags, barrels). • Dust disturbed during use of vibrating equipment used to compact powdered product in containers. Housekeeping • Dry sweeping and vacuuming silica-containing materials.

* Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility.
Source: Document ID 1720, p. IV-115.

For each of the job categories listed in Table IV.4.5-B and for dental equipment and supplies industry as a whole, OSHA concludes that Table IV.4.5-B represents baseline conditions.

4.5.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.5-B includes 5 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for workers in the dental equipment and supplies manufacturing industry. The median is 12 μg/m^3, the mean is 68 μg/m^3, and the range is 10 μg/m^3 (the limit of detection (LOD)) to 214 μg/m^3. Table IV.4.5-B shows that, of the 5 samples, 2 (40 percent) exceed 50 μg/m^3 and 1 (20 percent) exceeds 100 μg/m^3. Available exposure information from the PEA for production operators was limited to only three personal breathing zone (PBZ) samples: two obtained from an OSHA Special Emphasis Program (SEP) inspection report of a dental materials supplier that blends and packages dental investment powders used for casting, and one from an interview with a manufacturer of silica-containing dental restorative material (Document ID 0043, pp. 43-44, 52-53; 0620). The rulemaking record provides two additional sample results, from OSHA Information System (OIS) inspection data, that OSHA has added to this analysis. The additional samples were from a single inspection, and both silica exposures were below the LOD (Document ID 3958, Rows 274, 275).

Sixty percent (3 out of 5) of the sample results are less than the final rules permissible exposure limit (PEL) of 50 μg/m^3.

Interviews conducted by OSHA and ERG, OSHA's contractor, with three dental equipment and supplies facilities indicate that local exhaust ventilation (LEV) was available on mixing and packaging equipment at all three facilities (Document ID 1720, p. IV-116). The manufacturer of silica-containing dental restorative material, discussed earlier, blends a silica-containing powder with other ingredients to form a paste product. This manufacturer has already achieved consistently low silica exposures, including a full-shift exposure level of 10 μg/m^3, through a combination of careful work practices, LEV at the weighing station, an air-tight cover on the mixer, and a hood/enclosure and conical exhaust trunk for hand-scooping of material from a raw materials bag to a weigh bucket (Document ID 1720, p. IV-116; 0620).

The two exposure sample results in the exposure profile (Table IV.4.5-B) that exceeded the new PEL of 50 µg/m^3 were collected in October 1994 at a dental investment materials supplier that had poorly designed LEV and inadequate work practices. LEV was positioned so the worker was between the LEV and dust generated by mixer charging, exhaust hoses had excessively sharp bends that potentially restricted exhaust airflow, and workers reportedly routinely spilled material. The respirable quartz levels associated with these conditions were 90 µg/m^3 and 214 µg/m^3 (Document ID 1720, p. IV-116; 0043, pp. 43-44, 52-53).

This facility made improvements in LEV, work station design, and work practices. Short-term samples taken before and after implementation of the improvements showed a dramatic reduction in exposures (Document ID 1720, pp. IV-115, IV-118). Since these samples were all less than 360 minutes in duration, OSHA did not include them in this exposure profile (see Sections IV-1 – Introduction and IV-2 – Methodology of this FEA). The improvements, however, and the resulting decreases in exposure, are described below in the discussion of additional controls.

For the two samples added to the profile from OIS, no description of work activities is available and the ventilation described is general dilution ventilation (Document ID 3958, Rows 274, 275).

Supplemental Data

The UAW, which represents workers at dental equipment and supplies manufacturing facilities, provided comments that included 519 exposure sample results from a plant that produced refractory materials for the dental industry. The UAW described the data in its comments, noting that 481 of the results (approximately 94 percent) were below the final rule's action level of 25 µg/m^3, and fewer than 4 percent of samples exceeded the PEL of 50 µg/m^3 (Document ID 2282, Attachment 1, pp. 1-14; Attachment 3, pp. 7-8). The UAW concluded that the evidence "shows that 25 µg is feasible in dental equipment manufacturing" (Document ID 3582, Tr. 1874; 2282, Attachment 3, p. 12). OSHA reviewed the data submitted by the UAW and agrees that the job descriptions are consistent with dental equipment manufacturing operations related to refractory handling. The Agency also agrees that the data appear to show a trend toward lower exposure levels, with exposures exceeding 50 $\mu g/m^3$ reported less frequently over the years covered by this dataset (1994-1997).

The data submitted by the UAW, however, are of limited use for the purposes of incorporating this data into the exposure profile. The 519 data values appear to represent a smaller number of air samples, each analyzed for three silica “hazard” types, labeled Q, C, and T, with the result for each hazard type reported separately rather than as total crystalline silica for each sample number. (OSHA notes that Q, C, and T could be interpreted as quartz, cristobalite, tridymite, although OSHA is unable to confirm this from the available documentation) (Document ID 2282, Attachment 1). These data could not be incorporated into the exposure profile because certain key data descriptors, including sampling duration and whether the exposure values present the concentrations for each “hazard” as 8-hour TWAs or in another form, were lacking. Nevertheless, OSHA concludes that the data provided by the UAW appear to support OSHA’s exposure profile with the vast majority of the exposures below the action level and shows that silica exposures are routinely at low levels in dental equipment and supplies manufacturing facility.

In fact, these data from the UAW suggest that OSHA’s exposure profile (Table IV.4.5-B) might overestimate silica exposures for workers in this industry. OSHA notes that four of the five samples in the exposure profile were drawn from OSHA inspections, which tend to measure the most highly exposed workers and are likely to overestimate median and mean exposures. Flanagan et al. (2006) illustrated this trend in a large set of silica data from the construction industry (Document ID 0677, p. 146). OSHA concludes that current worker exposures in this industry are no higher than those presented in the exposure profile (Table IV.4.5-B) and likely are routinely lower.

Table IV.4.5-B
Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Dental Equipment and Supplies Industry (NAICS 339114)

	Exposure Summary			**Exposure Range**		**Exposure Profile**				
Job Category	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**	**<25 (μg/m³)**	**≥25 and ≤50 (μg/m³)**	**>50 and ≤100 (μg/m³)**	**>100 and ≤250 (μg/m³)**	**>250 (μg/m³)**

4.5.3 Additional Controls

The exposure profile in Table IV.4.5-B shows that 40 percent (2 out of 5 samples) of production operators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

The exposure profile indicates that silica exposure levels for 60 percent (and, according to the UAW, up to 96 percent) of all production operators are already 50 μg/m^3 or less. To achieve this level for the remainder of production operators, dental supply manufacturers will need to use a combination of improvements or upgrades in existing LEV systems and improved work practices to reduce the amount of silica dust that becomes airborne.

Controls such as those used effectively by the manufacturer of silica-containing dental restorative material, described in the preceding section on baseline conditions, could be implemented by those facilities that have not yet achieved exposures below 50 μg/m^3. This dental restorative material facility achieved consistently low silica exposures, including a full-shift exposure level of 10 μg/m^3, through a combination of careful work practices, LEV at the weighing station, an air-tight cover on the mixer, and a hood/enclosure and conical exhaust trunk for hand-scooping of material from a raw materials bag to a weigh bucket (Document ID 0620).

The investment materials manufacturing facility described earlier, which was evaluated by OSHA compliance and consultation officers, achieved a reduction in median exposures from 430 μg/m^3 to 31 μg/m^3, with maximum exposures reduced from 885 μg/m^3 to 66 μg/m^3 based on short-term results. Prior to the improvements, OSHA obtained three short-term results of 885 μg/m^3, 430 μg/m^3, and 372 μg/m^3. After the facility implemented the improvements listed below, OSHA obtained five more short-term silica samples results below the LOD (24 μg/m^3, 26 μg/m^3, 29 μg/m^3, 32 μg/m^3, and 40 μg/m^3) and one short-term result of 66 μg/m^3 during two visits to the facility. The median for these final six results is 31 μg/m^3. Although these data represent samples collected over less than four hours, and the samples therefore were not included in the exposure profile, OSHA believes that the data demonstrate the success of the improvements in exposure controls (Document ID 1720, p. IV-118; 0043). Worker exposures dropped dramatically when the facility:

- Improved LEV systems, including:
  - Use of enhanced hood designs;
  - Realigned ventilation exhaust points to improve capture;
  - Improved duct angles and upgraded exhaust fans;
  - Reduced leaks in the mixer and packaging systems and enclosed a portion of the packaging operation;
  - Added High-Efficiency Particulate Air (HEPA)-filtered exhaust to a bag dumping station;
  - Added a partially enclosed and ventilated sleeve at the mixer charging port (to contain ingredients during mixer charging);
- Changed workstation designs to limit the drop distance for empty raw material bags (a source of dust) and reduce product overflow from packaging activities;
- Encouraged work practices that minimized spilled material and maintained the LEV between the workers' breathing zone and the point where dust was released; and
- Improved housekeeping, using a sweeping compound to reduce dust during all clean-up activities (Document ID 1720, p. IV-118; 0043).

The two exposures above the new PEL of 50 μg/m^3 in Table IV.4.5-B are from a dental material blending operation that involved dumping bags of silica-containing material into a mixing machine. Blending and mixing operations in this industry are typical of mixing operations in any manufacturing industry that require powdered raw materials to be handled and mixed prior to processing. These operations may require properly designed bag dumping stations with LEV to control silica dust. The effectiveness of ventilated bag dumping stations, equipped with integrated bag disposal and compaction, in reducing exposures to below the new PEL has been demonstrated in a paint manufacturing facility's mixing process (Document ID 0199, pp. 4, 6, 7, 11), and in a NIOSH engineering assessment of a bag dumping station (Document ID 1369, p. 1). OSHA expects such ventilated bag dumping stations to be equally effective in the dental equipment and supplies industry, which uses similar equipment for similar tasks. Such systems are commercially available (Document ID 1224).

4.5.4 Feasibility Finding

Based on the exposure profile in Table IV.4.5-B and other record evidence discussed above, OSHA concludes that, by implementing a combination of controls that reduce the amount of dust that becomes airborne and using LEV to capture dust that is released, manufacturers of silica-containing dental equipment and supplies can achieve the final PEL of 50 $\mu g/m^3$ or less for most workers, most of the time.

Such controls include installing ventilation systems or improving existing systems (at bag dumping stations, weighing and mixing equipment, and packaging machinery) and designing workstations to minimize opportunities for silica-containing materials to spill, fall, or drop (*e.g.*, adding a sleeve to guide raw materials into an open mixer). Additionally, it will be necessary for facilities to ensure that workers properly use the LEV systems and to encourage work practices that minimize spills and release of airborne silica dust. Accordingly, OSHA finds a PEL of 50 $\mu g/m^3$ is technologically feasible for the Dental Equipment and Supplies industry.

4.6 DENTAL LABORATORIES

4.6.1 Description

Dental laboratories use silica-containing materials as a component of dental appliances (crowns, bridges, orthodontic appliances, and dental prostheses), in mold materials for casting dental appliances, and as an abrasive material for finishing these products. Dental laboratories are classified in the six-digit North American Industry Classification System (NAICS) 339116, Dental Laboratories.

Dental technicians produce custom dental appliances, first by constructing plaster models from dental impressions, and then using these models as templates to make molded metal, plastic, or ceramic castings. The major tasks in dental product manufacture that involve potential silica exposure include plaster model and mold production, investment casting[33] using ceramic mold materials, and finishing of metal castings and coating dental appliances with porcelain enamel. Table IV.4.6-A summarizes the major activities and primary sources of silica exposure in this industry.

[33] Investment casting is a form of metal casting that involves enclosing a three-dimensional pattern in a heat-resistant ceramic mold called investment material. Lost-wax casting is an example of a type of investment casting commonly used in the dental laboratory industry (Document ID 0201).

Table IV.4.6-A Job Categories, Major Activities, and Sources of Exposure of Workers in Dental Laboratories (NAICS 33911)	
Job Category*	**Major Activities and Sources of Exposure**
Dental Technician	Constructing plaster models of dental impressions. • Manual mixing of plasters, some of which can contain silica (e.g., 30% quartz). • Molding and grinding of dry plaster models. • Casting of dental products using plaster models. • Dry sweeping or using compressed air to clean work areas. Using investment casting techniques to produce metal dental appliances. • Manual mixing of powdered investment material containing up to 70% silica as quartz and cristobalite. • Breaking investment materials to release metal castings. Finishing cast metal appliances. • Grinding metal castings to remove adhered investment material. • Abrasive blasting of castings to remove embedded investment material (typically in a ventilated glove box). Applying and finishing porcelain coatings on dental appliances. • Grinding and polishing porcelain coatings. • Abrasive blasting of porcelain coatings (typically in a ventilated glove box).
*Job categories are intended to represent job functions; actual job titles may differ and responsibilities may be allocated differently, depending on the facility. Source: Document ID 1365, p. 6-2.	

For each of the job categories listed in Table IV.4.6-A and for dental laboratories as a whole, OSHA concludes that Table IV.4.6-B represents baseline conditions.

4.6.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.6-B includes 36 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for workers in the dental laboratory industry. The median is 10 μg/m^3, the mean is 14 μg/m^3, and the range is 5 μg/m^3 (the limit of detection (LOD)) to 58 μg/m^3. Table IV.4.6-B shows that, of the 36 samples, 1 (3 percent) exceed 50 μg/m^3 and none exceed 100 μg/m^3. Available exposure information for dental technicians used in preparing the PEA consisted of 31 full-shift personal breathing zone (PBZ) silica results from 14 dental labs; one was provided by the OSHA contractor ERG, and the other 13 by the New Jersey Department of Health and Senior Services (NJDHSS) (Document ID 0201, pp. 11-12; 0913, pp. 3-15). The rulemaking record provides five additional sample results, from OSHA Information System (OIS) inspection data, that OSHA has added to this analysis. The samples were from two inspections – four exposures were below the LOD,[34] while a fifth, at 48 μg/m^3, was below the new permissible exposure limit (PEL) of 50 μg/m^3 (Document ID 3958, Rows 140, 141, 142, 143, 313). The controls in the sampled activities were all described as using general dilution ventilation and local exhaust or “process enclosed/ventilated cab or booth.” The highest exposure of 48 μg/m^3 was taken on a technician during activities described as a “Grind in / Contour Tech” performing shaping and contouring bridge and crown work using a micropencil air abrasive unit, lathe with guard and air suction, enclosed/ventilated process, and general dilution ventilation. Sampling results for the “Grind in/Contour Supervisor” performing grinding and contouring work in the same facility and using the same controls were below the limit of detection. The supervisor’s respirable dust exposure was slightly higher; however, no silica was detected in the sample. Activities described in the other samples included, but were not limited to, casting, grinding, polishing, and metal finishing.

Ninety-seven percent of the sample results are less than the revised PEL of 50 μg/m^3, with 21 (58 percent) below the LOD. While silica continues to be present in dental laboratories, the work practices and controls currently in use produce exposures less than 50 μg/m^3 the vast majority of the time.

The baseline conditions for this group of workers typically include the use of local exhaust ventilation (LEV) such as positionable ventilated hoods and enclosures on work benches; enclosed, ventilated equipment for abrasive blasting (i.e., a ventilated glovebox); and ventilated or water-fed grinders (Document ID 0201, pp. 12-14; 3958). These controls, together with the small amounts[35] of silica-containing materials handled and the short duration of use, result in exposures below the final rule’s action level of 25 μg/m^3 for 83 percent of workers. This finding is consistent with a Korean study by Kim et al. (2002) that showed sample means less than 25 μg/m^3, with a sample maximum of

[34] Results reported as “none detected” are assigned a value equal to the LOD. The LOD is determined individually for each sample based on the volume of air sampled and the method used to analyze the sample; therefore, the limit of detection varies among samples. See Section IV-2–Methodology for additional information on LODs. For OIS data, a value of 12 μg/m^3 is used as the LOD.

[35] Since dental laboratories produce custom dental appliances, technicians handle and process small work pieces on an individual basis.

51 μg/m^3, for dental technicians working in laboratories equipped with LEV systems (Document ID 0763).

No additional data was submitted to the docket by stakeholders that relate to the feasibility of achieving the revised PEL in dental laboratories. Based on the best available information, OSHA concludes that the vast majority of dental laboratory technicians are currently exposed to silica at levels well below 50 μg/m^3.

Table IV.4.6-B
Respirable Crystalline Silica Exposure Range and Distribution of Results for Dental Laboratories (NAICS 339116, 621210)

Sources: Document ID 1720, p. IV-124; 3958; 0201; 0913.

4.6.3 Additional Controls

The exposure profile in Table IV.4.6-B shows that 3 percent (1 out of 36 samples) of dental technicians have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

OSHA's contractor report noted the potential for dental technicians to be exposed to elevated levels of silica at least occasionally (Document ID 1365, p. 6-4). For that worker and other similarly overexposed dental technicians, improved engineering controls and work practices would be necessary to reduce exposure to below the new PEL. Examples of available controls include installing and using properly designed and operated LEV and enclosures, such as abrasive blasting cabinets and laboratory hoods. For these systems, an important feature is effective filtration of the air discharged from the hoods and blasting cabinets (if not exhausted outdoors) (Document ID 0201, pp. 12-13). The feasibility of implementing improvements to ventilation systems in dental labs was corroborated in hearing testimony by Ms. Diane Matthew Brown of the American Federation of State, County and Municipal Employees (AFSCME), representing workers in dental facilities in public health and university settings, who noted that dental laboratories "are not settings that move.… You can put controls in place" (Document ID 3585, Tr. 3128-3129). Likewise, Mr. John Adams, Vice President of the American Federation of Government Employees (AFGE) Local 2778, representing dental laboratory workers at the Atlanta Veterans Administration hospital, noted that in dental laboratories "when there are not good [silica-free] substitutes, exposure can be reduced by the use of ventilation systems…. used to remove work dust from the work area" (Document ID 1763, p. 3). Mr. Adams also noted that exposures may occur when abrasive blasting cabinets are not installed, maintained, or used properly:

> Leaks in a blasting box can cause exposure. Exposure is also caused by opening the door to the blasting box before the dust had settled. Dust in a blasting box must be removed by a dust collection system to prevent dental lab workers from being exposed to silica (Document ID 1763, p. 2).

ERG (2000) described the effective controls in place in a facility where all five exposure samples were below the LOD (12 μg/m^3), even with use of modeling plaster containing 30 percent silica, and investment casting material containing 70 percent silica (Document ID 0201, pp. 12-15). The controls at this dental laboratory included LEV for mixing, abrasive blasting, and finishing operations, and enclosures and ventilation for mixing dry ingredients, and use of clean blast media for each abrasive blasting session. Other controls used for some tasks in this same facility, which could be used to control elevated exposures that may occur in some dental laboratories, include wet methods for grinding and divesting castings (investment mold breaking), and silica-free abrasive blasting agents (e.g., glass beads, aluminum oxide, walnut shells) (Document ID 0201, pp. 5, 13). Further substitution of non-silica or low silica materials may be possible for abrasive blasting or casting (plaster and investment materials). Mr. Adams of AFGE noted that "materials that contain crystalline silica should be replaced with materials that do not … [such as] aluminum oxide" (Document ID 1763, p. 2). Other silica-free abrasive blasting media used in dental laboratories include walnut shells and glass beads (Document ID 0201, p. 5). In addition to silica-free abrasive blasting media, ERG noted that no silica was detected in the porcelain or die stone materials used at Dental Laboratory A, and stated that "in some cases it may be possible to substitute non-silica or low silica plaster and investment materials for casting" (Document ID 0201, p. 12; 1365, p. 6-10).

Improved housekeeping practices, (i.e., elimination of dry sweeping and compressed air cleaning, and use of high-efficiency particulate air (HEPA) filter-equipped vacuums, daily where necessary) have proven successful in other industries (Document ID 1720, pp. IV-155, IV-157, IV-165). Mr. Adams of AFGE noted the importance of good housekeeping, i.e., that "work areas in the Dental Lab should be kept as free of dust as possible" (Document ID 1763, p. 3).

Based on the best available evidence in the record, OSHA estimates that facilities will need to add or improve controls at the workstations of approximately 3 percent of dental technicians. Where exposures exceed 50 μg/m^3, options for reducing exposure include improved housekeeping (particularly in the areas where refractory molding materials are mixed and the resulting molds broken, and where silica-containing plasters are handled) and work practices, enhanced LEV, use of wet methods, and use of silica-free abrasive blasting agents and non-silica or low silica materials for casting.

4.6.4 Feasibility Finding

Based on the exposure profile in Table IV.4.6-B and other record evidence discussed above, OSHA concludes that dental laboratories can limit the silica exposure during most operations, most of the time, to 50 μg/m^3 or less using currently available technology. The vast majority of dental laboratories currently have effective exposure controls, in that almost all technicians (97 percent) are currently exposed to silica at levels less than 50 μg/m^3, and 83 percent are exposed to levels less than 25 μg/m^3. Accordingly, OSHA finds that a PEL of 50 μg/m^3 is technologically feasible for Dental Laboratories.

4.7 ENGINEERED STONE PRODUCTS

4.7.1 Description

Engineered stone (also called quartz surfaces) is a man-made, composite material comprised mainly of mineral aggregate and resin. Engineered stone products are primarily used as an alternative to granite and other natural rocks for custom countertops although they may be used in other applications such as interior and exterior cladding, table tops, and flooring (Document ID 1365, p. 23-1; 0569, p. 10). Engineered stone product manufacturing is classified under the six-digit North American Industry Classification System (NAICS) code 327999, All Other Miscellaneous Nonmetallic Mineral Product Manufacturing.

The engineered stone discussed in this section is differentiated from other related products, such as manufactured precast concrete, by its very high concentration of silica aggregates and distinctively different production process. The primary component of engineered stone products is ground quartz (usually 93 percent) along with resin, pigments, and other additives (Document ID 0759, p. 2). Other formulations may contain recycled glass or other aggregates and less quartz.

In addition to engineered stone, there are other products made in the United States using a combination of plastic resin and natural stone materials. Cultured marble is an example of a manufactured product that mimics natural stone. OSHA contractors investigated these related industries and found no evidence of silica exposure because these industries use low- or non-silica-containing mineral fillers such as calcium carbonate (Document ID 1365, p. 23-2). Concrete-based products commonly used in outdoor applications are discussed in Section IV-4.3 – Concrete Products.

Instead of the poured mold and curing process utilized for concrete products, engineered stone uses an automated, patented process of vibration, compression under vacuum, and heat to produce engineered stone slabs (Document ID 1365, pp. 23-3-23-4; 0570). Through 2012, only one manufacturer of engineered stone (natural quartz surfaces) operated in the United States under an exclusive rights agreement with the owner of the processing technology (Document ID 1248, p. 1). This is an emerging industry in the

U.S. and OSHA expects that it will continue to grow domestically as engineered stone products grow in popularity among residential and commercial builders and home owners[36] (Document ID 1248, p. 2).

The engineered stone production process begins with receipt of bulk raw materials, primarily ground quartz, bonding resin, and other additives (Document ID 1365, p. 23-2). The raw materials are mixed and processed in a vibro-compression vacuum machine and cured in a constant temperature kiln to produce engineered stone slabs (Document ID 1365, pp. 23-1, 23-3). The slab finishing process includes machine grinding and polishing using wet methods to achieve the desired uniform width and surface finish (Document ID 1365, p. 23-3). The finished engineered stone slabs are shipped to fabrication facilities (covered under Section IV-4.4 – Cut Stone) where they are cut, shaped, and installed (Document ID 1365, p. 23-3).

Workers who might be exposed to silica during the slab production process include production workers who operate automated equipment and perform related activities to support production (e.g., moving bulk materials, collecting samples, cleaning the machines and work areas) (Document ID 1365, p. 23-2; 0650, pp. 1-2).

Material handling and mixing operations are comparable to similar operations in the paint and coatings industry (see Section IV-13 of this technological feasibility analysis) although the engineered stone batch process is more highly automated (Document ID 0650, p. 1; 1365, p. 23-2). Slab finishing is similar to grinding and polishing operations in the cut stone industry (see Section IV-4.4) when wet methods are used. The primary job category, major activities, and sources of exposure for engineered stone products are summarized in Table IV.4.7-A.

[36] The engineered stone industry is well established in other countries, where the product is distributed as a functional substitute for granite. The United States imports more engineered stone than it produces.

Table IV.4.7-A
Job Categories, Major Activities, and Sources of Exposure of Workers in the Engineered Stone Products Industry (NAICS 327999)

Job Category*	Major Activities and Sources of Exposure
Production Worker (equipment operators, (includes material handling. mixing operations, inspections, quality control, maintenance, housekeeping)	Performing intermittent manual production and maintenance tasks (e.g., receiving and storing raw materials, transferring silica-containing raw materials (e.g., ground quartz) from storage to mixing station, performing housekeeping and maintenance). • Dust from manually opening sacks of ground quartz and moving bulk raw materials. • Dust from cleaning and scraping the mixers. • Dust from cleaning baghouse filters, dry sweeping, or using compressed air for cleaning. Monitoring automated processes or engaging in manual process support activities (weighing, dispensing, mixing raw materials; slab finishing). • Dust from raw material transfer stations, hoppers, and mixing stations. • Dust from finishing operations (e.g., cutting, grinding, polishing). • Dust associated with leaks and spills from raw material conveyance ductwork and dust collection systems.

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility.

4.7.2 Exposure Profile and Baseline Conditions

As indicated in Table IV.4.7-A, potential silica exposure occurs among most plant production workers from a variety of work activities that involve possible exposure sources. A review of the OSHA Information System (OIS) database contained silica sampling data for cut stone and concrete products but no specific data on engineered stone (Document ID 3958). In addition, OSHA received no comments or testimony regarding specific exposures in the engineered stone industry. In the absence of silica exposure data and comments on this application group, OSHA relied on the following descriptive information on engineered stone manufacturing and then extrapolated exposure information from analogous operations to estimate exposures for plant production workers. The descriptive information includes personal communications in 2008 between the OSHA contractor Eastern Research Group (ERG) and an individual familiar with a domestic engineered stone manufacturing facility (Document ID 0650). The interview provided information on the production process, various work activities, controls, and worker exposure conditions (Document ID 0650). Additional information on the same facility was obtained from a 2008 interview and follow-up interview of an individual involved in an OSHA compliance inspection at the facility in 2007 (Document

ID 0816; 0817). The company's silica exposure database was reviewed at the time of the inspection and was described as extensive. The individual results, however, are not available for review (Document ID 1365, p. 23-4; 0817, p. 1). OSHA also relies upon silica sample results from analogous material handling and mixing operations, under the production worker category, in the paint and coatings industry (Section IV-4.13) and slab finishing operations in the cut stone industry (Section IV-4.4) to estimate silica exposures in the engineered stone industry. Engineered stone slabs are further processed by fabrication and installation contractors for end users. Fabrication of finished products from engineered stone and natural stone slabs is covered in Section IV-4.4 – Cut Stone.

Information obtained during the interviews and personal communications describes a highly automated production process where many potential silica exposure points are isolated, fully enclosed, or ventilated (Document ID 1365, pp. 23-2-23-4; 0650, p. 1; 0816, p. 1). Ground quartz is received either in bulk by tanker truck or in large sacks and stored in silos or on racks in the material storage room. Bulk quartz is pneumatically transferred to the mixing hoppers while the sacks of quartz must be opened manually before the contents are dumped by crane into mixing hoppers. The hoppers deliver the raw materials to the mixing room and are equipped with manually activated local exhaust ventilation (LEV) systems, which exhaust to a baghouse. The automated mixing and slab production process is isolated in a separate, ventilated room. Workers only enter this room to perform maintenance between run cycles (Document ID 0650, p. 1). The cured slabs undergo automated wet grinding in an enclosed area to produce a uniform slab width (Document ID 0816, pp. 1-2; 0650, p. 2). The slab surface is polished also using wet methods (Document ID 1365, 23-3; 0650, p. 2). Observations during the OSHA compliance inspection indicated that all processing steps are automated, with very little worker interaction (Document ID 0816, p. 1). One commenter supported these observations, stating that the process used in this engineered stone facility is "among the most automated" of the processes used to make these and similar types of products (Document ID 1769).

John Schweitzer of the American Composite Manufacturers Association testified during the silica hearings that manufacturers of highly-silica filled polymer products such as engineered stones have very few employees potentially exposed to silica, and that this exposure usually occurs when workers handle bags of dry silica material (Document ID 3588, Tr. 3932). Based on the information in the record, discussed further below, OSHA concludes that exposures in the engineered stone industry occur when workers manually open bags containing silica, but that exposures can also occur during machine cleaning, housekeeping, and maintenance activities.

Information obtained from the interview of the individual involved in the OSHA inspection indicated that the facility was free of visible dust (Document ID 0816, p. 1). The interviewee stated that the company knew where the few exposure points were that required respirators (Document ID 0816, p. 1). In the follow-up interview, the interviewee stated that employees with silica exposure were limited but that the facility had some overexposures (i.e., above 100 μg/m^3) to silica (Document ID 0817, p. 1). However, in response to an interview question about tasks where silica exposures exceeded the OSHA PEL, the interviewee answered that there were many overexposures but there were also many engineering controls to reduce exposure and respirator use was required in certain areas of the facility (Document ID 0817, p. 2). There is no additional material in the rulemaking record that would permit OSHA to account for this conflicting information, from the same source, on exposure levels.

All of the information about this facility, however, indicated that the company's air monitoring program was extensive and that it identified some silica exposures that exceeded the previous permissible exposure limit (PEL) (Document ID 0650, pp. 1-2; 0817, p. 1). Silica exposures were said to slightly exceed the 100 μg/m^3 PEL in the material storage room (silo storage and baghouse area) (Document ID 0650, p. 1). The company did require workers to wear respirators in the material storage room and when cleaning the baghouse filters (Document ID 0650, p. 1). Workers also wore respirators when performing maintenance and cleaning in the mixing process room (Document ID 0650, p. 1). The number of employees required to wear respiratory protection was estimated to be 10 percent or less of the workforce (Document ID 0817, p. 1). Housekeeping included the use of HEPA vacuums and compressed air and was routinely performed by most production workers. Wet methods were not used for housekeeping

(Document ID 0650, pp. 1-2). Poor maintenance and condition of the baghouse (located inside the material storage room) and ductwork, due in part to the abrasive nature of the quartz, were described and likely contributed to the silica exposures in the material storage room (Document ID 0650, p. 2). Inappropriate housekeeping methods, such as the use of compressed air, also likely contributed to silica exposures in the plant (Document ID 0650, p. 1).

In the Engineered Stone Products section of the Preliminary Economic Analysis, OSHA estimated the median silica exposure level in this industry to be approximately 98 $\mu g/m^3$ respirable dust, or slightly below the then-applicable PEL (Document ID 1720, p. IV-129). This number was based on the percentage of quartz in the product and a general statement that the company's exposure levels were close to the previous PEL. OSHA has concluded that the information in the rulemaking record on silica exposures in this facility is inadequate to support broad conclusions about the company's, much less the industry's, overall exposure levels. In this FEA, OSHA instead draws conclusions about silica exposures based on sampling data from related industries. OSHA concludes that these new estimates represent a more reliable picture of exposures in the engineered stone industry.

To estimate silica exposures of production workers in the engineered stone industry when they are handling and mixing quartz material, silica sampling data on material handlers and mixer operators from the paint and coatings industry were evaluated. The paint and coatings industry was chosen because of the similar practice of adding bulk silica material to the product (see Section IV-4.13 – Paint and Coatings). The percent silica content of engineered stone is likely higher than in paint and coating products and thus may contribute to higher silica exposures in engineered stone workers. However, the percent silica concentrations in samples from the paint and coatings application group were some of the highest – including one sample containing 67 percent silica – in the OIS database (Document ID 3958, Row 238). In addition, information from ERG's visit to a different manufacturer in the paint and coatings industry indicated that up to half the bags of raw materials being handled by workers contained 70 to 93 percent silica (in the form of cristobalite) (Document ID 0199, p. 4). OSHA expects that any underestimate of exposures due to the higher percentage of silica in engineered stone products is offset by the highly automated material handling and mixing operations in engineered stone manufacturing relative to paint and coatings.

The paint and coatings exposure data for material handlers and mixer operators is based on a total of 23 samples derived from two OSHA Special Emphasis Program (SEP) inspection reports, samples taken at two companies in the paint and coatings industry and contained in the OIS database, and an OSHA contractor site visit (Document ID 0105; 0943; 3958; 0199). Material handlers typically perform tasks involving the transfer, weighing, and dispensing of silica-containing raw material. Eleven samples from four paint and coatings facilities were used to characterize material handler exposure. All 11 samples for material handlers are below 25 μg/m^3 (Document ID 3958, Row 532, 533, 534; 0199, pp. 7, 11; 0105). Since material handling in the engineered stone industry is mostly automated, and there is considerable manual handling in the paint and coatings facilities, OSHA concludes that worker exposure to silica would similarly be at or below 25 μg/m^3 in the engineered stone industry.

Mixer operators perform tasks involving the transfer of raw material to mixing stations and machines. This may involve opening bags of material, weighing material, mixing raw material, and pouring material into hoppers. Twelve personal exposure samples from four facilities are used in OSHA's characterization of mixer operator exposure in the paint and coatings industry. Eight of these samples for mixer operators were below 25 μg/m^3, 1 sample was between 25 μg/m^3 and 50 μg/m^3, and 3 samples exceeded the new PEL of 50 μg/m^3 (Document ID 3958, Rows 238, 239; 0199, p. 7, 11; 0943; 0105). While the median exposure level for all 12 mixer operator samples is 13 μg/m^3 (the LOD), all three samples over the new PEL exceeded 200 μg/m^3 (Document ID 3958, Row 238; 0943; 0199, p. 11).

OSHA determined that exposures among material handlers and mixer operators in the paint and coatings industry are due primarily to airborne dust generated as: 1) bags are opened, 2) materials are transferred into hoppers, and 3) empty bags are compressed for disposal. The Agency also determined from a site visit to a paint manufacturer that exposures are higher when LEV is not available (Document ID 0199, pp. 9-10). Sampling data from the OSHA contractor (ERG) site visit in the paint and coatings industry provide clear evidence of how LEV is instrumental in preventing silica exposure in material handling and mixing operations. At this paint manufacturer, material handlers and mixer operators were handling bags of silica-containing material. As many as half the bags contained 70 to 93 percent cristobalite (a form of crystalline silica) and many of the other bags contained up to 30 percent quartz (Document ID 0199, p. 4). Fourteen of fifteen full-shift TWA PBZ samples indicated no measurable levels of respirable quartz or respirable cristobalite (Document ID 0199, pp. 7, 11).[37] Most of the sample results represent a typical, routine work shift, during which the local exhaust ventilation systems were operating (Document ID 0199, pp. 8-9). One sample on a mixer operator, however, found a respirable quartz level of 263 μg/m³ (Document ID 0199, p. 11). The LEV system was not operating for approximately two hours in the morning while this mixer operator added raw materials to the dispersion tanks while producing a paint batch (Document ID 0199, p. 9). The resulting high level of exposure demonstrates how exposure levels can spike when the LEV is not operating and, by negative inference, illustrates the effectiveness of LEV in controlling exposures for material handlers and mixer operators. In another example from the paint and coatings industry of the importance of LEV in controlling silica exposure, an OSHA inspection found a silica exposure of 237 μg/m³ in a sample taken on a mixer operator during a period in which the OSHA compliance officer noted only general dilution ventilation was being used (Document ID 3958, Row 238). Since the mixing area in the engineered stone industry is automated and the mixing hoppers are equipped with LEV, OSHA concludes that the exposures greater than 200 μg/m³ are not representative of the engineered stone manufacturing process; the samples above 200 μg/m³ from a paint manufacturer were taken while workers manually charged an unventilated (or poorly ventilated) mixer (Document 0199, pp. 9-10; 3958, Row 238; 0943). OSHA expects that the exposure levels for mixer operators in engineering stone facilities will ordinarily be below the new

[37] OSHA excluded one of the fifteen samples from its exposure profile, as the laboratory technician does not fall under one of the relevant job classifications of material handler and mixer operator.

PEL of 50 µg/m³, similar to exposure levels for most mixer operators using LEV in the paint and coatings industry.

A number of limitations exist in comparing exposure levels in the engineered stone and paint and coatings industries. An important difference is that the engineered stone industry is a relatively new industry with modern plants that use highly automated material handling and mixing processes, including integrated LEV. The results from the paint and coatings industry reflect considerable manual handling of packaged and bulk raw materials, which increases the exposure risk to material handlers (Document ID 1365, p. 9-9; 0943; 0105). Another difference between these two industries is that because of the highly automated process in engineered stone manufacturing, production workers in this industry do not operate as material handlers or mixer operators on a full time basis. The workers perform a variety of tasks across the production process, including housekeeping (which contributes to the production operators overall exposure). This variety of tasks which results in less time spent in material handling and mixing (Document ID 0650, pp. 1-2).

Slab finishing processes in the engineered stone industry, such as grinding and polishing slabs, can result in worker exposure to silica. These operations are part of the production process and are done by machine using wet methods. The cut stone industry (Section IV-4.4 – Cut Stone) also processes natural stone (granite, etc.) slabs using cutting, grinding, and polishing procedures. The silica content of engineered stone is likely higher than natural stone products and may contribute to higher silica exposures in engineered stone workers. However, the highest percent silica concentration sample in the OSHA OIS database for cut stone was 71 percent respirable silica (Document ID 3958, Row 1084). OSHA expects that any underestimate of exposures in engineered stone facilities due to a higher percentage of silica will be offset by the fact that the engineered stone manufacturing process is better controlled.

To estimate silica exposures from slab finishing operations in the engineered stone industry, OSHA reviewed approximately 85 recent silica samples from the OIS database on fabricators involved in grinding and polishing activities in the cut stone industry

(Document ID 3958). From this sample group, samples where fabricators performed grinding and polishing operations using wet methods were selected, as this closely resembles the wet method controls used in machine grinding and polishing in the engineered stone industry.[38] OSHA eliminated samples involving cutting, samples with no mention of wet methods being used, and samples where handheld tools were used, because these samples did not represent similar exposure conditions to those in the engineered stone industry. The resulting nine samples ranged from 16.4 μg/m³ to 91.8 μg/m³ with a mean silica exposure level of 33.6 μg/m³ and a median exposure level of 27.9 μg/m³ (Document ID 3958, Rows 1015, 1088, 1018, 1004, 1001, 1017, 1003, 1002, 933). The highest silica exposure (91.8 μg/m³) occurred during a granite polishing operation using a wet method (Document ID 3958, Row 933). The sample information also noted the use of fans to move dust from the shop, which may have contributed to this exposure level. Four other samples from polishing operations had silica exposure levels below the new action level of 25 μg/m³ and one polishing sample was between the action level and the new PEL (Document ID 3958, Row 1015, 1088, 1004, 1018, 1003). The remaining three samples were from grinding operations. These results ranged from 27.9 μg/m³ to 39.3 μg/m³, all between the new action level of 25 μg/m³ and the new PEL of 50 μg/m³ (Document ID 3958, Rows 1001, 1017, 1002). Based on these data, OSHA expects that most exposures to silica during wet grinding and polishing operations in the engineered stone industry will be under the new OSHA PEL of 50 μg/m³.

4.7.3 Additional Controls

OSHA finds that, because existing controls in this relatively new and modernized industry likely maintain exposure levels below the final PEL of 50 μg/m³ most of the time, no additional engineering controls are likely to be necessary for most of these operations. The engineered quartz slab manufacturing plant evaluated by OSHA was a new, proprietary-built plant (constructed around 2000) with engineering controls and automated material handling and slab processing machinery designed to minimize dust generation (Document ID 1365, p. 23-7; 0816, p. 1). A comment from a representative of

[38] The use of wet methods by cut stone fabricators is sporadic, as demonstrated in a Washington state study in which only one-third of the fabricating facilities evaluated were primarily using wet methods at the time of the initial visit (Document ID 1146, pp. 578-579).

a distributer of stone-working equipment noted that most large scale or high volume new equipment is being manufactured with dust control in mind and reiterated that most large grinding machines are water-fed and equipped with dust collectors (i.e., LEV) (Document ID 1156). New equipment has the added advantage of increased automation, allowing the production workers to operate at a distance from the dust source.

Production workers in engineered stone products facilities are reportedly exposed to silica from intermittent work activities such as bulk bag opening (material handling), for mixing operations, mixing machine cleaning, compressed air use, and baghouse maintenance (Document ID 0650, p. 1). If additional administrative controls are necessary, they could include an improved method of opening and handling the large sacks of quartz prior to mixing to avoid creating dust. Engineering control technology is being used for most sources of exposure, but poor maintenance and rapid deterioration of the material delivery and exhaust ventilation ducting could result in exposure to airborne silica above the 50 µg/m³ PEL (Document ID 0650, p. 2). A new production line at the engineered quartz slab manufacturing plant discussed above that incorporates (undisclosed) improvements in the design of the line, as well as the use of more durable material in the pneumatic material delivery and local exhaust ventilation systems (ceramic ductwork), will reportedly improve performance of these systems (Document ID 0650, pp. 2-3). The new mixing area, in particular, can further control silica exposures during production operations such as through implementation of improved housekeeping procedures (e.g., eliminating the use of compressed air) and duct work maintenance; however, supporting exposure data are not available to OSHA (Document ID 1365, p. 23-5; 0650, p. 2)

To maintain worker exposures at or below 50 µg/m³, facilities will need to increase inspection and maintenance of pneumatic conveying systems (including the exhaust ventilation system). The extremely hard quartz particles abrade ductwork and eventually damage duct integrity, causing the system to leak. Specific concepts evaluated as improvements to the existing production line include installing new baghouses, replacing ductwork with ceramic piping for pneumatically conveyed raw materials, enhancing housekeeping, and using HEPA vacuums instead of compressed air (Document ID 0650, pp. 1-2). Additionally, as discussed in Section IV-4.4 – Cut Stone, rigorous control of water from wet processes prevents dust from being disturbed and becoming airborne after water evaporates (Document ID 1365, p. 11-21).

A potentially significant source of silica exposure in this industry is the use of compressed air for cleaning and housekeeping purposes. The information obtained during the interviews with a manufacturer described compressed air used for cleaning and listed the raw material storage and baghouse areas as locations where HEPA-filtered vacuums might be an option for cleaning (Document ID 0650, pp. 1-2). OSHA expects that in the engineered stone industry, using HEPA-filtered vacuums to clean surfaces contaminated with quartz dust and eliminating the use of compressed air for this purpose will substantially reduce airborne dust levels in the material handling area of the plant.

4.7.4 Feasibility Finding

OSHA received no comments related to the technological feasibility of the proposed rule for engineered stone manufacturing. Based on the above analysis, OSHA has determined that exposures for most production workers can be kept at or reduced to below 50 $\mu g/m^3$ with existing engineering controls that are operating within manufacturers' specifications and properly maintained. Comparable exposure data from material handling and mixing operations in the paint and coatings industry show 20 of 23 samples (87 percent) below the final PEL of 50 $\mu g/m^3$. Comparable exposure data on grinding and polishing operations in the cut stone industry using engineering controls similar to those in engineered stone manufacturing show 8 of 9 samples (89 percent) below the new PEL of 50 $\mu g/m^3$. OSHA concludes from these data that, with proper engineering controls such as wet methods and LEV, proper housekeeping, and regular maintenance of material delivery and ventilation systems, most exposures in production operations in the Engineered Stone industry where silica exposure is likely to occur can be kept at or reduced to below 50 $\mu g/m^3$ most of the time. Facilities should have a routine schedule for inspecting, maintaining, and replacing worn materials-handling and dust control systems with more durable materials to ensure that raw material conveyance ducts and dust collection systems work efficiently. Even then, because of the high silica content of the raw materials (93 percent quartz), OSHA expects that some workers will continue to experience elevated intermittent exposures during maintenance tasks, particularly in baghouses and raw material storage areas, and while cleaning the mixing machines. OSHA acknowledges that respirator use may be necessary during these short-term tasks to protect workers from exposures above the PEL.

Thus, OSHA concludes that, by controlling exposures to airborne dust generated during engineered stone production work like material handling, mixing, and slab finishing operations, engineered stone operations, most manufacturers can achieve exposure levels of 50 $\mu g/m^3$ or less for most workers, most of the time. Therefore, OSHA finds that the final PEL of 50 $\mu g/m^3$ is technologically feasible for the Engineered Stone Products industry when baseline and additional controls previously discussed are used. Supplemental respirator use may be necessary, however, for some maintenance activities.

4.8 FOUNDRIES (METAL CASTING)

Foundries melt and cast metal in molds to produce precisely formed metal castings, which workers then trim and clean to create finished products. Major end-use markets for these metal castings are manufacturers of automotive parts, pipe, industrial machinery, transportation equipment, and aerospace equipment. Depending on the casting processes used, workers in as many as a dozen foundry job categories work directly with materials that contain silica, including sand used to create molds, refractory mold release agents, furnace linings, and residual sand mold material that adheres to castings and scrap metal (Document ID 1365, p. 2-1).

Workers can be exposed to silica at many points throughout the coremaking or casting process. Table IV.4.8-B provides a list of the job categories and major sources of silica that contribute to workers' exposures. For the purpose of this analysis, OSHA has divided the foundry industry into four subsectors, based primarily on the types of metal and processes employed:

- Ferrous sand casting foundries.
- Nonferrous sand casting foundries.
- Non-sand casting foundries (ferrous and nonferrous).
- Captive foundries.

This division of the foundry industry into ferrous and non-ferrous casting is consistent with how foundries were divided in the Preliminary Economic Analysis (PEA) and is also consistent with the approach to describing the foundry industry presented by the American Foundry Society (AFS) (Document 2379, Attachment 2, p. 42). Non-sand casting foundries were analyzed separately since this type of foundry does not use large quantities of sand containing crystalline silica, and thus has a lower exposure to respirable crystalline silica (RCS). Captive foundries can be either ferrous or non-ferrous casting, but are analyzed separately for economic reasons since these are associated with various manufacturing industries other than foundries.

Ferrous sand casting foundries are foundries that produce molded products from molten iron or steel. They employ a major share of foundry workers potentially exposed to silica and are covered extensively in the first part of this section. Separate discussions are then presented for the other foundry sectors. Table IV.4.8-A shows the four foundry sectors and the associated North American Industry Classification System (NAICS) industries.

Sand casting is used to produce an estimated 60 percent of all cast metal products, both ferrous and nonferrous (Document ID 1460, pp. 27-28). The silica exposure hazards of casting using sand molds are far greater than those of casting methods not involving sand, such as permanent casting and die casting (Document ID 1365, p. 2-1; 1382). Therefore, the discussion in this section focuses on job categories with potential for silica exposure applicable primarily to sand casting foundries.

Among sand casting foundry workers, the workers at ferrous foundries typically have higher silica exposures than workers in other types of metal casting facilities, primarily because the higher temperatures required for melting ferrous metals, such as iron and steel, result in sand molds that are hotter, drier, and hence dustier than in other metal casting facilities (Document ID 1365, pp. 2-1 – 2-2; 0926). Although data from all types of ferrous sand casting foundries (NAICS 331511 and 331513) are included in OSHA's analysis of ferrous sand casting foundries, silica exposures of workers in gray and ductile iron foundries, (NAICS 331511) serve as the primary basis for discussion, since these foundries are the most numerous and the best studied with respect to worker exposure to silica.[39] While the potential for exposure is higher, the recommended controls to reduce workers' exposures in gray and ductile foundries are applicable to other foundries. Therefore, workers in these foundries serve as a basis of comparison for the three other major foundry groups addressed later in this foundry industry analysis.

[39] Gray iron is a type of cast iron known for its high compression strength but low ductility. Ductile Iron is a kind of malleable iron known for its high ductility (ability to deform and high tensile strength).

4.8) Foundries (Metal Casting)

Table IV.4.8-A
Foundry Sector NAICS

Foundry Sector	**NAICS Industries**	**Comment**
Ferrous Sand Casting Foundries	331511, Iron Foundries 331513, Steel Foundries (except Investment)	Foundries in these NAICS industries perform sand casting.
Nonferrous Sand Casting Foundries	331524, Aluminum Foundries, (except Die-Casting)—Part* 331525, Copper Foundries (except Die-Casting)—Part* 331528, Other Nonferrous Foundries (except Die-Casting)—Part*	Foundries in these NAICS industries perform sand casting.
Non-Sand Casting Foundries	331524, Aluminum Foundries, (except Die-Casting)—Part* 331525, Copper Foundries (except Die-Casting)—Part* 331528, Other Nonferrous Foundries (except Die-Casting)—Part* 331512 Steel Investment Foundries	Foundries in these industries do not perform sand casting.
Captive Foundries	Various manufacturing industries	Foundries in this sector perform metal casting as part of a parent company's operations. Captive foundries can be either sand casting or non-sand casting foundries

* "Part" included in the notation means that only part of this NAICS group is included in the indicated foundry sector, while the remainder of the group is included in another foundry sector. For example, some of the aluminum foundries in NAICS 331525 perform sand casting (placed in the non-ferrous sand casting foundry sector) and the remainder performs non-sand casting (in the non-sand casting foundry sector).

4.8.1 Ferrous Sand Casting Foundries

Description – Ferrous Sand Casting Foundries

The metal casting industry is diverse, employing many different casting processes for a wide variety of applications. The production of castings using sand molds includes the following basic processes: 1) preparing a mold, and often a central core; 2) melting and pouring the molten metal into the mold; and 3) cleaning the cooled metal casting to remove molding and core material and extraneous metal (Document ID 1368, p. 3). The sand molds are formed using moist sand created by mixing sand and clay. This malleable mixture is termed "green" sand.

The volume, size, and type of castings produced vary widely from one foundry to another, ranging from a few large specialized castings to thousands of small castings per shift. Depending on the size of the foundry, operators might be responsible for a single task or several tasks. In high-production foundries, workers are likely to be responsible for a single task (e.g., molder, core maker, shakeout operator), whereas in small shops a single worker might be assigned to several operations, such as combined responsibilities for furnace operation, hot metal transfer, and pouring (Document ID 1365, pp. 2-11 – 2-12; 1382).

Table IV.4.8-B presents a summary of the job categories, major activities, and primary sources of silica exposure of workers in sand casting foundries. For detailed descriptions of jobs, see Document ID 1365, pp. 2-11 – 2-95. The list of job categories presented in Table IV.4.8-B was developed based on review of more than 50 case files, numerous site visits conducted by the OSHA consultant, Eastern Research Group (ERG), and a variety of reports issued by NIOSH (Document ID 1365, p. 2-15). The categories are consistent with the exposure data presented by the American Foundry Society (AFS). In fact, of the over 8,000 exposure measurements described by AFS, 90 percent fall into the job categories listed by OSHA (Document ID 2379, Appendix 1, p. 9).

In addition to the categories listed in Table IV.4.8-B, foundries typically conduct the following operations in which the metal parts are further shaped or treated after they have been formed, unmolded and cooled: pattern-making, welding, arc-air gouging, heat treating, annealing (heat hardening), X-ray inspection of castings, machining, and buffing. However, these operations are not associated with substantial silica exposure and often take place in areas of the foundry that are not associated with sand and the metal molding process. For this reason, they are not discussed in detail in this analysis. Additionally, as described by Frank Mirer, currently at CUNY School of Public Health, who was the Director of Safety and Health at the United Auto Workers (UAW) for 25 years, for many job categories that do not involve working with silica containing materials, the primary source of silica exposure is the cross contamination from silica-emitting processes (Document ID 4204, Attachment 1, p. 31). Therefore, OSHA concludes that, to the extent there is exposure for workers performing these operations, reducing silica exposures from other sources will reduce exposures for these job categories as well.

Table IV.4.8-B
Job Categories, Major Activities, and Sources of Exposure of Workers in Ferrous Sand Casting Foundries

Job Category*	Major Activities and Sources of Exposure
Sand Systems Operator	Controlling processing and mixing of new sand, recycled sand, and mold or core additives in mixer (muller) or sand reclamation equipment. Sand is typically fed via hoppers. Might be batch or continuous. • Dust released during loading of hoppers. • Dust released during sand transport. • Dust raised by using compressed air for cleaning.
Molder	Monitoring molding machine operation. Might apply mold parting/coating compound. • Dust generated by handling dry cores and refractory mold coatings (washes). • Dust raised by using compressed air for cleaning mold surfaces. • Dust released by adjacent operations.
Coremaker	Overseeing transfer of mixed sand and additives to automated coremaking equipment. Cleaning and finishing cores. Applying core coatings. • Dust created by grinding, filing, and sanding cores. • Dust raised by using compressed air for cleaning. • Dust released by adjacent operations.
Furnace Operator	Controlling and monitoring furnaces used to produce molten metal. In small operations, might hand-load metal into furnaces. • Dust generated as furnace emissions. • Dust from molding sand adhered to scrap metal for remelt. • Dust from adding sand to molten metal (e.g., stainless steel). • Dust released by adjacent operations.
Pouring Operator	Transferring molten metal into ladle or holding furnace, then into molds, typically via a crane or monorail configuration. • Dust released by adjacent operations.
Shakeout Operator	Overseeing shakeout operation. Contact with equipment and castings depend on the degree of automation. • Dust generated by agitating, breaking, and separating molds from castings.
Knockout Operator	Removing sprues, gates, and risers (waste metal that is formed as molten metal passes through the cone-shaped conduit needed to fill the mold) from castings. • Dust generated by the use of hammers and saws to remove excess metal from the castings. • Dust released from adjacent operations.

Table IV.4.8-B Job Categories, Major Activities, and Sources of Exposure of Workers in Ferrous Sand Casting Foundries	
Job Category*	**Major Activities and Sources of Exposure**
Abrasive Blasting Operator	Cleaning residual mold or core material from castings typically operating an abrasive blasting cabinet. • Dust generated by performing shotblasting on open floor (if the casting is large) or in blasting booth. • Dust raised by using compressed air for cleaning surfaces. • Dust released from poorly maintained abrasive blasting cabinet. • Dust released form adjacent operations.
Cleaning/Finishing Operator	Removing remaining molding sand from castings. • Dust generated by using portable or bench tools such as chippers, grinders, and polishers. • Dust raised by using compressed air for cleaning surfaces.
Material Handler	Transporting sand, castings, or other materials using a front-end loader, forklift, or other material moving equipment. • Dust generated when adding or removing materials from the sand system. • Dust raised by manually sweeping or shoveling dry sand. • Dust raised by using compressed air for cleaning surfaces. • Dust released from adjacent operations.
Maintenance Operator	Repairing and maintaining foundry and sand-handling equipment. Might perform repair and maintenance of refractory furnace linings. • Dust released during repair and maintenance of equipment. • Dust generated during removal of old refractory linings using hammers, pneumatic chisels, and jackhammers. • Dust released from adjacent operations.
Housekeeping Worker	Removing spilled sand and debris from floors, conveyor discharges, abrasive machines, and dust collectors. • Dust raised during dry sweeping, vacuuming, shoveling, or front-end loader operations.
*Job categories are intended to represent job functions; actual job titles may differ and responsibilities may be allocated differently, depending on the facility. Source: Document ID 1365, p. 2-13.	

Ferrous Sand Casting Foundries—Exposure Profile and Baseline Conditions

To develop the exposure profiles for these job categories, OSHA compiled the best available data from all identified industrial hygiene literature that included sample information, and exposure monitoring conducted at selected site visits, using only information from 1990 to the present. OSHA relied on OSHA Special Emphasis Program (SEP) inspection reports, NIOSH reports, reports from state programs that performed workplace evaluations, and from OSHA Information System (OIS) data ranging from 2010 through 2014 (Document ID 1365, pp. 2-15 – 2-17; 3958).

The exposure profile for ferrous sand casting foundries appears in Table IV.4.8-E. The profile includes a total of 838 full-shift (8-hour) personal breathing zone (PBZ) samples, covering the twelve distinct job categories in Table IV.4.8-B. The overall median exposure is 58 μg/m^3, the mean is 131 μg/m^3, and the range is 6 μg/m^3 (LOD) to 5,851 μg/m^3. Of the 838 samples, 457 (54.5 percent) are above 50 μg/m^3, and 244 (29.1 percent) exceed 100 μg/m^3.

In their comments, AFS identified 11 of the foundries contained in the case studies used in this analysis. Five of these foundries are now out of business. AFS argues that OSHA should disregard data from defunct establishments when establishing feasibility. Furthermore, AFS believes that these defunct foundries can be used as examples to provide evidence of infeasibility (Document ID 4229, p. 17).

OSHA disagrees with AFS's assertions that the sampling data from these foundries should be disregarded. The AFS provided no explanation to support its assertion that these foundries went out of business as a result of being required to comply with the previous PEL. In addition, the exposure profiles are intended to be representative of the range of exposures in the foundry industry, and these foundries likely represent working conditions in foundries that that have not ceased operations, and should be included in OSHA's exposure profile. OSHA concludes that the case studies – even those representing establishments that are no longer operating – provide useful information on the job processes and resulting exposures, because the same activities continue to occur in other foundries. Furthermore, the 63 samples from these five foundries represent less than 5% of the 1267 samples from over 98 foundries included in the exposure profiles for the foundry industry, and therefore, removing or retaining these samples does not significantly alter the exposure profile.

The UAW submitted summary data that show geometric mean exposures at two foundries. Data from the first foundry, the General Motors Defiance foundry, show that geometric mean exposures remained below the previous PEL from 1998 through 2013, except for one year (Document ID 4031, Attachment B2). The second data set, from the General Motors Saginaw foundry, shows that geometric mean exposures remained below the previous PEL from 1998 through 2013 (Document ID 4031, Attachment E2). OSHA has not incorporated this data set in the exposure profile because individual personal breathing zone (PBZ) samples and job descriptions were not provided. However, while the data from this set tend to show slightly lower exposures than in OSHA's profile, the range of exposures is consistent with OSHA's data.

AFS also submitted to the record a survey it conducted to which 92 establishments, involving more than 8,000 workers, responded (Document ID 2379, Attachment 2, p. 27). These data show that 50 percent or more of the samples in 12 of the 13 job categories identified by AFS are below the 50 μg/m^3 PEL, which indicates that a PEL of 50 μg/m^3 is feasible for most of these job categories. AFS argues that "OSHA's data are 10 to 35 years old and significantly overstate current exposures," and that "the number of current workers exposed to levels of silica above 100 μg/m^3 is less than half of the number OSHA uses in the PEA" (Document ID 2379, Attachment 2, p. 27). As discussed further below, OSHA has updated the data used in the final exposure profile although, as in the case of the UAW data, OSHA has not included AFS data in the final exposure profile because individual PBZ results were not provided.

OSHA reviewed the AFS survey data that was submitted to the record and compared that data to exposure data from the PEA exposure profile and the more recent data from OSHA's OIS database (see this comparison in Table IV.4.8-C below). The more recent OIS data, which is from 2010 through 2014, and the AFS survey data indicate that exposures generally continue to be reduced in the foundry industry.

Table IV.4.8-C

* PEA and OIS data correspond to ferrous sand casting foundries.
** AFS did not specify the distribution of which types of foundries responded to the survey
Sources: Document ID 3958; 1720, p. IV-136; 2379, Attachment 2, p. 27.

Additionally, the AFS provided an analysis for the difference between the exposure profile presented in the PEA and the summary data from the AFS survey. AFS states (Document ID 2379, Attachment 2, p. 27):

> The difference between the older OSHA enforcement data and the current foundry data not only reflects continued efforts to reduce exposures, but also reflects a significant bias in the OSHA data. One reason for this is that OSHA uses high bias data from enforcement. There is a tendency for compliance officers to sample employees whose exposure is perceived to be the highest. Follow up sampling tends to be focused where problems have been found, so the sample database is further skewed toward higher exposures rather than a non-biased statistical sample. These sample data are not random and are not statistically representative.

OSHA agrees with AFS that the exposure profile from the PEA may overestimate exposures, as the OIS data also shows. For consistency, OSHA used only individual measurements in the exposure profiles. Given the absence of individual sample results in the AFS data, OSHA has relied upon the data from the PEA and augmented it with data from OIS and from the rulemaking record when the data included individual data points and sample descriptions. Nonetheless, the AFS data is useful to the agency in supporting its overall finding that a PEL of 50 μg/m^3 is technologically feasible for the foundry industry.

As the AFL-CIO noted regarding the AFS survey, "[t]he AFS data state that 67 percent of foundry operations, weighted for job distribution, are now below the 50 μg/m^3 PEL. This would appear to be 'most of the operations,' a criterion for feasibility" (Document ID 4204, p. 29). OSHA agrees with the assessment from the AFL-CIO that the AFS data indicate that, overall, exposures are already predominantly below the final PEL.

In addition to its own enforcement data, for this final exposure profile OSHA is also relying on data collected by NIOSH, individual States' evaluations, and the stakeholder public which constitute the entirety of publicly available and submitted data. To make the final exposure profile as representative as possible, and based on the stakeholder comments, OSHA has, in accordance with its general methodological approach to final exposure profiles, (see Section IV-2 – Methodology) modified the exposure profile for foundries to remove older exposure data and update the profile with more recent data available in the record. Thus, all samples collected prior to 1990 – a total of 154 samples – have been excluded from the final profile. The more recent OIS data, constituting 266 samples collected between 2010 and 2014, were added to the final profile.

In Table IV.4.8-D, OSHA has provided a new comparison of the data submitted by AFS and the final exposure profile. While the OSHA profile still tends to overestimate exposures compared to the AFS data partly due to the enforcement bias of the OIS data as discussed above, OSHA is convinced, based on the entirety of the rulemaking record, that its profile is a reasonable representation of the current exposures.

Baseline working conditions vary among facilities, and industries use a variety of controls, ranging from no controls to comprehensive facility-wide control strategies. As a result, foundries experience a wide range of exposures. Baseline conditions can be described by the distribution of exposures for each job category.

Table IV.4.8-D below shows that despite uncertainties in the biases inherent in the AFS survey data, the final exposure profile in the Final Economic Analysis (FEA) likely overestimates exposures in comparison to the AFS survey data. Comparison of the exposure data in the FEA to that in the Preliminary Economic Analysis (PEA) suggests that the final exposure profile reflects reductions in the percentage of measurements above 50 μg/m^3 in 9 out of 12 job categories. This reduction is likely due to the removal of older (pre-1990) data and replacement with newer OIS data (2010-2014).

Relatively Well-Controlled and Poorly Controlled Foundries

Among the foundries with exposure results included in the Table IV.4.8-E are two subsets of facilities selected to represent foundries in which silica is relatively well controlled and foundries in which it is poorly controlled. OSHA reviewed reports from several foundries that have been relatively successful in reducing exposures and several that experienced widespread elevated exposures. The Agency focused on foundries where OSHA, NIOSH, or a State agency had collected air samples for multiple job categories and provided some documentation of working conditions at the time. OSHA then compared the exposure controls and work practices reported in the documentation for each (Document ID 1365, pp. 2-18 – 2-19).

Specifically, the group of relatively well-controlled foundries includes facilities at which the majority of the full-shift results were less than or equal to 50 $\mu g/m^3$, although a few results occurred above that level. These results indicate the level of silica exposure that workers can experience in foundries where their own activities generate little airborne silica and, at the same time, where other sources are also limited. The group of relatively well-controlled foundries includes four gray and ductile iron foundries evaluated in 1989, 1994, 1997, and 1999 (Document ID 1365, pp. 2-18 – 2-19; 1409, pp. 2, (pdf) p. 10; 0268, pp. 3, 6 and Table 2; 0147, pp. 49, 51, 70-93; 0082, pp. 3, 37, 59-64, 186). The four poorly controlled foundries are three gray and ductile iron foundries and one stainless steel foundry that range in size from 55 to 340 production workers. Two of these facilities were evaluated in 1992, while the others were visited in 1996 and 1999 (Document ID 1365, pp. 2-18 – 2-19; 1463, p. 3 and Table 2 (pdf) pp. 26-29; 1379, p. 2 and Table 2 (pdf) pp. 24-25; 0080, pp. 52, 54, 56-220; 0131, pp. 8, 15, 17, 25-26, 29-72).

The well-controlled foundries and the poorly controlled foundries were well matched with respect to size. The range of the number of production workers for the four well-controlled foundries was 39 to 400 workers (Document ID 0082, p. 3; 0147, p. 49; 0268, p. 3; 1409). For the poorly controlled foundries, the production employment range was 55 to 420 workers (Document ID 0080, p. 54; 0131, p. 15; 1379, p. 2; 1463, p. 3). OSHA does not have the information to compare the two groups with respect to other characteristics such as size of castings, and process details. However, the agency has no reason to believe that these foundries differ significantly except in the implementation of worker exposure controls.

The relatively large number of measurements available to OSHA for ferrous sand casting foundries (838 silica sample results) permits a more detailed treatment for foundries than other industry sectors for which OSHA has more limited data sets. The evaluation of well-controlled and poorly controlled facilities allows OSHA to understand the impact of facility-wide control on overall exposures.

The review of relatively well-controlled and poorly controlled foundries shows some clear distinctions between the two groups. The relatively well-controlled facilities were more likely to have installed enclosures and local exhaust ventilation (LEV) for dusty activities, such as for sand-handling equipment, shakeout, knockout, and cleaning/finishing tasks. These foundries were also more likely to have automated processes, such as for mold making or core making, routine grinding, shot-blasting, and conveying parts into enclosures for dusty processes (shakeout, shot blast equipment). Workers normally controlled these processes remotely, sometimes from behind partitions. Additionally, records describing these foundries are more likely to note other special controls in place to reduce airborne silica dust. Examples include adding pneumatic sand transport equipment, using washed lake sand (with low respirable-sized particle content), and purchasing sand additives premixed (because the mixing process released additional dust) (Document ID 1365, pp. 2-18 – 2-19; 1409, p. 2; 0268, pp. 7-8; 0147, pp. 53, 72-75; 0082, pp. 88-89, 91, 120, 135).

The poorly controlled facilities tend to rely more heavily on general exhaust ventilation (ceiling or wall fans not associated with any specific process). Notes on the facilities often commented on the lack of LEV (or on having LEV installed for a process such as welding, but not for adjacent processes associated with elevated silica levels, such as grinding in the cleaning/finishing area). Sand systems equipment (e.g., sand mill or reclaimer) were more likely to be unventilated, require maintenance and/or leak. Leaking equipment often contributes to the exposure of workers in more than one job category. For example, OSHA reported that the reclaimed sand mill at one foundry contributed to the silica exposure levels of a material handler and several cleaning/finishing operators who worked nearby. Furthermore, these foundries used compressed air extensively to remove silica contamination from surfaces, a practice that was associated with multiple job categories (Document ID 1365, pp. 2-18 – 2-19; 1463, pp. 18-19; 1379, pp. 7, 15; 0080, p. 16; 0131, pp. 12, 73).

Additionally, Dr. Mirer similarly observed in written testimony that many workers' silica exposures are due to dust released from adjacent operations. He stated that if these dust releases are controlled, the exposures of workers in adjacent areas will be substantially reduced, as follows:

> For molder, coremaker, furnace operator, knockout operator, abrasive blasting operator, material handling, and maintenance operator, "dust released from adjacent operations" is listed as a source of exposure, and is listed as the only source for pouring operator. Thus, for furnace operators (median 34 μg/m^3, mean 109 μg/m^3) and pouring operators (median 48 μg/m^3, mean 79 μg/m^3), their own activities at their work stations do not emit silica. Yet, these workers suffer substantial silica exposures. This demonstrates that a cloud of silica permeates these factories, and some fraction, perhaps 40 μg/m^3, of the median exposure would be reduced by control of other, silica-generating operations (Document ID 4204, p. 104).

The importance and feasibility of controlling all sources of silica and its effect on exposure to workers in other job categories is thus reflected in the final exposure profile and its representation of baseline conditions in both well-controlled and poorly controlled facilities, as well as those falling in between those two extremes.

Exposure Profile and Baseline Conditions for Sand Systems Operators

The exposure profile in Table IV.4.8-E for sand system operators includes 56 samples of respirable crystalline silica.[40] The median exposure is 74 μg/m^3, the mean is 197 μg/m^3, and the range is 11 (<LOD) to 2,430 μg/m^3. Of the 56 samples, 35 (62.5 percent) are above 50 μg/m^3, and 24 (37.5 percent) exceed 100 μg/m^3.

Most sand systems operators use automated mixers to blend sand with clay, water, and additives. While most facilities have some form of local exhaust ventilation (LEV), the mixing equipment (mixers, screens, hoppers) typically is not fully enclosed or equipped with effective LEV (Document ID 1365, p. 2-21).

The two highest exposures were obtained at two separate facilities and are associated with poor ventilation and work practices, both over 2300 μg/m^3 (Document ID 1365, p. 2-20; 1375, pp. 1, 13, 16; 0094, pp. 60-61, 119-120, 143, 162-181).

[40] All samples in Table IV.4.8-E are full-shift, personal breathing zone (PBZ) samples.

The lowest results (both limits of detection (LOD) values) for this job category are associated with sand systems operators working in areas where sand transport systems were isolated (enclosed or pneumatic) and mullers were fitted with exhaust ventilation (Document ID 1365, p. 2-21; 0018, p. 93; 0268, pp. 8-9).

Baseline conditions include inconsistent use of LEV, with only 38 percent of workers currently exposed at or below the 50 μg/m^3 PEL. Additionally, AFS reports that 47 percent of its members' sand system operators have exposures that are at or below the PEL. This indicates that OSHA's analysis of baseline exposures is similar to AFS's assessment of sand system operators and both sets of data suggest that there are inadequate controls in many facilities.

Exposure Profile and Baseline Conditions for Molders

The exposure profile in Table IV.4.8-E for molders includes 158 samples. The median exposure is 43 μg/m^3, the mean is 65 μg/m^3, and the range is 6 (LOD) to 1,417 μg/m^3. Of the 158 samples, 68 (43 percent) are above 50 μg/m^3, and 26 (16.4 percent) exceed 100 μg/m^3.

OSHA finds that baseline conditions for molders include the use of various semi-automated molding machines designed to shape and compact silica sand (Document ID 1365, p. 2-29). The processes used often require manual handling of the mold. Although general exhaust ventilation is often present (e.g., wall or ceiling exhaust fans), it is also common for molders to work without LEV (Document ID 1365, p. 2-29). Molders typically use green sand (a moldable mixture of sand and clay) (Document ID 1139, p. 18) and use compressed air to clean molds.

Exposure levels for molders tend to be higher in facilities where silica dust is poorly controlled throughout the facility. Some of the highest results for molders are associated with facilities where the results for other job categories also exceed 100 μg/m^3 (Document ID 1365, p. 2-28; 1379; 0104).

Some of the lowest results (two 13 μg/m^3 [LODs], one 20 μg/m^3, and one 23 μg/m^3) were obtained by NIOSH and OSHA for four molders working in two foundries where pneumatic or enclosed conveyors were used to transport sand (Document ID 1365, p. 2-28; 0268, p. 13; 0501, p. 6).

Baseline conditions include the use of semi-automated compacting machines and inconsistent use of LEV, with 57 percent of all samples below the final PEL. Additionally, AFS has reported that 63 percent of its members' molding operations already experience levels at or below the final PEL of 50 μg/m^3. OSHA's description of baseline exposures for molding operations is similar to that of AFS.

Exposure Profile and Baseline Conditions for Core Makers

The exposure profile in Table IV.4.8-E for core makers includes 108 samples. The median exposure is 39 μg/m^3, the mean is 75 μg/m^3, and the range is 8 (LOD) to 1,780 μg/m^3. Of the 108 samples, 46 (43 percent) are above 50 μg/m^3, and 14 (13 percent) exceed 100 μg/m^3.

Core makers use sand to make inserts for molds that allow for hollow metal parts to be molded. Core makers operate or work near automated equipment associated with sand processing for core making. Additionally, some coremakers manually handle cores to coat, clean, assemble, or position the cores. Work is typically conducted without LEV, but general ventilation might be present (Document ID 1365, p. 2-34).

Core makers are routinely exposed to silica dust generated by adjacent sand processing and transport equipment, use of compressed air, and dust migrating into the core making area from sources elsewhere in the foundry. The two highest results (380 μg/m^3 and 1,780 μg/m^3) were obtained in 1999 in a California foundry (Document ID 1365, p. 2-33; 1175, p. 9). At the same time, a result of 90 μg/m^3 was obtained for a third core maker at the same facility. Although no information is available on the specific activities of the core makers, the report suggests that ventilation was "stagnant" in the core area and that air from the melting and charge preparation area entered the space where the core makers worked (Document ID 1175, p. 2). In contrast, eight exposure levels, all lower than the final PEL, were obtained for core makers working in two foundries that employed pneumatic sand transport systems (Document ID 1365, p. 2-34; 0268, pp. 8, 12-13; 0132, pp. 238, 242).

Baseline conditions include the use of automated equipment and manual handling to process the casting cores, with 57 percent of core makers already experiencing levels at or below the 50 μg/m^3 PEL. AFS has reported that 73 percent of its members' core-making activities are already at levels of less than 50 μg/m^3. As such, OSHA may be underestimating the core maker population that already achieves the final PEL.

Exposure Profile and Baseline Conditions for Furnace Operators

The exposure profile in Table IV.4.8-E for furnace operators includes 11 samples. The median exposure is 20 μg/m^3, the mean is 83 μg/m^3, and the range 12 μg/m^3 (LOD) to 281 μg/m^3. Of the 11 samples, 3 (27.3 percent) are above 50 μg/m^3 (all 3 exceed 100 μg/m^3).

The primary sources of exposure for most furnace operators include the silica dust generated from poorly controlled adjacent operations, such as emissions from hot, dry sand released from molds at shakeout (Document ID 1365, p. 2-38; 1382; 1368, p. 78), and dust released when operators add sand to the furnace to correct slag acidity (Document ID 1365, p. 2-38; 0518). However, no information was available to indicate exposure levels specifically associated with these practices.

The highest reading (281 μg/m^3) was obtained in 1995 for a furnace operator who repaired the furnace lining (with refractory materials) every day (Document ID 1365, p. 2-38; 0025, p. 177).[41] Similarly, readings of 198 μg/m^3 and 280 μg/m^3 were obtained for furnace operators in a foundry where the respirable quartz levels were largely uncontrolled, according to NIOSH, and the sources of exposure included not only furnace emissions but also adjacent operations (Document ID 1376, pp. 10, 13-14). The report does not indicate whether these furnace operators participated in maintenance of refractory furnace linings.

Three of the lowest readings for furnace operators (29 μg/m^3 and two less than or equal to 12 μg/m^3) were measured at a single facility where operators worked in a control booth

[41] See the foundry "maintenance operator" job category for information on other foundry workers whose primary silica exposure is from work with refractory materials.

or on a ventilated melt deck (Document ID 1365, p. 2-38; 0028, pp. 27-36). At another facility, a result of 20 μg/m^3 was obtained for a furnace operator tending a furnace with slotted hoods above and a retractable enclosing hood for charging the furnace with iron (Document ID 1175, p. 9).

Baseline conditions for furnace operators include exposures from adjacent operations and exposures from furnace emissions. Engineering controls are effective in reducing exposures but are not used consistently (Document ID 0025, pp. 113, 149; 1376, p. 13; 0028; 1175, p. 2). The exposure profile shows that 73 percent of furnace operators already achieve the 50 μg/m^3 PEL. AFS survey data agree with OSHA's profile, as the survey data indicate that 70 percent of furnace operators have baseline exposures of 50 μg/m^3 or less.

Exposure Profile and Baseline Conditions for Pouring Operators

The exposure profile in Table IV.4.8-E for pouring operators includes 20 samples. The median exposure is 48 μg/m^3, the mean is 69 μg/m^3, and the range is 10 μg/m^3 (LOD) to 176 μg/m^3. Of the 20 samples, 10 (50 percent) are above 50 μg/m^3, and 6 (30 percent) are above 100 μg/m^3.

Two high readings (both 150 μg/m^3) for pouring operators were obtained from a single foundry visited by the Industrial Commission of Ohio in 1987 (Document ID 1365, p. 2-41; 0265, p. 12). Respirable quartz levels throughout this foundry were poorly controlled. Even though these samples were removed from the profile because the data were obtained prior to 1990, they demonstrate that elevated exposures occur in uncontrolled environments.

Another elevated level, 157 μg/m^3 was obtained for a worker operating a pouring crane at a foundry visited by NIOSH in 1992 (Document ID 1365, p. 2-41; 1379, p. 25). At this foundry, half of the results from four job categories exceeded 100 μg/m^3, indicating airborne respirable quartz was released in or spread to most areas in the facility. According to the NIOSH report, the pouring crane operators at this facility were exposed to respirable quartz primarily from shakeout operations (Document ID 1365, p. 2-42; 1379, p. 12).

Based on available reports, OSHA has determined that pouring operators commonly perform manual manipulation of ladles or operating cranes and might use automated equipment in an open pouring area with no engineering controls or dust suppressing work practices. Furthermore, pouring operations are generally located in the same area as furnace and shakeout operations, which can release considerable silica dust. LEV is not a standard feature of pouring areas in ferrous foundries. Where LEV was reportedly associated with a pouring task, the ventilation system was noted to be in poor condition (Document ID 1365, pp. 2-41 – 2-42; 0008, pp. 3, 16-40, 32-34; 1376, p. 13; 1379, p. 3; 1354, p. 4).

The exposure profile in Table IV.4.8-E shows that 50 percent of pouring operators currently achieve the 50 μg/m^3 PEL. AFS reports that 67 percent of these workers already achieve the PEL (Table IV.4.8-C and Table IV.4.8-D), suggesting that OSHA is overestimating the population of pouring operators exposed over the final PEL.

Exposure Profile and Baseline Conditions for Shakeout Operators

The exposure profile in Table IV.4.8-E for shakeout operators includes 90 samples. The median exposure is 59 μg/m^3, the mean is 83 μg/m^3, and the range is 10 μg/m^3 to 361 μg/m^3. Of the 90 samples, 51 (56.6 percent) are above 50 μg/m^3, and 20 (22.2 percent) exceed 100 μg/m^3. The 90 shakeout operator results were collected during de-molding operations under a variety of working conditions.

At a gray iron foundry producing 100,000 tons of castings like engine blocks and cylinder heads, NIOSH measured exposures of 12 μg/m^3 (LOD), 21 μg/m^3, 22 μg/m^3, and 53 μg/m^3 for shakeout area crane operators working in cabs supplied with fresh air (Document ID 1365, p. 2-46; 0268, pp. 3, 5, 6). At that facility, which also had an active silica management program, nine results obtained for manual shakeout operations were mixed, ranging from 22 μg/m^3 to 104 μg/m^3 (Document ID 1365, p. 2-46; 0268, pp. 6, 12).

Four full-shift PBZ respirable quartz exposure results for shakeout operators at another foundry evaluated by NIOSH ranged from 37 to 214 μg/m^3, again indicating the potential for variability in respirable quartz exposures for a single job category at a single facility.

Based on notes included in the report, these higher results are assumed to be associated with the use of an open shaker table and the use of a front-end loader to break large molds on the open floor (Document ID 1365, p. 2-46; 1463, (pdf) p. 14, Table 2).

Shakeout conditions vary dramatically depending on the age and condition of the equipment or facility. A review of OSHA SEP, NIOSH, and State reports indicate that foundries frequently have installed LEV in the shakeout area. However, enclosures and ventilation are not uniformly effective as used, particularly on older equipment. New and modern shakeout equipment is generally associated with LEV designed to help manage dust from this process (Document ID 1365, p. 2-46; 0764; 1148).

Baseline conditions include the frequent use of LEV, showing that more modern shakeout equipment is more effective in reducing exposures. Additionally, the exposure profile shows that 43 percent of shakeout operations already achieve the 50 μg/m^3 PEL. AFS reports that 58 percent of its members' shakeout operations achieve exposure levels equal to or below 50 μg/m^3, which indicates that OSHA may be overestimating the extent of workers exposed above the final PEL.

Exposure Profile and Baseline Conditions for Knockout Operators

The exposure profile in Table IV.4.8-E for knockout operators includes 35 samples. The median exposure is 50 μg/m^3, the mean is 81 μg/m^3, and the range is 13 μg/m^3 (LOD) to 497 μg/m^3. Of the 35 samples, 17 (48.7 percent) are above 50 μg/m^3, and 9 (25.8 μg/m^3) exceed 100 μg/m^3.

Knockout operators use hand and power tools or vibrating equipment on castings delivered from the shakeout process to remove sand from castings and unwanted scrap metal left from the pouring process. Knockout procedures involve use of manual or semi-automated stationary workstations, typically with some form of LEV. However, these ventilation systems are not necessarily well maintained or operating efficiently (Document ID 1365, p. 2-56).

Five elevated readings for knockout operators (540 μg/m^3, 380 μg/m^3, 310 μg/m^3, 140 μg/m^3, and 90 μg/m^3) were collected at a single foundry where the workers used vibrating equipment to remove sand from casting interiors (Document ID 1365, p. 2-54; 1374, p. 4, (pdf) p. 24 Table 6, (pdf) p. 25 diagram). While knockout operators (along with sandblasters) had the highest exposure levels at this facility, NIOSH found elevated silica exposures in all foundry departments and recommended that the facility investigate the use of engineering controls such as local exhaust ventilation, downdraft molding platforms, and isolation of work areas to reduce worker exposure to silica, indicating that exposures at this facility were largely uncontrolled (Document ID 1374, p. 18). These samples were removed from the final profile, as the data predate 1990. However, this example shows that elevated exposures can occur as a result of poor overall control of airborne dust.

Three of the lowest results (13 $\mu g/m^3$, 24 $\mu g/m^3$, and 30 $\mu g/m^3$) and one moderately elevated reading (87 $\mu g/m^3$) were obtained on two sampling dates for two workers who used pneumatic chisels to open holes in castings (Document ID 1365, p. 2-55; 0268, pp. 5-7). On each of the two sampling dates, these knockout operators spent half the shift at ventilated workstations chiseling castings that had already passed from an enclosed two-stage shakeout area to an automated, enclosed abrasive grinder, and were carried to the knockout operator on a partially enclosed conveyor.

Baseline conditions for knockout operators include the use of LEV, with varying efficiencies in dust control. Additionally, the exposure profile shows that 51 percent of knockout operators already achieve the PEL. AFS data also support OSHA's baseline exposure assessment as AFS reports that 52 percent of its members' knockout operations achieve levels below 50 $\mu g/m^3$.

Exposure Profile and Baseline Conditions for Abrasive Blasting Operators

The exposure profile in Table IV.4.8-E for abrasive blasting operators includes 61 samples. The median exposure is 80 $\mu g/m^3$, the mean is 148 $\mu g/m^3$, and the range is 13 $\mu g/m^3$ (LOD) to 1,002 $\mu g/m^3$. Of the 61 samples, 41 (67.2 percent) are above 50 $\mu g/m^3$, and 25 (41 percent) exceed 100 $\mu g/m^3$.

Abrasive blasting operators use abrasive media to remove tightly adhered mold and core materials and prepare the surfaces of castings for further processing. Based on a review of OSHA, NIOSH, and State reports, OSHA concludes that the vast majority of abrasive blasting operators (95 percent) in the foundry industry use automated or semi-automated blasting equipment (e.g., steel shot blast machines) (Document ID 1365, p. 2-62).[42] This equipment is typically designed to be fully (or nearly fully) enclosed and connected to an exhaust ventilation system with a dust collector; however, enclosures often leak and the associated ventilation is not necessarily effective (Document ID 1365, p. 2-62).

Elevated exposures appear to be associated with poor work practices. Two of the highest results, 238 μg/m^3 and 1002 μg/m^3 (as well as a third result of 91 μg/m^3) were obtained in 1992 at a gray and ductile iron foundry. NIOSH noted that the workers used compressed air (presumably for cleaning) while they operated steel shot blasting machines equipped with LEV (Document ID 1365, p. 2-61; 1463, pp. 15, (pdf) pp. 26-27 Table 2). At a different foundry visited by OSHA, a result of 909 μg/m^3 was reported for an abrasive blasting operator who monitored a continuous process steel shot blast machine as well as the dust collection tote (bag). This worker replaced the tote when it was full (Document ID 1365, p. 2-61; 0056, p. 104). This result suggests that the dust collection system performed poorly, that the act of monitoring and replacing the dust tote contributed to the silica exposure, or that both might have been factors.

Some of the lowest results for this job category are associated with control measures that isolate the operator from the process and control sources of dust surrounding the shot blasting machine. A result of 46 μg/m^3, approximately half the median for this job category, is associated with an abrasive blasting operator who operated an enclosed shot blasting machine from behind a transparent barrier. Automated manipulators positioned the parts. This gray iron foundry had implemented numerous exposure controls throughout the facility and results rarely exceeded 50 μg/m^3 in most job categories (Document ID 1365, p. 2-62; 0268, pp. 5-7). OSHA obtained two results of 34 μg/m^3 and 47 μg/m^3 at a gray and ductile iron foundry that had enclosed and ventilated sand- and casting-handling equipment leading to and from the automated shot blasting machine.

[42] Most of the foundry industry abrasive blasting machines use steel shot as media. Therefore, the silica exposure to these abrasive blasting operators is predominantly from residual mold and core materials adhered to the casting, rather than originating in the abrasive blasting media. However, recycled abrasive blasting media that are poorly cleaned can carry residual mold and core materials.

These abrasive blasting operators spent a couple of hours sorting castings and the remainder of the shift operating the shot blasting equipment. Results obtained during earlier evaluations of this facility were substantially higher, as discussed in the review of additional controls for this job category (Document ID 1365, p. 2-62; 0128, pp. 16, 19, 24, 72).

Baseline conditions include the use of ventilated enclosures. The exposure profile shows that 33 percent of abrasive blasting operations currently achieve the 50 μg/m^3 PEL. AFS reports that 63 percent of its members' abrasive blasting operations currently achieve exposures below 50 μg/m^3, suggesting that OSHA is overestimating baseline exposures for abrasive blasting.

Exposure Profile and Baseline Conditions for Cleaning/Finishing Operators

The exposure profile in Table IV.4.8-E for cleaning/finishing operators includes 228 samples. The median exposure is 81 μg/m^3, the mean is 202 μg/m^3, and the range is 12 μg/m^3 (LOD) to 1,868 μg/m^3. Of the 228 samples, 148 (65 percent) are above 50 μg/m^3, and 105 (56 percent) exceed 100 μg/m^3. Considering that 24 percent of exposures (54 samples) exceed 250 μg/m^3, cleaning/finishing operators have many of the highest silica exposures in the foundry industry.

Based on NIOSH, OSHA SEP, and State reports, OSHA concludes that most cleaning/finishing operators use handheld grinding equipment, without LEV, for a substantial portion of the shift. While the same workers also might use stationary grinding equipment, OSHA finds that it is the handheld equipment that is both most typical and the greater source of exposure (Document ID 1365, p. 2-70).

A 2009 study by Lee obtained results of 161 μg/m^3, 181 μg/m^3, 216 μg/m^3, and 245 μg/m^3 for cleaning/finishing operators grinding on casings during an inspection of a facility (Document ID 0779, p. D16; 1359, p. 1). Although grinding stations were equipped with LEV, the LEV did not appear to be effective based on the amount of dust observed in the air and on the work surfaces (Document ID 0779, p. D15).

Some of the highest results (all greater than 500 μg/m^3) were associated with three facilities where most exposures for multiple job categories also were elevated (Document ID 1407, pp. 8-10; 1379, pp. 24-25; 1175, p. 9). One of the highest respirable quartz readings, 1,120 μg/m^3, was obtained for a cleaning/finishing operator who performed hand grinding on large castings on the open floor (Document ID 1365, p. 2-68; 1463, p. 26).

Some of the highest exposures for grinders were at a facility visited by NIOSH that performed only casting cleaning operations. Castings at this facility were delivered on flatbed trucks. The castings were cleaned by workers operating 25 individual grinding stations separated by plywood partitions. Compressed air was used to remove excess sand from internal cavities. The 20 results for cleaning/finishing operators ranged from 300 μg/m^3 to 1,868 μg/m^3. Based on NIOSH recommendations for controlling exposures of the use of downdraft tables for small castings, high velocity low volume tool hoods and the use of flexible exhaust duct for large castings, OSHA infers that these readings are associated with minimal or no such controls (Document ID 1365, p. 2-69; 1378, pp. 4-5, 14-15, (pdf) 29-30 Table 2).

OSHA concludes that baseline conditions include the widespread use of handheld grinders to perform cleaning and finishing operations. LEV is not commonly used for control. Additionally, the exposure profile shows that 35 percent of workers engaged in these operations currently achieve the final PEL. AFS reports that 62 percent of cleaning/finishing operations already achieve exposures at or below 50 μg/m^3, suggesting that OSHA may be overestimating baseline exposures for cleaning/ finishing operators.

Exposure Profile and Baseline Conditions for Material Handlers

The exposure profile in Table IV.4.8-E for material handlers includes 36 samples. The median exposure is 49 μg/m^3, the mean is 75 μg/m^3, and the range is 11 μg/m^3 (LOD) to 231 μg/m^3. Of the 36 samples, 18 (50 percent) are above 50 μg/m^3, and 7 (19.4 percent) exceed 100 μg/m^3.

Material handlers use mobile equipment to transport materials and castings throughout foundries and are subject to background silica dust associated with the conditions and controls found in those work areas. Information contained in OSHA SEP, NIOSH, and State reports suggests that enclosed cabs are not typically available or used to limit exposures (Document ID 1365, p. 2-79). Material handlers routinely assist with cleaning tasks, typically involving dry sweeping or using compressed air.

Some of the lowest exposure levels are associated with a facility that had made substantial and successful efforts to control silica dust across the entire facility. NIOSH obtained four results, all at or below the LOD (11 µg/m^3 to 13 µg/m^3), for two material handlers who operated powered equipment in a well-controlled facility (Document ID 1365, p. 2-79; 0268, pp. 8, 9, 12-13).

Baseline conditions include the use of open-cab equipment to transport materials and castings throughout the facilities. OSHA estimates that 50 percent of material handlers already achieve the final 50 µg/m^3 PEL. AFS reports that 79 percent of its members' material handling operations already achieves levels below 50 µg/m^3, suggesting that OSHA may be overestimating baseline exposures.

Exposure Profile and Baseline Conditions for Maintenance Operators

The exposure profile in Table IV.4.8-E for maintenance operators includes 24 samples. The median exposure is 63 µg/m^3, the mean is 369 µg/m^3, and the range is 12 µg/m^3 (LOD) to 5,851 µg/m^3. Of the 24 samples, 13 (54.1 percent) are above 50 µg/m^3, and 7 (29.1 percent) exceed 100 µg/m^3. Based on a review of OSHA SEP, NIOSH, and State reports, OSHA finds that most reported silica exposure for maintenance operators is due to work repairing (patching) or replacing refractory furnace and ladle lining materials (Document ID 1365, p. 2-84).

Section IV-4.19 – Refractory Repair addresses the similar (but more frequent and often large scale) activities of contractors who travel from facility to facility providing refractory maintenance services. Those contractors are more likely to perform the periodic complete tear-out and replacement of refractory linings,[43] while foundry

[43] According to a supplier, 75 percent of establishments that use refractory furnaces also use a contract service to reline the furnaces (Document ID 1365, p. 2-81; 1159).

maintenance operators are more likely to perform small-scale patch and repair jobs to maintain refractory linings between replacement cycles. The patch and repair tasks are typically performed weekly (Document ID 1365, p. 2-81; 0121, pp. 15-19, 25-26), but that might be necessary more or less frequently depending on several factors such as the type of refractory material and how the furnace is used.

Maintenance operators most commonly perform these manual refractory repair processes in areas with general ventilation only. Furnace ventilation systems cannot be considered an effective control for those maintenance operators who maintain refractory furnaces. The ventilation systems associated with furnaces are designed to exhaust heat and rising fumes but they are inadequate to control silica dust and often are not functional during refractory maintenance activities (Document ID 1365, p. 2-84; 0080, p. 30).

Maintenance operators also are subject to background levels of silica dust associated with the conditions and controls found in the work areas where they maintain equipment or make repairs during upset conditions. However, the results available to OSHA for maintenance operators are primarily associated with refractory repair activities (Document ID 1365, p. 2-84).

Baseline conditions include small-scale repair operations on furnace linings, usually without dedicated ventilation. The exposure profile shows that 46 percent of maintenance operators already achieve the PEL under these uncontrolled conditions. The AFS reports that 74 percent of its members' maintenance operations already achieve 50 μg/m^3 or less, suggesting that the profile may be overestimating the amount of workers exposed above the final PEL.

Exposure Profile and Baseline Conditions for Housekeeping Workers

The exposure profile in Table IV.4.8-E for housekeeping workers includes 11 samples. The median is 71 μg/m^3, the mean is 66 μg/m^3, and the range is 16 μg/m^3 (LOD) to 172 μg/m^3. Of the 11 samples, 7 (63.6 percent) exceed 50 μg/m^3, and 1 (9.1 percent) exceeds 100 μg/m^3.

Based on a review of OSHA SEP, NIOSH, and State reports, OSHA concludes that housekeeping workers most frequently use manual methods to perform cleaning tasks. Exposures of housekeeping workers are closely related to the general exposure levels within the facility and to the specific area where they spend most of their time. Although reports contain few details regarding the specific activities that expose housekeeping workers to silica dust, data suggest that adjacent operations are the primary source of exposure for housekeeping workers, although their own work will likely contribute to their exposure when dry sand is involved (e.g., cleaning up spills from upset conditions) (Document ID 1365, p. 2-92).

Some of the lowest results for housekeepers include a value for a housekeeping worker shoveling and sweeping spilled mold sand. In this case, the result was less than or equal to 16 μg/m^3, the LOD. At the same gray and ductile iron foundry, results for a maintenance operator and two knockout operators were also below 50 μg/m^3 (Document ID 1365, p. 2-91; 0038, pp. 37-46, 51-57). Two other results, both 30 μg/m^3 (one was the LOD), were obtained at two ferrous metal sand casting foundries evaluated by the Michigan Department of Public Health in the early 1990s. One worker reportedly was responsible for cleaning an area where LEV was present. The other was classified as a “floor sweeper” (no further information available) (Document ID 1365, p. 2-91; 0249, p. 10; 1408, p. 9).

The highest exposure was reported for a foundry visited by OSHA, where a result of 172 μg/m^3 was obtained for a “cleanup” worker whose duties included vacuuming sand. Other exposure values obtained on the same date at this facility included results of 87 μg/m^3 and 96 μg/m^3 for pouring operators (nearly twice the median level for that job category). The following month, two results of 276 μg/m^3 and 291 μg/m^3 were obtained for shakeout operators (nearly five times greater than the median for this group), suggesting that the shakeout line might have been a contributing source of silica exposure for the other workers (Document ID 1365, p. 2-91; 0118, pp. 4, 13, 15, 22, 25-26).

Baseline conditions include manual cleaning such as shoveling and sweeping, with indications that airborne silica from adjacent operations contribute to elevated exposures for housekeeping workers. The exposure profile shows that 36 percent of these workers are currently exposed to levels at or below the final PEL. AFS reports that that 72 percent of its members' housekeeping operations already achieve levels below 50 μg/m^3, suggesting that OSHA may be overestimating baseline exposures for housekeeping workers.

Table IV.4.8-E
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Ferrous Sand Casting Foundries (NAICS 331511, 331513)

	Exposure Summary			Exposure Range		Exposure Profile

Ferrous Sand Casting Foundries—Additional Controls

In evaluating additional controls needed to improve upon the baseline and reach the PEL for most foundry workers most of the time, OSHA has considered the differences in foundry sizes and processes, and concludes that the control technologies discussed in this section can be applied to foundries of different sizes and processes. Where the processes differ and those differences could substantially impact OSHA's conclusions (such as working with large castings), the Agency has evaluated appropriate alternative controls. The Agency has reviewed the control technologies that address each of the sources of exposure for each job category. As discussed further below, the comments and data provided, if anything, tend to support the Agency's conclusions that engineering controls and work practices are technologically feasible to reduce exposure to or below the PEL for most operations in most foundry environments.

OSHA thus disagrees with the general argument made by the AFS in its post-hearing comments that, because there are significant differences among foundries such as the melting process, molding and core chemistry, and cleaning and finishing methods (Document ID 4229, p. 13), the Agency is mistaken to generalize or extrapolate about exposure controls for foundries. AFS has additionally provided more specific critiques of the PEA analysis (Document ID 2379, Appendix 2; 4229, p. 15) to which OSHA responds below in the sections on additional controls for each job category. More general comments, which OSHA addresses here, include criticisms of:

- The use of data from foundries that have ceased operation;
- The way OSHA uses some specific data;
- The recommended use of substitutes such as olivine sand for regular sand;
- The recommended use of low-silica refractories;
- OSHA's understanding of the use and maintenance of refractories; and
- The recommended use of housekeeping methods other than compressed air to clean molds.

Each of these points made by AFS is addressed below.

AFS's criticism of OSHA's use of data from foundries that are no longer in operation implies that the implementation of the engineering controls caused the business failure. If this was AFS's implication, it failed to provide evidence proving it. It is well known that foundries in various sectors like automotive and steel have been experiencing consolidations for many years; these circumstances, rather than the implementation of engineering controls, may have led to the foundries in question going out of business. The processes used in these foundries are similar to those processes used in foundries that continue in business. The exposures and the processes associated with these exposures are therefore instructive in assessing worker exposure levels and the efficacy of controls.

With respect to OSHA's use of specific data, AFS argues that OSHA has been selective in presenting data. For example, AFS criticizes OSHA's reliance on Irwin (2003) to show exposure reductions relevant to molding, shakeout, and housekeeping activities. AFS argues that the samples in this study show that there was substantial variability in the exposure levels and that several of the samples exceed the final PEL, implying that it would not be feasible to assure that exposures are below the PEL (Document ID 2379, Appendix 2, pp. 6-7).

OSHA believes that AFS misunderstood how OSHA used various studies. OSHA uses all relevant exposure data for the exposure profile to represent how workers are being exposed prior to the promulgation of this standard. The exposure profile includes data from both well and poorly controlled facilities. Accordingly, in the exposure profile a specific job category may show a wide variability in exposures, in some cases ranging from below the LOD to 100 times greater than the PEL. However, OSHA's methodology is to use data from both before and after engineering controls are applied, if such data is available in the studies. For example, if sampling data show a significant decrease in exposure after the implementation of control measures, these data are used as evidence of the effectiveness of that control.

AFS also commented that that olivine sand is not currently available in the United States and that it is not suitable for all applications (Document ID 2379, Appendix 2, p. 5). In proposing this substitution, OSHA understands that substitution is not a viable option for all foundries, but concludes that it is viable for some foundries and applications. Substitution is an important component of the hierarchy of controls and OSHA has investigated all of the available types of controls that help reduce exposures. In fact, AFS's publication, “Control of Silica Exposure in Foundries,” acknowledges that “[s]ubstituting with a low or no silica-containing material is a prime example” of a silica exposure control (Document ID 3733, pp. 3-5). OSHA also notes that, although none of the feasibility findings are based on substitution, the record shows that some facilities have successfully substituted less silica-containing granular media (Document ID 1365, pp. 2-24, 2-52 – 2-53; 0268, pp. 5-13). The use of substitutes is also discussed below in the individual job categories where substitution is a relevant topic.

AFS also commented that using low-silica refractories may be limited for the following reasons:

> Being one of the three building blocks of nearly all refractories, Silica (along with Alumina and Magnesia) is present in nearly all refractory products. Even “low silica” formulations may contain 5 –30 percent Silica.
>
> For most foundry applications “low silica” may not be feasible. Silica provides refractory property benefits such as low thermal conductivity and thermal dimensional stability which are required for successful refractories.
>
> (Document ID 2379, Appendix 2, p. 21).

OSHA understands that low-silica refractories are not feasible for every operation. However, in the PEA, OSHA presented evidence for commercially available low-silica refractories associated with exposures below the LOD (Document ID 1720, p. IV-153). OSHA is presenting this as an alternative control option for some operations.

AFS also states that OSHA has mischaracterized the nature of foundry refractory work as follows:

> OSHA may also be confused on the nature of foundry refractory work. There are large relining jobs that happen only periodically, but just as much (if not more) refractory work occurs on an ongoing basis to maintain

> runners, ladles, melting units, etc. which are degraded from daily contact with molten iron.
>
> (Document ID 2379, Appendix 2, p. 20).

OSHA has included a description for the job activities of maintenance workers, and it is not inconsistent with what AFS argues. Table IV.4.8-B of this analysis states that Maintenance Operator duties include repairing and maintaining refractory furnace linings. Controls for these workers are discussed below in the additional controls section for this job category. In addition, Section IV-4.19 – Refractory Repair separately analyses refractory repair operations performed by contractors specializing in this type of work. OSHA understands that large scale refractory repair is typically performed by a separate industry but that foundry workers on occasion may also perform this type of work.

Another AFS comment is on the use of compressed air. AFS stated that "[i]n some cases the only feasible method for cleaning is the use of compressed air guided through long, narrow wands that can be inserted into the part." AFS states (Document ID 2379, Appendix 2, p. 14):

> In castings of complex or intricate shape excess sand may accumulate in voids and crevices. It is not possible to reach many of these locations with a vacuum attachment. Beyond access issues, even intense vacuuming will often not provide the needed power to dislodge excess sand from casting voids and crevices. It also is not feasible to use wet methods as this would damage the equipment and create a safety hazard due to water accumulation on the surrounding floors. (<u>Id.</u>)

OSHA understands that in some situations compressed air may be the only feasible alternative to clean the casting. This is why the final rule contains a provision that allows employers to use compressed air for cleaning under limited circumstances. Specifically, paragraph (h)(2) of the standard for general industry and maritime states, in pertinent part, as follows:

> (2) The employer shall not allow compressed air to be used to clean clothing or surfaces where such activity could contribute to employee exposure to respirable crystalline silica unless:
>
> > (i) The compressed air is used in conjunction with a ventilation system that effectively captures the dust cloud created by the compressed air; or
> >
> > (ii) No alternative method is feasible.

One of the effects of using compressed air is the generation of dust that can expose other workers. As Dr. Mirer testified, control of dust emitting sources, so-called "cross-contamination, has a profound effect on silica-dust levels. Dr. Frank Mirer, stated he wanted to:

> …emphasize that the sources emitting silica exposures of >100 μg/m^3 are a major source of the worker silica exposures between 50 μg/m^3 and 100 μg/m^3. Were the >100 μg/m^3 exposures controlled, most worker exposures currently in the 50-100 μg/m^3 range would be below 50 μg/m^3, and substantial numbers would be less than 25 μg/m^3. . . . Thus, for furnace operators (median 34 μg/m^3, mean 109 μg/m^3) and pouring operators (median 48 μg/m^3, mean 79 μg/m^3), their own activities at their work stations do not emit silica. Yet, these workers suffer substantial silica exposures. This demonstrates that a cloud of silica permeates these factories, and some fraction, perhaps 40 μg/m^3, of the median exposure would be reduced by control of other, silica-generating operations. Similar subtractions could be applied to all operations, which would reduce the grand median to close to 25 μg/m^3 (Document ID 4204, p. 104).

OSHA agrees with Dr. Mirer's analysis and presents data below that indicate that Dr. Mirer's reductions may be conservative estimates. See discussion under Additional Controls for Molders (Ferrous Sand Casting Foundries).

Additional Controls for Sand Systems Operators

The exposure profile in Table IV.4.8-E shows that 38 percent (21 of 56 samples) of sand systems operators in ferrous sand casting foundries have exposures at or below the final PEL of 50 μg/m^3. AFS reported that 47 percent of its members' sand system operations currently achieve the PEL, suggesting that OSHA may be overestimating baseline exposures for this job category (see Table IV.4.8-D).

Based on the Table IV.4.8-E exposure profile and other information in the rulemaking record, OSHA concludes that exposures at or below the PEL are generally attributable to the use of enclosed and ventilated sand processing and transport equipment. For the remaining sand system operators who are exposed above 50 μg/m^3, OSHA concludes that additional controls will be needed to achieve the PEL, and that foundries can achieve significant exposure reductions through effective LEV and enclosures for sand mixing, processing, and transport equipment. Published industry and voluntary guidelines for sand mixer and mullers, bins, hoppers, and screens specify that equipment must be well enclosed and exhausted at a minimum rate of 150 cubic feet per minute (cfm) (200 cfm in the case of screens) per square foot of opening (Document ID 1365, p. 2-22; 1607, pp. 10-23).

Some of the lowest results are associated with sand systems operators working in areas where sand transport systems were isolated (enclosed or pneumatic) and mullers were fitted with exhaust ventilation. For example, an exposure level of less than or equal to 11 μg/m^3 was attained for a sand systems operator controlling a muller that had both the muller belts and elevator fully enclosed (Document ID 0018, pp. 93, 98-100). Exposure levels of less than or equal to 13 and 30 μg/m^3; (two sampling days) were associated with pneumatic sand transport equipment (Document ID 1365, p. 2-21; 0268, pp. 5-13).

AFS argues that the automated process used at the facility visited by NIOSH is atypical, and that the facility could “take advantage of automation because it has reduced production to relatively few part numbers compared to most other foundries” (Document ID 2379 Appendix 2, p. 4). AFS argues that the automation control used for this foundry cannot be extrapolated to other smaller foundries that have different configurations. AFS also mentions that 11 of the 63 samples in this foundry exceeded the PEL (Document ID 2379, Appendix 2, p. 4; 4229, p. 14).

AFS is implying that other foundries that produce more parts would not be able to rely on automated processes. However, AFS has not provided evidence to support this claim. At this foundry, NIOSH makes no mention of the impact of automation on production rates, and NIOSH describes this as a "modern, highly automated facility with the management and workers committed to continuous improvement" (Document ID 0268, p. 11). Regarding automation, NIOSH further states:

> Automation of activities has reduced the number of employees potentially exposed and facilitated the isolation of dusty processes where employee presence is no longer required. Activities where this has had discernable impact include automatic shaker conveyors replacing the beef line [overhead power chain conveyor], automated high pressure molding units, automatic grinding and shot blast equipment, and a muller that only requires the operator to monitor sand quality (Document ID 0268, p. 8).

Additionally, automation has been observed in multiple studies in different environments in foundries (Document ID 1365, pp. 2-22 – 2-23). AFS also asserts, with no evidentiary basis, that automation and some controls such as pneumatic sand moving systems often increase exposures to respirable silica rather than reducing them (Document ID 2379, Appendix 1, p. 14). OSHA finds these assertions unpersuasive given NIOSH's observations and the data collected and presented in this section on the effectiveness of a wide variety of controls, including pneumatic sand moving systems (Document ID 1365, pp. 2-22 – 2-23; see, *e.g.*, 0268, pp. 8, 12-13; 0132, pp. 238, 242).

An OSHA SEP report shows that a steel foundry used a combination of controls to reduce exposures by 82 percent, from 159 $\mu g/m^3$ to 28 $\mu g/m^3$. This facility achieved this exposure reduction by: fully enclosed mullers and hoppers, improving existing LEV, renovating the sand handling system across the entire facility, wetting hot sand reclaimed from the shakeout area, changing work practices, improving housekeeping, using pre-mixed additives, and controlling silica exposure sources throughout the facility (Document ID 1365, p. 2-23; 0511, pp. 1-6).

Enclosed, ventilated, continuous-process sand recycling and reclamation equipment is commercially available for foundries (Document ID 1365, p. 2-23; 1148). According to the manufacturer, this type of multifunctional equipment can be configured to accomplish most sand handling, from shakeout and cast cleaning to screening and mixing in fresh molding sand. These systems can be used with a multitude of sand products for various castings (Document ID 1365, pp. 2-23 – 2-24; 1714; 1465).

Substitution may be an option for some foundries. Substituting non-silica granular media (which is less toxic than silica) for silica sand used for molds and cores can virtually eliminate the silica exposures of all sand systems operators. Although the extent of exposure reduction from the use of substitution materials has not been quantified for sand systems operators in ferrous sand casting foundries, it has been documented in nonferrous sand casting foundries (Document ID 1365, pp. 2-24, 2-52 – 2-53).

Additional Controls for Molders

The exposure profile in Table IV.4.8-E shows that 57 percent (90 out of 158 samples) of molders have exposures at or below the final PEL of 50 μg/m^3. AFS reports that 63 percent of its members' molding operations already achieve these levels as well (see Table IV.4.8-D). These data show that exposures of most molders are already at or below the final PEL.

For molders that are still above the PEL after controlling for major sources emitting silica dust, OSHA finds that additional controls will be necessary to achieve the PEL, and that minimizing molders' contact with dust released from dry sand and silica mold washes will further reduce their exposures. Additional controls include installing or upgrading LEV near molding equipment, improving housekeeping procedures to minimize the spread of sand, reducing use of compressed air and dry sweeping, and controlling dust from nearby processes (e.g., sand mixing, transport, recovery, shakeout). Alternatively, non-silica substitutes that are less toxic than silica can be used for washes and cores.

NIOSH and OSHA evaluated pneumatic and enclosed systems to isolate the storage and transport of dry sand in two facilities. The four molder results from these foundries include two results of 13 μg/m^3 (LOD), 20 μg/m^3, and 23 μg/m^3 (Document ID 1365, p. 2-28; 0268, p. 13; 0501, p. 6). At another facility, OSHA reported a 65- to 70-percent reduction in exposures (from 140 μg/m^3 to 50 μg/m^3 and 42 μg/m^3) after the facility made improvements to sand delivery systems and exhaust ventilation systems throughout the facility (Document ID 1365, p. 2-30; 0132, pp. 238, 242, 244).

AFS argues that OSHA fails to mention the other sampling results associated with SEP report 100494079 (Document ID 0132), such as the overexposures of core makers and a grinder operator. Additionally, AFS argues that the use of this reference contradicts OSHA's argument that enclosed/automated sand delivery systems are effective as follows: "The reference in the PEA also indicates that the pneumatic sand system operation, listed as a solution in the first example above, was part of the exposure problem for the core room" (Document ID 2379, Appendix 2, p. 6).

OSHA notes that the inspection data demonstrate that improvements made to sand delivery systems and exhaust ventilation systems throughout the facility resulted in a 65 to 70 percent reduction in exposures. The inspection report finds:

> Efforts to reduce employee exposure to respirable silica dust to levels within the OSHA Standard appeared to be successful. The continued effectiveness of these engineering controls is dependent on ongoing machinery, exhaust ventilation and sand delivery system maintenance program (Document ID 0132, pp. 238, 242, 244).

OSHA understands that overexposures and variability in exposures occur due to operational situations. The fact that the employer made improvements to the sand delivery system, and that this improvement is associated with exposure reduction, shows that enclosed and ventilated transport systems are effective in reducing exposures.

Because work activities can vary throughout the day, a combination of engineering controls and housekeeping may be needed to reduce exposures below 50 $\mu g/m^3$. A foundry evaluated by OSHA showed a 60-percent reduction in exposure (from 123 $\mu g/m^3$ to 49 $\mu g/m^3$) when the facility implemented a wide variety of controls. The controls included installing an efficient dust collector, enclosing a sand chute, adding a water spray to a sand feed belt, adding LEV to the return sand belt and bucket elevator, and improving housekeeping (Document ID 0182, pp. 41, 201-203).

While the contribution to exposure reduction from housekeeping alone has not been quantified in ferrous sand casting foundries, poor housekeeping practices that disturb dust (dry sweeping and using compressed air) can diminish the effects of other controls

(Document ID 1365, p. 2-30). However, data suggest that good housekeeping in combination with other controls will provide substantial exposure reduction. Irwin (2003) reported on a foundry that used a combination of LEV (enclosing and ventilating the mold dumping and sand return areas) and adding a rotary media tumbler to substantially reduce worker exposure levels (Document ID 0752, p. 20). In addition, the foundry changed work practices and performed aggressive housekeeping. Altogether, implementing these controls reduced the exposure levels by at least 80 percent. The precise reduction could not be determined because no silica was detected in the sample; however, ERG estimated an 8-hour TWA exposure level of less than or equal to 40 µg/m^3.[44] Similar results were obtained on multiple sampling dates (Document ID 0752, p. 20).

AFS objected strongly to OSHA’s prohibition on dry sweeping and the use of compressed air for removing residual sand during molding operations. AFS noted that many molding operations require molders to sweep excess dry sand into the sand recycling system. AFS also mentioned that fixed brushes on automated equipment are used to direct waste sand into the recycling system. AFS contends that OSHA’s rule would replace these activities with vacuum systems which they claim are ineffective and not feasible (Document ID 2379, pp. 34-35; 4229, pp. 24-25).

First, OSHA’s prohibition on dry sweeping is contained in Paragraph (h) – Housekeeping of the standard for general industry and maritime. As discussed in the Summary and Explanation for this paragraph, dry sweeping or dry brushing is prohibited where such activity could contribute to employee exposure to respirable crystalline silica. Thus, the final rule would not prohibit dry brushing unless it could contribute to employee exposure. Moreover, paragraph (h) only prohibits dry sweeping and dry brushing where wet sweeping, HEPA-filtered vacuuming or other methods that minimize the likelihood

[44] Irwin (2003) did not report sample durations. This estimate is based on the respirable dust result (0.55 µg/m^3 after controls were in place) and the OSHA-calculated PEL (1.0 µg/mm^3) provided for the initial uncontrolled sample and derived using the general industry equation for the PEL for respirable dust containing silica. ERG reversed the calculation to find the percentage silica in the initial respirable dust sample. Assuming the percent silica would be similar in the two samples, ERG estimated that the 8-hour TWA was less than or equal to 40 µg/m^3 (Document ID 1365, p. 2-31).

of exposure are feasible. Therefore, the use of dry brushing would be permitted if other methods are not feasible.

Second, the prohibition on the use of compressed air contained in paragraph (h)(2) is also qualified. As OSHA explains in the Summary and Explanation for paragraph (h), the Agency has found convincing evidence that wet methods and HEPA-filtered vacuums are not safe and effective in all situations. Therefore, paragraph (h)(2) allows employers to use compressed air for cleaning where the compressed air is used in conjunction with a ventilation system that effectively captures the dust cloud created by the compressed air, or where no alternative method is feasible. These limited exceptions should encompass the situations described above by AFS, and give employers the necessary flexibility in permitting the use of compressed air where wet methods or HEPA-filtered vacuums are infeasible, or where the dust cloud created by use of compressed air is captured and therefore does not present a hazard to employees.

OSHA, nonetheless, concludes that vacuuming of molds offers an alternative to using compressed air for removing silica contamination. This conclusion is supported by a NIOSH report on a foundry that occasionally used vacuums, in addition to compressed air, for removing loose sand from molds and flasks. NIOSH recommended enclosing the cleaning operation with a receiving hood or replacing the use of compressed air cleaning with vacuuming. NIOSH also recommended the use of a sweeping compound during sweeping or replacement with portable vacuums to minimize dust generation and accumulation (Document ID 1365, p. 2-31; 0233, p. 22).

Additional Controls for Core Makers

The exposure profile in Table IV.4.8-E shows that 57 percent (62 out of 108 samples) of core makers have exposures at or below the final PEL of 50 μg/m^3. AFS reported that 73 percent of core making activities already achieve the PEL (see Table IV.4.8-D) (Document ID 2379, Attachment 2, p. 27), indicating that OSHA may be overestimating the percentage of workers currently exposed above this level. OSHA concludes that this evidence shows that exposures can be reduced to levels at or below 50 μg/m^3.

The primary cause of exposures over 50 μg/m^3 for core makers is often dust from adjacent sand processing and transport equipment or other foundry processes. Therefore, OSHA finds that controlling dust from adjacent sources will substantially reduce the exposures of most core makers. For example, installing a pneumatic transport system reduced exposures to below 21 μg/m^3 from levels ranging from 80 μg/m^3 to 360 μg/m^3 (Document ID 1365, p. 2-35; 0132, pp. 238, 242-244). NIOSH saw similar results of low exposures (less than 36 μg/m^3) for core makers working in an area with a pneumatic sand transport system (Document ID 1365, p. 2-35; 0268, pp. 8, 12-13).

Area sample results from a foundry evaluated by OSHA further demonstrate the extent to which other foundry operations can affect background silica levels in the core making area. This foundry identified sand systems operations, molding, and shakeout areas as the primary sources of silica in the facility. Migrating dusts settled into other areas causing elevated exposures to adjacent workers. An initial area sample collected in the core making area showed worker exposures of 200 μg/m^3. The foundry took steps to control the release of silica and improve the general ventilation and sand-handling systems, and clean accumulated dust in all production areas within the building. Additional samples showed exposures to core makers dropped at least 75 percent to 12 μg/m^3 and 24 μg/m^3 (Document ID 1365, pp. 2-35 – 2-36; 0511, pp. 1-6).

Additional Controls for Furnace Operators

The exposure profile in Table IV.4.8-E shows that 73 percent (62 out of 108 samples) of furnace operators have exposures at or below the final PEL of 50 μg/m^3. Similarly, AFS reports that 70 percent of its members' furnace operations currently achieve the final PEL (see Table IV.4.8-D). Therefore, OSHA finds that additional controls will be required to achieve the PEL for the remaining furnace operators who are overexposed.

Where adjacent operations release silica dust, OSHA finds that control of these operations will reduce exposure levels of furnace operators. Since furnace and pouring operations are often located in the same general area, control strategies described below for pouring operators also would benefit furnace operators to a notable extent. For example, in a highly automated foundry that made substantial efforts to control silica in all operations, NIOSH reported exposure readings of 27 μg/m^3 and 29 μg/m^3 for a worker called a chill tester who was performing tasks between the furnace and the pouring machine (Document ID 1365, p. 2-39; 0268, pp. 4, 9, 13).

Furnace operators handle sand or sand-contaminated scrap metal when they add these items to furnaces. In foundries where silica-contaminated foundry returns contribute to the exposure of furnace operators, the use of cleaner scrap and removal of sand from such returns prior to furnace charging will further reduce exposures. Metal scrap can be cleaned using rotary media mills (Document ID 1715). Regarding this citation, AFS argues:

> OSHA presents no data from any site using this control equipment, but instead relies on a supplier's claim of applicability. This evidence is hardly convincing. Moreover, for this job category the exposure assumption that OSHA (sic) about furnace operators is not consistent with foundry experience. Furnace operator exposure to silica is more likely to come from refractory repair operations than from contaminated scrap. OSHA deals with controls for refractory work under maintenance, but maintenance workers are more often engaged in machine repair activities and seldom in refractory repair which requires highly specialized knowledge and skill (Document ID 2379, Appendix 2, p. 11).

AFS appears to be arguing that silica-contaminated scrap does not generate silica-dust exposures for furnace operators but stops short of stating that contaminated scrap is never a source of silica exposure for furnace operators. OSHA's finding, however, is simply that in those facilities where contaminated scrap does contribute to furnace operators' exposures, equipment exists to clean the scrap, lessening the amount of silica that furnace operators handle. Moreover, with respect to AFS's assertion that furnace operators are more likely exposed to silica dust during refractory repair, the evidence shows that this source can be feasibly mitigated by using remotely controlled equipment, portable exhaust ventilation systems, and other controls; or employing a contractor using these controls. See Section IV-4.19 Refractory Repair.

AFS asserts based on a settled enforcement case that controlling exposures from furnace refractory repair is not feasible (Document 2379, Appendix 3, p. 14). AFS argues that

OSHA's failure to re-inspect this facility after the firm notified OSHA that they had instituted limited worker exposures through rotation and the use of powered air purifying respirators was evidence that the agency agreed that controls for furnace refractory repair were not feasible.

AFS's perspective on this case is incomplete and must be understood in the context of the settlement agreement. According to the records presented by AFS (Document ID 2379, Appendix 3, p. 28) the firm had installed a refractory push-out system that addressed the major part of the overexposures cited in this case and the administrative controls and respirators were used only to remove the refractory from the top cap of the furnace. Settlement agreements are an effort by OSHA to achieve the safest working conditions for the employees in the facility as a whole and take into account many other factors, not the least of which is achieving exposure reductions expeditiously by avoiding protracted legal proceedings. This is applicable in this case.

Facilities might need to alter work practices where furnace operators introduce silica sand as an additive to molten metal. For example, the operator might add sand at a point where existing ventilation will capture dust generated by the process. Other options include installing retractable enclosing hoods to add sand under controlled circumstances (Document ID 1365, p. 2-39; 1175, p. 4).

AFS stated that "sand would be an unusual additive to metal in a furnace and adding sand would be a minor contributor to furnace operator exposure" (Document ID 2379, Appendix 2, p. 11). However, the AFS's "Casting Answers and Advice" describes adding silica sand to maintain an "acid" slag (Document ID 0518). NIOSH also describes the addition of bags of silica-containing silicon carbide graphite (Document ID 1365, p. 2-37; 1382).

Ensuring that ventilation systems are installed and functioning properly as well as installing well-ventilated climate controlled monitoring booths (where feasible) will further reduce exposures. Use of a furnace operator control booth was associated with an exposure reading of 13 $\mu g/m^3$ (LOD), a 50-percent decrease compared to the exposure result for one of two furnace operators working outside the control booth at the same facility (Document ID 1365, p. 2-40; 0028, pp. 27-36). The other furnace operator that worked outside the booth had an exposure level of 13 μg/m^3 as well, making it difficult to confirm the benefit of this particular booth. The option of a booth for exposure control has proven effective in other industries; however, in foundries they are only effective for the more automated furnaces that require little hands-on tending.

Additional Controls for Pouring Operators

The exposure profile in Table IV.4.8-E shows that 50 percent (10 out of 20 samples) of pouring operators have exposures at or below the final PEL of 50 μg/m^3. AFS reports that 67 percent of its members' pouring operations already are below 50 μg/m^3 (see Table IV.4.8-D). Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for the remaining pouring operators who are overexposed.

During mold pouring, molten metal is poured into molds of compacted sand that are often contained in pouring boxes or other containers (Document ID 1365, pp. 2-40 – 2-41). The sand is not actively disturbed while pouring, and thus little silica emission is expected to directly result from pouring activities. As a result, pouring operator exposures above 50 μg/m^3 are generally due to uncontrolled dust in adjacent operations. As previously stated, furnace operations and pouring operations often are located near each other. It is also typical for the shake-out operations, a source of significant silica emissions, to be located adjacent to the mold pouring area (Document ID 1365, pp. 2-41 – 2-42). Therefore, controlling adjacent operations will reduce the exposure levels of pouring operators. Balancing (adjusting) the overall facility ventilation to prevent airflow patterns that draw dusty air from other processes into the pouring area will achieve an additional level of control and further reduce exposures for workers in adjacent areas.

In cases where exposures cannot be reduced below the PEL through controlling silica emissions in adjacent operations, pouring operators can be isolated with operator booths or cabs supplied with fresh air maintained under positive pressure. NIOSH recommended enclosing crane cabs and ventilating them with fresh outside air, as well as controlling silica dust in adjacent operations to control exposures for pouring crane operators (Document ID 1379, p. 13). A mobile duct system that provides the cab with fresh outdoor air is commercially available for bridge crane operators (Document ID 1406, p. 664). While the benefit of this control has not been quantified for pouring operators, OSHA reported a result of less than or equal to 13 μg/m^3 (below the LOD) for a furnace operator working in a control room provided with fresh air; this result was less than half the exposure level of a furnace operator working outside the control room at the same foundry (Document ID 1365, p. 2-40; 0028, pp. 27-36).

Pouring operators conducting manual processes might be isolated by creating a pouring room physically separate from other activities. During an inspection, OSHA measured an exposure level of 22 μg/m^3 for a pouring operator isolated from other operations while exposures for molders exceeded 80 μg/m^3 for the same facility (Document ID 1365, p. 2-42; 0008, pp. 3, 16-40, 43-44). An alternative approach to isolating pouring operations might be through controlled airflow. AFS and the American Council of Government Industrial Hygienists (ACGIH) both describe LEV controls for several different pouring configurations (Document ID 0517; 0515).

Additional Controls for Shakeout Operators

The exposure profile in Table IV.4.8-E shows that 43 percent (39 out of 90 samples) of shakeout operators have exposures at or below the final PEL of 50 μg/m^3. AFS reports that 58 percent of its members' shakeout operations currently are exposed to levels below the PEL (see Table IV.4.8-D). Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for the remaining shakeout operators who are overexposed.

The selection and relative effectiveness of controls is dependent on the size of the castings. Those facilities whose shakeout operators mainly work with small or medium-sized castings can effectively control silica levels in the shakeout area by enclosing the process and improving ventilation in a coordinated control effort to reduce exposures.

Several cases demonstrate the value of enclosed and ventilated shakeout equipment, particularly when combined with other dust control measures. An enclosed dust collection system was associated with full-shift PBZ readings for shakeout operators of less than or equal to 13 μg/m^3 (2 readings), 30 μg/m^3, and 41 μg/m^3. These readings were obtained at a foundry that had made a systematic effort to identify and abate all sources of dust emission with the establishment of an abatement team consisting of an engineer, maintenance and production supervisors, and workers (Document ID 1365, p. 2-51; 1408, p. 9).

Regarding the use of this study in this analysis, AFS commented:

> It is clear from the discussion in the report that the exposure result of 41 μg/m^3 cannot be extrapolated to other foundries and that OSHA does not believe that it represents a reliable example of either accurate exposure measurement or exposure control for even this foundry. It cannot be appropriately cited as evidence of feasible control for shakeout operations. Few foundries have open air shakeout operations (Document ID 2379, Appendix 2, p. 12).

In the original site visit report, OSHA provides a description of the shakeout process:

> All doors in the shake-out area were open to the outside thus providing ample natural ventilation. We would recommend that monitoring be conducted during the winter when this area is enclosed. Respirable dust can remain suspended for several hours which would allow for greater exposures to silica. The potential for an excessive exposure to silica is significant if allowed to accumulate in an unventilated room (Document ID 1408, p. 2).

OSHA has included the PBZ exposure of 41 μg/m^3 taken from the shakeout operator at this facility as evidence of the level of exposure achieved during working conditions at that time. The report shows that three samples below the 50 μg/m^3 PEL were reported for shakeout operators. The report stated that the shakeout room had natural (general) ventilation, and that in the absence of this ventilation higher exposures could occur. General ventilation can be achieved by an HVAC system in facilities with doors and windows closed. Additionally, this foundry made facility-wide efforts to control silica exposures. OSHA concludes that this general ventilation was one of the factors that contributed to the low silica exposures. OSHA also recognizes that shakeout operations can produce elevated exposures in uncontrolled conditions (Document ID 1365, p. 2-46).

In another example, a foundry enclosed the shakeout conveyor and exhausted the enclosure at a rate of 8,000 cfm (for a 10-foot segment, or a rate of 800 cfm/linear foot) as part of a comprehensive effort to reduce exposure throughout the facility. With the enclosure in place, results of 13 μg/m^3 and 37 μg/m^3 were obtained for workers in the shakeout area (Document ID 1365, pp. 2-51 – 2-52).

For small and medium-sized casting applications, alternatives to vibrating shakeout equipment that enclose the shakeout operation are available. Such systems include rotary sand/casting separators, rotary media drums, or shotblast machines (Document ID 1434; 0927; 1148). When connected to an appropriate exhaust ventilation system, this equipment (which entirely encloses the process of separating sand from castings) can separate the shakeout operator from the source of exposure. For example, at one of the same foundries mentioned earlier in the discussion of molders, a combination of enclosed and ventilated sand handling and mold dumping areas and a rotary media tumbler substantially reduced shakeout operator exposure levels at a foundry evaluated by OSHA (Document ID 0752, pp. 19-20). At this facility, shakeout operators dump molds onto a shaker conveyor, operated a rotary media drum that removes additional sand from the casting, and then hung the castings on an overhead conveyor. Initially, this process was associated with an operator exposure level that was 380 percent of the calculated PEL, measured as respirable silica-containing dust (or 326 μg/m^3 RCS). The employer then "designed and built an enclosure that ran the length of the shakeout conveyor from the mold dump position to the [media tumbler]" and also increased exhaust ventilation to the area. Once these changes were in place and the facility had been vacuumed and power washed, shakeout operator silica exposure levels decreased to levels in the estimated range of 20 μg/m^3 to 40 μg/m^3 (Document ID 0752, p. 20).[45]

For larger castings, enclosing the process is preferred to isolating the operator from the process because emissions from shakeout operations have been shown to contribute to excessive exposures not only for the shakeout operator but also in adjacent operations. However, isolating the operator from the process can be effective when the entire process

[45] Silica was not sampled, so this estimate is based on the initial 2,930 μg/m^3 (2.93 mg/m^3) and post-abatement 550 μg/m^3 (0.55 mg/m^3) respirable dust results (Document ID 0752, p. 20).

is isolated within the facility. NIOSH evaluated a facility that enclosed an entire shakeout and finishing line in an isolation room. The crane operators worked in a positive pressure cab supplied with fresh air (Document ID 0268, pp. 4-5). Exposures for operators on two different days ranged from the LOD (less than or equal to 12 μg/m^3) to 53 μg/m^3 (Document ID 0268, p. 6). Furthermore, a Mine Safety and Health Administration (MSHA) evaluation of heavy equipment cabs reported an 86 percent reduction in respirable dust (inside compared with outside the cab) for well-sealed, filtered cabs with air conditioning. This reduction was associated with an exposure to respirable dust inside the cab of 0.13 mg/m^3, with 24 percent silica content, resulting in an exposure to a silica-dust level of 31 μg/m^3 (Document ID 1365, p. 2-80; 0823, p. 5). OSHA concludes that when large-casting shakeout operations can be conducted remotely, an operator's booth using similar technology would offer the operator a comparable level of protection.

For very large castings that must be de-molded manually, ventilation can still provide some exposure reduction. The use of portable enclosures and portable ventilation systems, as well as ventilated tools, can help reduce exposures (Document ID 1365, p. 2-49). OSHA estimates that such controls can reduce exposures below 100 μg/m^3 and additionally will reduce exposures of adjacent operations where shakeout operations are the major source of exposures (Document ID 1365, p. 2-53). Based on available information, OSHA concludes that no more than 5 percent of shakeout operators are involved in producing castings of this size (Document ID 1365, p. 2-47).

Alternatively, silica exposures can be eliminated by substituting non-silica granular molding media for silica sand and using alternative refractory mold coatings (Document ID 1365, p. 2-52; 1287; 1691; and see discussion above). These alternatives are readily available from commercial sources and are associated with silica exposures below the LOD (Document ID 1365, p. 2-52; 1412, p. 10). OSHA understands that substitution is not a practical alternative in many situations, but employers should be aware of the potential benefits in reducing silica exposures when possible.

Additional Controls for Knockout Operators

The exposure profile in Table IV.4.8-E shows that 51 percent (18 out of 35 samples) of knockout operators have exposures at or below the final PEL of 50 µg/m^3. Similarly, AFS reports that 52 percent of its members' knockout operations are at or below the final PEL (see Table IV.4.8-D). Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for the remaining knockout operators who are overexposed. Additional control for reducing exposures include reducing the amount of sand on the castings that enter the knockout area and installing or improving LEV on the tools and workstation where operators remove sand and excess metal from castings.

For example, a combination of controls reduced knockout operator exposures to levels of 50 µg/m^3 or less at a foundry visited by the Michigan Department of Public Health's Bureau of Environmental and Occupational Health. Between 1989 and 1994, the foundry installed new controls in the knockout area and added some new shakeout equipment. Two samples collected for "knock off" operators in 1994 resulted in full-shift PBZ concentrations of 30 µg/m^3 and 50 µg/m^3. The improvements to the knockout line included the installation of a 50,000-cfm canopy hood exhaust system, a 10,000-cfm make-up air system, baffle plates and side shields, and a new vibrator to the monorail conveyor carrying castings. The vibrating monorail conveyor shook off most excess sand in a ventilated tunnel while transporting the castings to the knockout area, where workers eventually removed residual scrap metal from the castings (Document ID 1409).

AFS argues that OSHA has selectively taken two sample results from a single day in 1994 out of context to support its feasibility argument. AFS points out that this report states "results indicate that employees remain slightly overexposed to silica on occasions" and that the report concludes by recommending continual improvement of ventilation controls. AFS argues that the standard requires compliance with the PEL at all times, not merely on certain days. The two-page report plus one data page makes it quite clear with two separate cautionary statements that the sample results cited in the PEA are not evidence of consistent control (Document ID 2379, Appendix 2, pp. 12-13).

OSHA did not selectively look at only two samples but used a traditional comparison of exposures before and after controls were installed to determine how effective the controls were in reducing exposures. The Michigan Department of Public Health inspectors noted "that the company was installing new ventilation controls in the knock-off area which are designed to reduce employee exposure to silica dust within permissible limits" (Document ID 1409, p. 2). In 1989, two samples prior to the installation of these controls in the knockout area were reported to be above 1000 μg/m^3. In 1994, after the installation of controls, which were reported as "new LEV" and "good ventilation" in the knockout area, inspectors obtained results of 30 and 50 μg/m^3 (Document ID 1365, p. 2-56; 1409, p. 2; (pdf) pp. 10-11 Air Contaminate Data). This before and after comparison is evidence that the engineering controls installed in the knockout area were successful in reducing exposures from exposures at least 20 times the final PEL to levels at or below 50 μg/m^3.

Foundries have several options for reducing the amount of residual sand adhering to castings to prevent them from reaching the knockout operator workstations. Rotary media drums that offer more vigorous or longer shakeout cycles can loosen additional sand. Modern high-frequency vibrating units offer another option. These machines can be used with exhaust ventilation and/or sand reclamation equipment to control dust (Document ID 1365, p. 2-56; 0622, 1434; 1715). NIOSH visited a foundry where, on two different product lines, castings were placed through a high-frequency shaking process after the primary shakeout was completed. On one product line, the high-frequency shaker was used after several other cleaning steps; on the second line, castings entered the high-frequency shaker prior to most other cleaning and knockout operations (Document ID 1365, p. 2-57; 0268, pp. 4-5). These two lines demonstrate that foundries have considerable leeway in assigning the order in which various cleaning and processing steps occur. The sooner that all but the most tightly adhered sand can be removed, the less likely the loose sand will affect the silica exposures of downstream workers.

AFS stated that the shakeout and knockout areas present challenges in applying ventilation because the ventilation system can interfere with the operator's access to the work. AFS offered no indication of how often such access is needed, nor did it offer any specific concerns about designs. OSHA acknowledges that large parts pose a greater control challenge but as described below, OSHA has determined that effective ventilated enclosures can be designed that allow appropriate access at work stations. AFS described one foundry that produces a 70,000 pound part. AFS stated that the shaker table for this part is ventilated but that the ventilation "does not guarantee 100 percent capture of the dust" (Document ID 2379, Appendix 1, p. 20). AFS further stated that the part must be moved with an overhead crane. The Agency notes that the ventilation system is not required to be 100 percent effective in capturing dust. It is only required to provide sufficient ventilation such that the PEL is not exceeded. It further notes, as discussed below, that only 5 percent of parts are considered too large for ordinary engineering controls (Document ID 1365, p. 2-47) AFS offered no exposure data that can be used to assess the effectiveness of the above-described ventilation system to achieve the PEL. The rulemaking record similarly did not contain such data. From the brief description provided by AFS, OSHA concludes that the worker that might be exposed in this situation is the crane operator. As noted above, there are feasible controls for crane operators, such as ventilated cabs, that are capable of reducing exposures by 90-95 percent. See Additional Controls for Shakeout Operators (Ferrous Sand Casting Foundries).

When removing adhered scrap metal from castings, saws and grinders can be fitted with LEV or located in partially enclosed, ventilated booths. Handheld tools used on larger castings also can be fitted with tool-mounted LEV or used in a ventilated booth. These tools are often associated with finishing operations and are discussed under that job category. See Additional Controls for Cleaning/Finishing Operators (Ferrous Sand Casting Foundries). AFS stated that one foundry had investigated the use of dust collection systems on handheld grinders and found that "at that time" there were no handheld grinders that could handle the size of the castings without grossly interru[pting] the finishing process (Document ID 2379, Appendix 3, p. 21). The AFS comment did not note when this assessment was done. OSHA points out that there are currently many effective and commercially-available controls for handheld grinders (see the Summary and Explanation for Paragraph (c) of the construction standard) and that studies have shown that hand held-grinders can be used successfully through a shift (Document ID

0521, p. 342). As has been discussed for other job categories in ferrous sand casting foundries, substitution of silica-containing mold and core materials with non-silica alternatives that are less toxic than silica would virtually eliminate the silica exposure of knockout operators. Alternative material, including ceramic media, and zircon sand, are readily available from commercial sources (Document ID 1365, p. 2-59; 1287; 1691).

Additional Controls for Abrasive Blasting Operators

The exposure profile in Table IV.4.8-E shows that 33 percent (20 out of 61 samples) of abrasive blasting operators have exposures at or below the final PEL of 50 μg/m^3. AFS reports show that 63 percent of its members' abrasive blasting operations currently are below the PEL, suggesting that OSHA may be overestimating baseline exposures (see Table IV.4.8-D). Based on this and other evidence in the rulemaking record, OSHA finds that additional controls will be necessary to achieve the PEL for 37 to 67 percent of abrasive blasting operators.

Abrasive blasting operators experience exposures from airborne dust originating from adjacent operations and from the blasting process. As discussed above, most of the workers whose exposures are between 50 and 100 μg/m^3 should see a reduction in exposure to 50 μg/m^3 or less when the foundry controls the silica emissions from adjacent operations. The blasting equipment typically used in foundries are enclosed systems that, when properly maintained, ensure that the silica remains in the system and is not available for worker exposure (Document 1365, p. 2-62).

To the extent that abrasive blasting operators experience secondary exposure from adjacent operations, the exposure levels of these workers will be reduced when the exposures of adjacent workers in other job categories, like shakeout and knockout processes, are reduced.

For abrasive blasting operator silica exposures that continue to be elevated once adjacent sources of respirable dust are controlled, the primary control methods involve repairing or enclosing the machines to seal leaks, and augmenting ventilation systems to achieve 500 feet per minute (fpm) air flow through all openings as recommended for blasting cabinets by the ACGIH or to achieve the air flow recommended by the machines' manufacturer (Document ID 1365, p. 2-63; 0515). Blasting machine manufacturers offer programs to rebuild and retrofit these machines and also provide long-term service contracts. New abrasive blasting machines are readily available from a variety of commercial sources (Document ID 1692). OSHA has determined that abrasive blasters used by the foundry industry are designed to be sealed systems from which silica contamination does not escape unless they are damaged or poorly maintained.

A series of air sampling results demonstrate the value of identifying, enclosing, and ventilating *all* substantial sources of exposure associated with abrasive blasting operations. OSHA visited a gray and ductile iron foundry where the abrasive blasting operator exposures were due to a combination of dust sources. The foundry made incremental modifications and eventually reduced operator silica results by 75 to 85 percent, to levels of less than 50 μg/m^3. Initially, in 1994, two workers sorted castings from a conveyor arriving from the shakeout area and loaded and unloaded an automated shot blasting machine. The ventilation was poor (“0 CFM”) in the sorting area, and results of 178 μg/m^3 and 184 μg/m^3 were obtained for these two operators. The facility replaced the shot blasting machine and associated ventilation, as well as covered and ventilated a section of the conveyor coming from the shakeout. During a second evaluation it was evident that these changes had not reduced the silica exposure levels (195 μg/m^3 and 246 μg/m^3) (Document ID 1365, pp. 2-63 – 2-64; 0128, pp. 72, 255-257, 258 [“0 CFM]-260).

Several months later, the workers continued to perform similar work, but were now placing castings sorted from the conveyor into skip buckets used to load the blasting machine. During this third evaluation, results of 47 μg/m^3 and 107 μg/m^3 were obtained for the two abrasive blasting operators, whose primary source of exposure was now reportedly dust from the shakeout conveyor and skip buckets. The foundry next added an enclosure over the skip buckets and further covered a sand conveyor next to the shot blasting machine. The shakeout conveyor, however, was noted to be a continuing source of exposure during a fourth evaluation, at which time results of 72 μg/m^3 and 80 μg/m^3 were reported for the abrasive blasting operators. Finally, 21 months after the initial evaluation, the facility added an enclosure and LEV to the exit from the shakeout, and also added LEV to the skip bucket enclosure. These controls, combined with previous modifications (new blasting machine with LEV, enclosed and exhausted sand and shakeout conveyors) produced results of 34 μg/m^3 and 47 μg/m^3 for the abrasive blasting operators who continued to sort castings (25 percent of the shift) and operate the shot blasting machine (Document ID 1365, p. 2-64; 0128, pp. 65, 72).

AFS has objected to OSHA's use of this evidence to demonstrate effectiveness of controls. AFS states that OSHA "incorrectly concludes that the isolated samples cited demonstrate reliable compliance" (Document ID 2379, Appendix 2, p. 16). Additionally, AFS cites the following passage from a 1996 letter from an OSHA area director (AD) to the foundry under review:

> Employee working as a Blast Operator on 2/7/96 was exposed to silica at a level greater than one half of the permissible exposure limit of 1.08 mg/m^3. The employee was exposed to a Time Weighted Average of .581 mg/m^3 which is 54 percent of the permissible exposure limit for a period of 431 minutes. It is reasonable to expect that on any particular day an overexposure to respirable silica could occur (Document 0128, p. 9).

AFS concludes incorrectly that this letter contradicts OSHA's use of these samples to show effective control. The issue that AFS raises is not a feasibility of controls issue, as the samples clearly show that controls were effective in reducing exposures. Instead, AFS raised an issue of general OSHA policy to encourage employers to engage in voluntary monitoring as part of a comprehensive approach to industrial hygiene. In this particular case, the OSHA representatives were concerned about airborne dust from the shakeout area and the effect on the shot blasters sampled. This is why the Area Director recommended further sampling after noting that dust could be seen coming from an "unshrouded section of the shaking conveyor" (Document ID 0128, p. 19), and why OSHA recommends controlling all sources of silica dust at the worksite, not only at the particular's employee's workstation. Nevertheless, the controls in the cited case were clearly feasible and effective to control excessive dust for the blasting operators (Document ID 0128, p. 19).

Another option for reducing sand on castings is to perform a two-stage blasting operation in which the casting is initially "pre-cleaned" using fully enclosed equipment before the blasting is finished by hand. OSHA visited a facility that manually blasted castings with aluminum oxide in a ventilated booth and obtained an initial exposure of 436 μg/m^3 (Document ID 0054, pp. 241, 243-244). After changing the process to include pre-cleaning the castings in an automated shot blasting machine before finishing the blasting by hand, the exposure declined to 51 μg/m^3, an 88 percent reduction (Document ID 0054, p. 8). At this facility, OSHA also obtained a result of 33 μg/m^3 for an operator who loaded and unloaded an automated shot blasting machine, which was fully enclosed and equipped with properly functioning LEV (Document ID 1365, pp. 2-64 – 2-65; 0054, pp. 246, 248-249, 251).

Work practices also affect the silica exposure levels of abrasive blasting operators. Sealed and ventilated abrasive blasting cabinets must remain closed for a period of time after blasting ceases (long enough for the ventilation system to cycle several complete air changes inside the cabinet). This period allows the ventilation system to remove residual airborne dust before the operator opens the door, releasing any contaminant remaining inside. In addition, the use of compressed air for cleaning dusty surfaces should be avoided. Two of the highest results in the exposure profile (1,002 μg/m^3 and 238 μg/m^3) are associated with workers who used compressed air to blow dust from surfaces around steel shot blasting machines (Document ID 1365, p. 2-65; 1463, pp. 4, 14, 19, and (pdf) pp. 26-28 Table 2).

Where very large castings (too large to fit into an abrasive blasting machine) must be blasted with abrasives, use of a ventilated blasting booth designed for this purpose can be an effective control. Although operator exposures might remain above the PEL, use of an enclosed booth will minimize the migration of silica dust to other areas of the facility. Abrasive blasting under these conditions must comply with 29 CFR 1910.94 – Ventilation, and the workers performing this abrasive blasting must be equipped with suitable respirators in accordance with 29 CFR 1910.94 and 29 CFR 1910.134 – Respiratory Protection.

Wet abrasive blasting is an additional control option for abrasive blasting operators working on very large castings (whether in the open or in a booth). Wet abrasive blasting is used on other silica-containing materials, such as concrete, and has the potential to limit silica exposures from this source if adequate water is used during the blasting (Document ID 1365, p. 2-65; 0230). The use of water on ferrous castings is rare, but not unprecedented. In 1997, NIOSH visited a gray and ductile iron foundry where finishing operators used water to wet castings while performing grinding (Document ID 1365, p. 2-66; 1381, p. 2).

As noted for other job categories, and in the discussion above for Additional Controls (Ferrous Sand Casting Foundries), by replacing silica sand with alternative granular media that is less toxic than silica for mold and core materials, foundries can eliminate these primary sources of silica exposure (Document ID 1365, p. 2-59; 1287; 1691).

Additional Controls for Cleaning/Finishing Operators

The exposure profile in Table IV.4.8-E shows that 35 percent (80 out of 228 samples) of cleaning/finishing operators have exposures at or below the final PEL of 50 μg/m^3. AFS reports that 62 percent of its members' cleaning and finishing operations already achieve 50 μg/m^3 or less, suggesting that OSHA may be overestimating the worker population exposed above the PEL. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for the remaining cleaning/finishing operators who are overexposed, some by a wide margin (54 out of 228 samples, or 24 percent have exposures above 250 μg/m^3). Additional controls include pre-cleaning castings, local exhaust ventilation, the elimination of cleaning with compressed air, and wet methods.

Exposure levels of cleaning/finishing operators are dependent on a number of factors, including size and shape of casting, degree of burnt-in sand, extent of defects requiring removal, and whether compressed air is used for cleaning. Therefore, options to reduce exposure focus on controlling these factors.

NIOSH has recommended the following general approaches to reducing dust levels in casting cleaning operations: reduce casting defects, pre-clean castings as thoroughly as possible prior to chipping/grinding, apply LEV to these operations, and eliminate the use of compressed air for cleaning (Document ID 1373, p. 35; 1381, pp. 9-10). Other control options include the use of wet grinding/finishing methods and process automation (Document ID 1365, p. 2-76; 0268, p. 8; 1381, p. 1).

Pre-Cleaning Castings

Casting defects can trap mold and materials that produce airborne silica dust during chipping and grinding. When residual mold and core material are present, most castings (small and medium sized) can be pre-cleaned using enclosed, automated, and ventilated processes, such as vibrating abrasive media, rotary media drums, or enclosed shot blasting (Document ID 1695; 1692; 1148). Pre-cleaning reduces the amount of time and effort required to clean and finish castings (Document ID 1714). Exposure levels of 27 $\mu g/m^3$, 36 $\mu g/m^3$, and 40 $\mu g/m^3$ were measured for cleaning/finishing operators working with handheld and stationary grinding equipment on castings that were pre-cleaned using a shot blast machine. Compared with the exposure levels measured before the introduction of pre-cleaning (93 $\mu g/m^3$ and 116 $\mu g/m^3$), these results represent an exposure reduction of 57 to 77 percent (Document ID 1365, p. 2-72; 0081, pp. 147-148, 431-433, 435-437).

AFS has commented that several issues should be considered for the pre-cleaning stage. AFS states (Document ID 2379, Appendix 2, pp. 18-19):

> This method of control is dependent on part configuration and results may not be consistent if operations or products change within the foundry. In addition, the performance of this control cannot be extrapolated to other operations with different processes and products.
>
> In some cases extraneous metal must be removed (manual cleaning) to facilitate use of automated processes because the extra metal prevents proper fixturing, blocks access to part interiors, or may cause damage to automated equipment.

OSHA understands these issues, but, lacking further information to characterize how limited the use of pre-cleaning parts is in relation to changes in product or operations, cannot agree with AFS. Nor has AFS described specific configurations for which pre-cleaning is not a workable solution. One configuration that OSHA has discussed at length in this analysis is the size of parts. OSHA has discussed the fact that the largest castings are difficult to enclose; however, these castings are estimated to make up only about 5 percent of operations (Document ID 1365, p. 2-53). Additionally, AFS has not provided information to characterize how much manual cleaning affects exposures in the context of ventilated and enclosed shot blasting. The evidence of exposure reduction offered in these studies is therefore still valid.

AFS commented on the data OSHA used in the PEA for assessing the effectiveness of controls in cleaning and finishing operations. AFS asserted that “there is no documentation of the reduction to levels … described in the PEA” (Document ID 2379, Appendix 2, p. 3). The exposure data that AFS objected to are derived from case files which display the exposure data in terms that compare to the formula-based PEL that existed prior to this standard. OSHA has recalculated the exposure results for the FEA to allow comparison to the new 50 $\mu g/m^3$ PEL. See Section IV-2 – Methodology for an explanation of this calculation. These data show that exposures below the 50 $\mu g/m^3$ can be achieved.

For several cases cited by OSHA, AFS observed that the agency agreed to extensions of abatement dates to allow the foundries to continue their efforts to reduce exposures. Such extensions are common in OSHA enforcement cases and are based on the Agency’s assessment of the circumstances in individual establishments, such as their good faith efforts to control exposures and other factors. Thus, extended abatement periods do not necessarily correlate with the time needed to install controls or to the ultimate feasibility of the controls.

Finally, in its post hearing brief, AFS contended that “[m]ost foundries already pre-clean castings before cleaning and finishing operations so the reduction would not apply” (Document ID 4229, p. 15). As described above, OSHA is relying on data from a case that PBZ sampling reflected exposures before and after pre-cleaning was instituted. These data reflected an exposure reduction of 57 to 77 percent, the direct effect of pre-cleaning in that facility (Document ID 1365, p. 2-72; 0081, pp. 147-148, 431-433, 435-437).

AFS's statement that most foundries already use pre-cleaning confirms for OSHA that pre-cleaning is a feasible method of reducing exposures.

Local Exhaust Ventilation (LEV)

To reduce exposures while using manually operated power tools in cleaning/finishing operations, NIOSH recommends the following options: 1) vacuum suction system on the tool itself (e.g., a high-velocity low-volume [HVLV] LEV system); 2) a mobile extraction hood; 3) stationary side-draft or downdraft LEV benches; and/or 4) retractable ventilation booth for castings that do not fit on benches (Document ID 1365, p. 2-72; 1368). However, there are limitations with these systems. Option 1 might interfere with tool operation, and clogging of inlet ports has been identified as a problem; and option 3 does not provide direct capture during cleaning of cavities. Still, LEV can provide substantial exposure reduction. NIOSH also notes for cleaning operations that downdraft and/or side draft LEV hoods are preferable to overhead exhaust systems, because overhead exhaust systems can draw silica dust from the point of generation through the worker's breathing zone (Document ID 0246, pp. 8-9).

Gressel, a researcher at NIOSH, reported on a study showing a 59 percent (cone grinder) to 77 percent (cup grinder) reduction of respirable dust exposures after workers switched to using a downdraft booth fitted with a turntable to allow manipulation of castings during cleaning (Document ID 0718, p. 357). The system was designed to ACGIH recommendations (reproduced in Document ID 0515) and included a new ventilation system that had an exhaust volume of 2,900 cfm. NIOSH recommended the use of such workstations as a means of reducing exposure.

Although HVLV hoods for controlling dust emission from portable tools have been available for many years, the foundry industry has not widely accepted them. Historically, HVLV systems involved the use of shrouds fitted to tools, which sometimes obscured the work from the worker's view and proved cumbersome to move about complex casting shapes (Document ID 1365, p. 2-73; 1383). AFS discussed the limitations of LEV on power tools (Document ID 2379 Appendix 1, pp. 25-26). AFS's objections were based on a 1979 NIOSH report. Ventilated tools, particularly grinders, continue to evolve and are becoming more widely available and better accepted in other industries. OSHA points out that there are currently many effective and commercially available controls for handheld grinders (see the Summary and Explanation for Paragraph (c) of the construction standard). In addition, testifying on the use of ventilation in the steel industry at the public hearings Mr. Michael Wright, the Director of Health, Safety and Environment at the United Steelworkers, stated in this context:

> Ventilation is a very good one [engineering control], and that can be applied, both on a very, very large scale, with very large ventilation equipment like we use in the steel industry, which basically removes contaminants from whole furnaces, down to, for example, in grinding and in some places where you're essentially grinding the sand off of a cast piece, the grinders can be equipped with ventilation systems on the handheld grinder. So it's an effective control, really, at all levels (Document ID 3584, Tr. 2577-2578).

LEV systems for stationary tools, such as bench grinders, are readily available and have been shown to reduce exposures in foundries. The ACGIH recommends specific LEV designs for seven different styles of grinding equipment (Document ID 0515). LEV booths present another option for controlling dust from both stationary equipment and hand tools. As noted under baseline conditions for this job category, exposure results of 30 $\mu g/m^3$ were obtained for two operators using separate booths, each with a grinding bench serviced by LEV (Document ID 1365, p. 2-74; 0257, pp. 1, 9, 14).

A case study completed at a foundry in New York showed that a ventilation system, which had been demonstrated to be effective in controlling emissions from another foundry process called air carbon-arc gouging (removing metal from a part using an electric arc), could be used to control silica exposures related to grinding with portable tools. Grinding benches were equipped with a “tabletop booth” consisting of a wrap-around design, which provided supply-air on both sides of the worker’s body as well as exhaust ports at the rear of the bench. The foundry reported that tabletop booths operated at exhaust rates with optimum exhaust rate of 15,000 cfm have “consistently controlled silica exposures during grinding to below OSHA’s Permissible Exposure Level” (Document ID 1720, p. IV-157; 0744, pp. 375-376). OSHA concludes that this type of

LEV could provide some exposure reduction, but the effectiveness of this approach depends on a number of variables, including the size and shape of the castings and the amount of grinding necessary.

Eliminate Cleaning With Compressed Air

NIOSH consistently recommends the elimination of compressed air for cleaning to reduce silica exposures (Document ID 1378, p. 15; 1381, p. 10). ERG, OSHA's contractor, describes an informal review of 26 results for cleaning/finishing operators working at five foundries where NIOSH or OSHA had observed use of compressed air (Document ID 1365, p. 2-75). The review showed that compressed air used by cleaning/finishing operators to blow sand off castings and equipment was associated with elevated exposure results, including a median of 487 μg/m^3 for those 26 results. Furthermore, all 26 results were 230 μg/m^3 and higher. These results are elevated compared with a median of 196 μg/m^3 for all cleaning/finishing operators shown in the exposure profile including exposures below the LOD. The majority of these results are associated with cleaning/finishing operators using pneumatic handheld grinding, sanding, and chipping tools. As an alternative to cleaning with compressed air, preferable practices include wet cleaning methods or vacuuming using appropriately filtered vacuums (see Summary and Explanation of paragraph (h) of the standard for general industry and maritime).

As workers use compressed air to clean, accumulated dust in the surrounding work area becomes airborne and can contribute to worker exposure. OSHA visited a foundry with background silica levels of 63 μg/m^3 associated with the use of compressed air. This background silica concentration would add to the exposures of those workers performing operations that generate silica dust.[46] The foundry made no physical changes in the casting cleaning department, but walls and dust accumulation points in the area were vacuumed and washed. As a result, no background silica dust was detected, and respirable dust levels were reduced 60 to 80 percent in the cleaning/finishing area. Thus, when the compressed air was no longer used and the areas where the dust that was

[46] This area sample result (as opposed to a breathing zone result) is not included in the industry profile.

disturbed by the practice of using compressed air had settled were cleaned, the background level was not detected; this demonstrates the extent to which accumulated dust from poor housekeeping practices and dust spread from other foundry departments can influence cleaning/finishing operator results (Document ID 1365, pp. 2-75 – 2-76; 0511, pp. 3-4).

AFS has commented that this foundry (cited Document ID 0511) visit by OSHA is not representative of other exposures in other foundries. AFS states (Document ID 2379, Appendix 2, pp. 7-8):

> The cleaning department data consist of thirteen samples over an approximately 75 day period. Only one sample contained silica, an extremely unusual finding for foundries and certainly not representative of other foundries' experience, which often find the level of silica in the cleaning room to be higher than in other areas of the foundry.

OSHA does not consider this facility to be unusual or unrepresentative, except perhaps to the extent that it is unusual for a foundry to control silica emissions throughout the facility - from controlling the dust at the source to implementing housekeeping measures to controlling background levels. The results documented during this inspection show that the implementation of the combination of control measures identified throughout the facility can successfully control exposures for cleaning/finishing operators (Document ID 0511, p. 4).

Wet Methods

Wet methods might be the best option for cleaning/finishing operators working on some of the largest castings, which cannot be pre-cleaned using automated methods and which are too large for conventional booths and downdraft tables. Although wet methods are not widely used in ferrous sand casting foundries, this control has been used in this type of facility. A foundry evaluated by NIOSH in 1996 used wet methods to help reduce dust during chipping and grinding of large grey iron castings ranging in mass from 1 to 28 tons (Document ID 1381, p. i). Although NIOSH noted that a worker frequently used water to wet castings, compressed air was also used to remove sand from internal cavities. As a result, an exposure of 380 μg/m^3 was recorded for the cleaning/finishing operator (Document ID 1365, p. 2-69; 1381, pp. 2, 12). OSHA has reason to believe that this exposure would have been substantially lower if a high-efficiency particulate air (HEPA)-filtered vacuum system had been used instead of compressed air.

Wet methods are successfully used in other industries such as the stone cutting industry. Kitchen countertop fabricators experienced up to an 88-percent decrease in silica exposures when finishing operators switched to water-fed angle and edge grinders (Document ID 1146, pp. 578-579).

NIOSH investigated a water-spray dust control used by construction workers breaking concrete with jackhammers. Compared with uncontrolled conditions, the use of water spray reduced exposures between 72 and 90 percent (Document ID 1365, p. 2-51; 0865, p. iv). Williams and Sam (1999) also reported that a water spray nozzle mounted on a handheld pneumatic chipper decreased respirable dust exposures approximately 70 percent, even in the enclosed environment of concrete mixing trucks (Document ID 1365, p. 2-76; 1226, p. 26).

Beamer et al. (2005) conducted a study of dust suppression using misting nozzles to reduce silica while brick cutting using a stationary saw. Misting at different flow rates resulted in respirable mass fractions of dust that were 63 to 79 percent lower using low misting and high misting nozzles, respectively, and 93 percent lower using free-flowing water (Document ID 0549, p. 503). NIOSH completed a similar study evaluating water spray devices to suppress dust created while jack hammering. The study reported between a reduction of between 72 and 90 percent (Document ID 1365, p. 2-88; 0865, p. iv). Foundries can apply these methods to achieve similar exposure reductions. Testifying at the public hearing on behalf of the Wisconsin Committee on Occupational Safety and Health, Mr. James Schultz opined that for a variety of foundry operations "[i]t's possible and with proper engineering, I think it could be very feasible to include misting to control dust" (Document ID 3586, Tr. 3238).

In summary, a number of silica control options are available to cleaning/finishing operators using handheld and bench tools to remove embedded mold and core materials.

Additionally, as discussed for other job categories, foundries that are able to switch to alternate granular media that is less toxic than silica sand can eliminate this source of exposure for cleaning/finishing operators.

Additional Controls for Material Handlers

The exposure profile in Table IV.4.8-E shows that 50 percent (18 of 36 samples) of material handlers have exposures at or below the final PEL of 50 μg/m^3. AFS reported that 79 percent of its members' material-handling operations already achieve levels of 50 μg/m^3 or less, suggesting that OSHA may have overestimated the percentage of material handlers exposed to silica above the PEL and that, instead (see Table IV.4.8-D), the PEL has already been achieved for most material handlers under baseline conditions.

OSHA finds that additional controls will be necessary to achieve the PEL for the remaining material handlers who are overexposed, and that the majority of the remaining overexposed workers, as discussed above, can be reduced below the PEL or lower when effective controls are implemented to reduce silica dust generated from other operations (i.e., sand systems, molding, shakeout, knockout, cleaning/finishing). Where material handlers generate dust through their own activities, additional controls or alternate work practices may be needed. For example, material handlers can minimize the distance that sand falls and the speed with which they add sand to hoppers, both of which will limit the amount of dust released into the air during these activities (Document ID 1365, p. 2-79).

Enclosed operator cabs operating under positive pressure equipped with air filtration and air conditioning offer another option for reducing the exposure of material handlers in facilities that have not implemented controls in high dust generating operations. NIOSH studied exposure reductions using enclosed cabs in the railroad industry and reported a 97 percent reduction in the concentration of respirable quartz inside a sealed cab - from 440 μg/m^3 outside the cab to below the limit of detection (14 μg/m^3) inside the sealed cab (Document ID 0884, pp. 14, 20). Similarly, Hall et al., demonstrated reductions of greater than 90 percent with simultaneous testing inside and outside cabs (Document ID 0719, p. 47). Exhaust ventilation on the material transfer points served by material handlers offers another control option. Improving or adding enclosures and exhaust ventilation on the bins and hoppers into which material handlers place sand would likely offer the same benefit (up to a 83-percent exposure reduction) achieved by foundries that have made such changes to sand transfer equipment (Document ID 1365, p. 2-80; 0139, pp. 59, 61, 134-136).

Finally, as noted for other job categories, essentially all silica exposures of material handlers can be eliminated by foundries that are able to substitute non-silica materials that are less toxic than silica as the granular media used in molds and cores.

Additional Controls for Maintenance Operators

The exposure profile in Table IV.4.8-E shows that 46 percent (11 out of 24 samples) of maintenance operators have exposures at or below the final PEL of 50 µg/m^3. AFS reported that 74 percent of its members' maintenance operations already achieve levels of 50 µg/m^3 or less, suggesting that OSHA may be overestimating the percentage of maintenance operators for whom additional controls are necessary to achieve the final PEL (see Table IV.4.8-D). Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for the remaining maintenance workers who are overexposed.

The primary silica exposure for maintenance operators occurs during routine patching or repair and periodic replacement of refractory materials. Additional sources of exposure, from adjacent processes and equipment maintained by the maintenance operator, will be controlled when the exposure levels of workers associated with those processes and equipment are controlled (Document ID 1365, pp. 2-81 – 2-84).

Additional controls, as discussed below, include the use of reduced-silica refractory materials, automated and remotely controlled processes, precast refractory materials, improved work practices, LEV, and wet methods. In describing these controls, OSHA has drawn from the experiences of contract refractory service providers and other industries, whose workers perform work similar to that of the foundry maintenance operators who patch, maintain, and occasionally replace refractory materials. OSHA expects that these controls will be equally effective for controlling silica exposure during refractory furnace maintenance.[47]

Reduced-Silica Refractory Materials

Refractory materials with low silica content (0 to 5-percent silica compared with 90-percent silica) are readily available from commercial sources, although low silica refractory material is often not compatible with the high temperature furnaces in which refractory materials are used (Document ID 0691).

OSHA visited a gray iron foundry that reduced the silica exposure of workers who relined furnaces by 90 percent after implementing a comprehensive exposure control program that included switching to a low-silica gunning refractory applied to furnace walls (for exposure levels reported at this facility, see below in the discussion of combined control methods). Since the replacement refractory material was stronger and lasted longer, refractory workers also were able to use less material during cupola repair operations (Document ID 1365, p. 16-12; 0121, pp. 10-21, 24).

When switching from high silica to low silica-content refractories, employers will need to consider the possible hazards of substitutes. For example, under high temperatures and oxidative conditions (as in a furnace), the chromite compounds contained in some refractories can be converted to hazardous chromium VI (Document ID 0527, p. 5; 0568, p. 9). Because both installation and removal activities can generate airborne dust,

[47] Increased reliance on professional maintenance contracts has decreased the amount of time foundry employees spend replacing refractory materials (Document ID 0969). An industry source confirmed that refractory relining services are used by an estimated 90 percent of all companies, across all industries that use furnaces requiring relining (including foundries) and this number has been constant for the past decade (Document ID 0969). These companies offer service contracts to reline and maintain refractories on a schedule, using trained personnel. Professional refractory contractors are better equipped for safe handling of refractory materials (e.g., with remotely controlled equipment and portable exhaust ventilation systems) than foundry workers who might perform this work only occasionally. More consistent installation quality also reduces the frequency of relining. Additionally, some refractory management companies also offer a service to reline furnaces off site (Document ID 0969). The exposures and additional controls for professional refractory maintenance contractors are addressed under Section IV-4.19–Refractory Repair.

employers must evaluate the need to protect employees from other contaminants found in refractories before *and* after service life.

Automated and Remotely Controlled Processes

Automated refractory demolition and installation methods can reduce the number of workers exposed, the duration of exposure, and possibly the exposure levels of workers who perform large-scale refractory removal jobs. Examples include “pusher” systems installed in coreless induction furnaces to push out refractory linings (Document ID 0684), remote chipping equipment attached to a hydraulically controlled articulated arm commonly available on some types of construction equipment (Document ID 1162), and automated systems for installing dry rammable refractory material in coreless induction furnaces (Document ID 1367, pp. 11-12). For additional discussion of these control options, see Section IV-4.19 – Refractory Repair, which covers the maintenance service contractors who repair and replace refractory materials. OSHA recognizes that, in general, these methods are more useful and more available to workers involved in large-scale refractory replacement than to maintenance operators who perform periodic patching and repair. However, this control method is included here because some foundry workers occasionally participate in large-scale removal activities.[48]

Precast Refractory Materials

Relining of induction and other furnace types also might be accomplished using precast refractory materials that are set in place as units, with minimal risk of exposure. Precast refractory materials can look like typical construction bricks, or they can have more sophisticated geometries that facilitate installation. For example, curved shapes can be cast that sit flush against the furnace wall. The custom-made precast materials are sealed with refractory grout, mixed from a powder (Document ID 1365, p. 2-86; 0713; 0969). When appropriate for a particular application, preformed refractory shapes can reduce

[48] Some furnace linings are replaced monthly, but most are replaced yearly or even every several years. Information in the record about the frequency of furnace relining is inconsistent. A foundry equipment supplier estimated that many foundry furnaces are relined every 3-4 weeks and some last as long as 8 weeks (Document ID 0691, p. 1). Other sources discussed annual relines (Document ID 1367, p. 9; 1161). A third source, an installer of refractories, stated that refractories usually last a lot longer than a few weeks (Document ID 0969). Another source, a refractory installer, stated that furnaces can last many years depending on maintenance (Document ID 1161).

installation labor, improve performance, and provide a longer service life compared with some brick and poured materials. When repairs are required, standard shapes mean that replacement parts can be kept on hand and that repairs can be isolated to the worn section of the lining, eliminating the need for complete tear-out (Document ID 1179). Because of these and other advantages, companies currently use precast shapes instead of powdered products (monolithics) for certain applications more frequently (Document ID 0713). In 2011, the growth of precast refractory shapes in the United States was expected to exceed monolithics (Document ID 0578, p. 1).

Work Practices

Work practices, such as limiting the number and location of operators working in a furnace at one time, can reduce refractory worker exposures during removal activities. Sweeney and Gilgrist (1998) reported a higher silica exposure level (170 $\mu g/m^3$) for a refractory worker operating in a lower position than a second refractory worker (78 $\mu g/m^3$) within a 1,100-pound holding furnace for molten aluminum. The authors reported 8-hour TWAs for both exposures, assuming zero exposure for approximately 1 hour of the 8-hour shift. The worker who experienced higher exposure levels reportedly bent over to grab and discard the pieces of refractory material debris while the other worker operated the jackhammer. This put the lower worker's breathing zone closer to the jackhammer's point of operation and dust generation than the breathing zone of the jackhammer operator. However, both workers were overexposed to silica-containing respirable dust (Document ID 1178, p. 1).

Where faulty equipment contributes to awkward work practices, a preventive maintenance program can help reduce worker silica exposures. Workers experienced an exposure reduction of 89 percent when a foundry initiated several control measures, including a preventive maintenance program to ensure proper function of air guns and related equipment used to spray refractory furnace lining materials (Document ID 1365, p. 16-15; 0121, p. 15) (for exposure levels reported at this facility, see the section below discussing combined control methods). In a second foundry, a worker's silica exposure level decreased after a foundry replaced the missing tool restraint on a pneumatic chipper used to remove the refractory lining from a large ladle. The tool restraint eliminated the need for this worker to lean into the ladle (where dust was generated) to hold the chipping blade in place. This improvement to the tool, in conjunction with other controls, reduced exposure levels of the worker by 70 percent (Document ID 1365, p. 16-15; 0576, pp. 719-720).

Ventilation (Local Exhaust Ventilation)

Several options are available to control dust generated when refractory workers must chip or apply refractory linings from a position inside the furnace. In addition to using low silica materials, appropriate controls include temporary general dilution ventilation installed in the furnace, LEV on the chipping tool, and wet methods.

A company that provides refractory overhaul services developed a method for installing temporary LEV in a gas-fired furnace. This method is used for complete lining removals, but also is applicable to smaller patching jobs. The method, associated with silica exposures between 50 $\mu g/m^3$ and 100 $\mu g/m^3$, involves company-built exhaust fans fitted with air filters (three filters of increasing efficiency in series). Plastic sheeting is used as necessary to ensure that fresh air enters the furnace only from the most advantageous point, causing clean air to flow past the worker's breathing zone (Document ID 1365, p. 2-87; 1161). Fan/filter boxes are set into the opposite and lower end of the furnace to exhaust dusty air from near the chipping point (Document ID 1365, p. 2-87). The position of sheeting and boxes might need to be moved in order to continue providing optimal air flow as the work progresses to other sections of the furnace. Although the fan/filter boxes are specially built for this purpose, they are made of materials readily available at hardware stores (Document ID 1365, p. 2-87; 1162).

LEV also is a dust control option for refractory workers who empty bags or mix refractory powders. For smaller jobs, workers who dump bags of silica-containing materials can empty the bags into a movable hopper (or other receptacle), then use a flexible sleeve to guide material from the hopper to the distribution point (e.g., a furnace bottom). A portable exhaust trunk (preferably with a semicircular slot or flanged hood) positioned near the bag dumping hopper can capture a portion of the dust released during that activity. Because additional silica exposure can occur when workers compress empty bags, this task also should be located near a portable exhaust trunk/hood. Bag dumping for large jobs can sometimes be eliminated by obtaining powdered materials in bulk bags (e.g., 1-ton sack) filled by the supplier with the predetermined amount of product required for the job. As a standard feature, bulk bags come fitted with a sleeve through which material is dispensed. Bulk bags and sleeves are used for installing high silica rammable refractory powder in induction furnaces. Maintaining the bottom of the sleeve, which releases material, at a level just below the surface of deposited material can keep dust emissions to a minimum (Document ID 1365, pp. 16-16 – 16-17; 0691; 1367).

The benefits of tool-mounted systems for controlling silica have been demonstrated in other industries, including the construction and ready-mix concrete industries. The chipping of refractory materials is similar to chipping concrete, another silica-containing material. NIOSH tested two tool-mounted LEV shrouds for handheld pneumatic chipping equipment (60 pound jackhammers), one custom built and the other a commercially available model. Comparing multiple short-term samples, NIOSH found that the shrouds were capable of reducing respirable dust by 50 to 60 percent from a geometric mean of 2,060 $\mu g/m^3$ when no controls were used to 0.87 mg/m^3 when the commercially available shroud was used. The custom made shroud was less effective. Although the commercially available and the custom-build shroud reduced respirable dust levels, the reductions were not large statistically (Document ID 1365, p. 2-74; 0865, p. 6).

In a separate evaluation, NIOSH showed that this type of LEV system controls dust equally well for smaller chipping equipment. NIOSH collected short-term samples while workers used 25- or 30-pound jackhammers to chip concrete from inside concrete mixer truck drums (comparable to a foundry furnace due to the quantity of hardened concrete accumulated over many months and the enclosed working conditions in the drum). During 90- to 120-minute periods of active chipping, mean silica levels decreased 69 percent (from 970 $\mu g/m^3$ to 300 $\mu g/m^3$) when the workers used a tool-mounted LEV shroud in these enclosed spaces (Document ID 1365, p. 2-74; 0862, pp. 10-11).

AFS challenges the application of the tool-mounted LEV studied in the NIOSH site visit (Document ID 0862) in applying this control to foundries. AFS states the reasons as follows:

> First, this example appears to be directed at refractory operations, which as noted above are a minor component of maintenance activities and do not apply at all to activities of most maintenance workers.
>
> Second, with respect to refractory operations the concrete mixers had consistent configurations whereas foundries typically have different sizes and shapes of melting, holding, pouring and transfer equipment which precludes using a single approach to control. In addition, foundry vessels utilizing refractory linings contain significantly more material than the surface buildup seen in a concrete mixer. The material removed from a concrete mixer is only the excess material accumulated on the surface of the drum. A foundry furnace contains excess material in the form of solidified metal on the surface, but also has a lining that is several inches thick covering the entire inside of the furnace (Document ID 2379, Appendix 2, p. 21).

OSHA agrees that tool-mounted LEV may not be applicable for all situations. However, NIOSH also evaluated a combination of ventilation controls as part of the same study. The tool-mounted LEV shroud plus general exhaust ventilation provided an additional exposure reduction compared with uncontrolled conditions, resulting in a 78 percent decrease in mean silica readings (from 970 μg/m^3 to 220 μg/m^3) (Document ID 1365, p. 2-74; 0862, pp. 10-13). While tool-mounted LEV shrouds on chipping equipment reduce worker exposures, their use is more complicated in very tight spaces (such as some furnaces), where maneuvering the additional air hose can be awkward. Although ventilated chipping tools by themselves may not achieve exposure levels below the PEL, their use will reduce exposure levels and may be combined with other methods like additional general ventilation. One refractory service provider noted that they worked outdoors when possible and that they utilized fans and filter boxes when working indoors (Document ID 1365, p. 16-17; 1161, p. 1).

Wet Methods

Wet methods can be successfully used to control silica exposures in a number of operations, including chipping, sawing, spraying, and handling of dusty refractory materials. The use of water in handling dusty refractory materials acts the same as it does in other silica-containing substrates such as concrete, brick, block and stone. For instance, wet methods are currently effectively used in refractory repair services (see Section IV-4.19 – Refractory Repair). Therefore, OSHA expects that wet methods will be equally effective in the handling of refractory materials during maintenance operations.

Studies have quantified the benefit of using wet methods to control respirable dust generated during chipping with handheld equipment. NIOSH investigated a water spray dust control used by construction workers breaking concrete with 60- and 90-pound jackhammers. A spray nozzle was fitted to the body of the chipping tool, and a fine mist was directed at the breaking point. Using both a direct reading instrument and a high-flow cyclone and filter media, NIOSH collected 10-minute readings with and without the spray activated, and found respirable dust concentrations were between 72 percent and 90 percent lower when the water spray was used (Document ID 1365, p. 2-76; 0865, p. 6). Williams and Sam (1999) reported that a water spray nozzle mounted on a handheld pneumatic chipper decreased respirable dust approximately 70 percent in the worker’s breathing zone (Document ID 1365, p. 2-76). Tool-mounted water spray devices can be assembled using materials obtained from a hardware store and include a garden spray nozzle, tubing, clamps, and a control valve (Document ID 1365, p. 2-88; 0741; 0838; 0914). NIOSH completed another study evaluating water spray devices to suppress dust created while jackhammering. The study reported a 72-percent reduction in PBZ respirable dust exposures (Document ID 1365, p. 2-88; 0865, p. iv).

Water spray also is useful for suppressing dust during cleanup. After chipping, one refractory services provider (2003b) used a garden mister to wet refractory debris in the bottom of the furnace (Document ID 1365, p. 2-89; 1162). This step helped control dust as the waste was removed from the furnace. Another supplier, however, noted that using water caused some problems because it makes the bottom of the furnace slippery (Document ID 1365, p. 16-18; 1161).

Workers must use caution when introducing water into a furnace. Some refractory materials crumble and become muddy or slippery when wet with excessive amounts of water (Document ID 1365, p. 16-18; 1414; 1161). Additionally, wetting portions of the furnace lining that will not be removed (when making smaller repairs) requires an extra step to dry the refractory material before the furnace is brought to working temperature. However, despite these complications, wet methods remain an effective option for controlling silica dust from high energy activities such as pneumatic chipping and should be considered when high silica materials are involved. A spray of fine mist directed at the point of dust generation has been shown to be effective. Several refractory services companies that work with furnace refractories in foundries noted that they routinely use water, applied with a garden hose or mister, but did not provide exposure assessment data to indicate the method's effectiveness (Document ID 1161, p. 1; 1162, p. 1). At an open air location, a flow rate of 350 milliliters (12 ounces) per minute reportedly dried quickly, without adding a substantial amount of water to the work site (Document ID 1365, pp. 16-18 – 16-19; 0865, p. iv). In indoor environments, workers can use a shop vacuum to collect the water (Document ID 0675, p. 1098), but need to ensure general dilution ventilation is sufficient and ensure that vacuum exhaust air does not contain silica or is collected so that it does not become an additional source of exposure in the work area.

Combined Control Methods

Depending on the sources of respirable dust, a combination of control methods can reduce silica exposure levels more effectively than a single method. A routine cupola relining (removal and replacement) in the ferrous foundry industry demonstrates the benefit of using a combination of controls by achieving up to a 92 percent reduction in exposures (Document ID 1365, p. 16-19). Before implementing controls, OSHA collected samples for three workers with results of 270 $\mu g/m^3$, 368 $\mu g/m^3$, and 630 $\mu g/m^3$. This facility then substituted refractory material with reduced silica and greater moisture content (8 percent, rather than 4 percent, moisture), improved equipment and materials to reduce malfunction and task duration, wet refractory material before removal, and assigned a consistent team of trained workers to the task. After the foundry made these changes, silica exposure samples were collected on three dates. The values included six results between 30 μg/m^3 and 50 μg/m^3, one of 61 μg/m^3, and a short-term result below the LOD (<70 μg/m^3).[49] Reduced silica in the respirable dust sample and shorter task times (relining required less time with the improved methods) account for most of the exposure reduction (Document ID 1365, pp. 16-19 – 16-20; 0121, pp. 5-9).

A second report on a facility performing refractory relining also demonstrates the benefits of using a combination of control measures. A full-shift silica result of 215 μg/m^3 was obtained while a worker chipped away the old refractory lining using faulty equipment, and then mixed the replacement refractory material. According to the manufacturer's material safety data sheet (MSDS), the ladle lining contained 56-percent silica. Burmeister noted that the "pneumatic chipper lacked a tool retainer, requiring the worker to hold the chipping bit, putting the worker much closer to the source of the exposure than would have been necessary had the pneumatic chipper been equipped with a retainer." The foundry responded to the high exposure result by holding a training meeting and seeking worker input on abatement actions; implementing a "water control system to reduce dust generated during the pneumatic chipping process"; purchasing chisel retainers to eliminate the need for the worker to reach into the ladle during chipping; and purchasing a vacuum to remove dust and debris from the ladle. With these changes in place, a consultant found that exposure was reduced to 74 μg/m^3, representing a 66-percent reduction. OSHA notes the absence of ventilation controls and concludes that this facility might have achieved still lower silica exposure levels by using LEV or tool-mounted vacuum suction to capture dust, or by managing fresh air flow past the worker's breathing zone (Document ID 1365, p. 16-22; 0576, pp. 719-720).

Additional Controls for Housekeeping Workers

The exposure profile in Table IV.4.8-E shows that 36 percent (4 of 11 samples) of housekeeping workers have exposures at or below the final PEL of 50 μg/m^3. AFS reported that 72 percent of its members' housekeeping activities already achieve the PEL, suggesting that OSHA may be significantly overestimating the percentage of housekeeping workers exposed above the PEL (see Table IV.4.8-D).

---

[49] One of the results of 30 μg/m^3 was also below the LOD (Document ID 1365, p. 16-20; 0121).

Exposure values at or below the PEL are often associated with facilities that make an effort to limit silica exposures of workers in other job categories across the facility. OSHA finds that additional controls will be necessary to achieve the PEL for the remaining housekeeping workers who are overexposed, and expects many of these workers to have reduced exposure levels of 50 μg/m^3 or below once modifications are made to control silica in the dustiest processes (i.e., sand systems operations, shakeout, knockout, abrasive blasting, clean/finishing).

For those housekeeping workers who must clean spills during upset conditions and clean areas where dust gradually accumulates over time, additional controls will be necessary to reduce worker exposures. Additional controls include wet methods, HEPA-filtered vacuums, portable exhaust ventilation, and reduced reliance on compressed air for cleaning.

Silica particles do not become airborne as readily when damp as when they are dry. Housekeeping workers can limit their exposures to silica by cleaning up spilled mold and core sand and washes while they are still damp. The material should be contained or removed so that it does not become a source of exposure when it dries. As evidence of the feasibility of this control method, NIOSH obtained six results for housekeeping workers who cleaned up damp, spilled molding sand every 2 to 4 minutes (with each mold cycle). Although their silica results (65 to 90 μg/m^3) were somewhat elevated because of other dust sources in the area, OSHA finds that the exposures were probably lower than if the sand had been allowed to dry before the workers removed it (Document ID 1365, p. 2-93; 0233, pp. 13-14, 20, 23-25).

Cleaning up spilled sand and core washes, by containing the waste before it dries, will reduce airborne dust generation. When housekeeping workers encounter dry sand, simply adding moisture will reduce dust generation during cleanup. Vacuuming, shoveling, and scraping generate less dust than dry sweeping (Document ID 1365, p. 2-93). A study of construction industry workers found that when compared with dry sweeping, exposures were approximately three times lower when construction workers used squeegees to scrape surfaces and approximately five times lower when workers used vacuums (Document ID 1163, pp. 216-217). OSHA expects similar results in foundries.

When exposures are controlled across the facility, the use of vacuums for cleaning can provide additional exposure control. However, if vacuums are not sealed properly, they can become a source of dust generation and exposure. Portable vacuums must be emptied frequently according to manufacturers' instructions to ensure adequate suction and prevent the vacuum contents from becoming an additional source of exposure (Document ID 1365, p. 2-93; 0632). Special precautions and work practices will need to be developed to make certain that the cleaning of filters does not introduce dust. As an alternative, large stationary or skid-mounted vacuum systems can provide adequate suction with vacuum ports at multiple locations. The suction ports can be positioned near locations where they are most likely to be needed, and the exhaust air and dust will pass through a traditional foundry air-cleaning device, such as a bag house.

Use of compressed air for cleaning also can contribute to workers' silica exposure levels. While low pressure compressed air is usually considered less of a safety hazard than high pressure air, any blowing can cause respirable sized silica particles to become airborne. In a study of construction workers in the United States, Flanagan et al. (2003) made 1-minute measurements using a direct reading dust monitor while 10 workers performed various cleaning tasks (Document ID 1365, p. 2-94; 0676). The investigators found that the cleaning equipment associated with the highest respirable dust exposure level was the backpack blower (Document ID 0676, p. 323).

Where dust accumulations are prevalent, control efforts should start with a thorough cleaning to remove silica dust from rafters, walls, and equipment. Irwin (2003) reported on a foundry (described previously) that reduced silica exposure levels in several job categories from levels in the range of 200 $\mu g/m^3$ and higher, to 50 $\mu g/m^3$ or lower (Document ID 1365, p. 2-94; 0752). Among other modifications, "the foundry temporarily shut down while the entire facility was thoroughly vacuumed and power washed down to remove many years of accumulated silica- containing dust." The down time was used to make other modifications as well, such as completely renovating the sand-handling system (Document ID 0752, p. 20).

Finally, with the substitution of non-silica containing materials for mold and coremaking, silica exposures can be virtually eliminated.

Ferrous Sand Casting Foundries—Feasibility Findings

Feasibility Findings for Sand Systems Operators

The exposure profile in Table IV.4.8-E shows that the silica exposures of 38 percent of sand systems operators in ferrous sand casting foundries are already 50 μg/m^3 or less. AFS survey data report that OSHA may be overestimating baseline exposures, as AFS reports that 47 percent of its members' sand system operations currently achieve the final PEL. Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for sand systems operators when baseline and additional controls previously discussed are used.

Two evaluations in the record demonstrate that employers can achieve the PEL for their sand system operators through the use of engineering controls. An OSHA SEP report shows that exposure reduction levels of up to 82 percent were achieved using a combination of controls. These controls include installing LEV and fixing leaks in the mixer combined with other controls, such as replacing existing equipment with completely enclosed or pneumatic sand processing and transportation equipment, as well as improved work practices and improved housekeeping (Document ID 1365, p. 2-23; 0511). A steel foundry that implemented this combination of controls reduced respirable dust levels to 0.99 mg/m^3, with a silica of 28 percent, resulting silica exposures of 28 μg/m^3 (Document ID 1365, p. 2-23; 0511). Similarly, a NIOSH evaluation found exposure results below 30 μg/m^3 for workers in areas where sand transport systems were isolated and mullers were fitted with ventilation (Document ID 1365, pp. 2-29 – 2-30; 0018, p. 93; 0268, pp. 8-9, 13).

Foundries can mostly eliminate the silica exposures of all workers by substituting for sand with one of the alternate non-silica granular media commercially available for foundries. For example, silica exposures dropped below the LOD for all workers when a foundry in Ohio used olivine sand, a non-silica containing sand (Document ID 1365, p. 2-26; 1412, p. 10). OSHA recognizes, however, that substitution may not be an option for many applications, and employers must evaluate alternate granular media to ensure that workers are adequately protected from any associated hazards.

Applying the 82 percent reduction to the 28 exposures between 50 μg/m^3 and 250 μg/m^3 as shown in Table IV.4.8-E results in 88 percent of the exposures for sand systems operators being below the 50 μg/m^3 PEL. Therefore, OSHA concludes that the 50 μg/m^3 PEL can be achieved for most sand system operators.

Feasibility Findings for Molders

The exposure profile in Table IV.4.8-E shows that the silica exposures of 57 percent of molders in ferrous sand casting foundries are already 50 μg/m^3 or less. AFS survey data report that 63 percent of its members' molding operations already achieve the final PEL. These two independent data sets agree that the final PEL is already being achieved for most molding operations most of the time.

Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for molders when baseline and additional controls previously discussed are used in combination. Additional controls that can be used include improving the enclosures and ventilation associated with equipment that delivers and processes sand in molding areas, and eliminating poor housekeeping and work practices that disturb dust (e.g., dry sweeping and use of compressed air). Evidence shows that exposure levels of 42 μg/m^3 to 40 μg/m^3 are associated with improvements in engineering controls (Document ID 1365, p. 2-30; 0132, pp. 238, 242, 244) and a silica exposure level of 40 μg/m^3 or less was achieved when a foundry also implemented aggressive housekeeping practices in addition to LEV and work practice controls (Document ID 1365, pp. 2-30 – 2-31; 0752, p. 20).

As was discussed under the heading Additional Controls for Molders (Ferrous Sand Casting Foundries), the controls that have been shown to be effective for molders are those controls that reduce contamination from other adjacent operations, particularly the sand handling system and general housekeeping. Thus, the exposure levels of workers in this job category will be reduced when facilities control the exposures of adjacent workers in other job categories. OSHA concludes that by implementing the controls described above and controlling adjacent sources of exposure, with few exceptions foundries will be able to reduce the exposure levels of molders to levels of 50 μg/m^3 or less.

Based on the available exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for most molders.

Feasibility Findings for Core Makers

The exposure profile in Table IV.4.8-E shows that the silica exposures of 57 percent of core makers in ferrous sand casting foundries are already 50 μg/m^3 or below. AFS survey data report that OSHA may be significantly overestimating baseline exposures, as AFS reports that 73 percent of its members' core making activities already achieves the PEL. Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for core makers when baseline and additional controls previously discussed are used.

OSHA thus finds that the exposure level of most of the remaining core makers can be reduced to levels of 50 μg/m^3 or less by effective control of silica release from adjacent operations (e.g., shakeout, finishing, sand systems operations). In addition, a thorough cleaning followed with improved housekeeping (i.e., switching to HEPA-filtered vacuums instead of compressed air) will reduce exposure levels further. A foundry that took steps to control the release of silica and also improved the general ventilation and sand-handling systems within the building reduced core maker exposure levels to 12 μg/m^3 and 24 μg/m^3, which shows that even higher reduced (Document ID 1365, p. 2-36; 0511).

Based on exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for most core makers.

Feasibility Findings for Furnace Operators

The exposure profile in Table IV.4.8-E shows that the silica exposures levels of 73 percent of furnace operators in ferrous sand casting foundries are already 50 μg/m^3 or below. Similarly, AFS reports that 70 percent of its members' furnace operations are at or below the PEL. These two independent data sets agree that the PEL is already being achieved by most furnace operators. Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for furnace operators when baseline and additional controls previously discussed are used, including when the spread of silica dust from other areas of the foundry to the furnace area is reduced and when better ventilation systems are used.

To reduce all furnace operator exposures to the PEL of 50 μg/m^3, OSHA finds that facilities will need to ensure that all existing emission control systems are functioning properly throughout the foundry, or install such systems where feasible to reduce dust generation from tasks specifically performed by furnace operators (Document ID 1365, p. 2-40; 0028; 0268; 0752; 1376).

In foundries where silica-contaminated foundry returns contribute to the exposure of furnace operators, metal scrap can be cleaned using rotary media mills (Document ID 1365, p. 2-39; 1434; 1715). If sand must be added to the furnace (as part of the formulation or to protect the furnace lining from aggressive metals), a retractable enclosing hood will permit the worker to add sand under controlled circumstances (Document ID 1365, p. 2-39; 1175, p. 9).

In the infrequent event that furnace operators repair refractory furnace linings, exposures can be reduced using the same controls available to workers in the foundry maintenance operator job category covered elsewhere in this section.

Based on exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for most furnace operators except for those conducting certain refractory lining repairs, which is an infrequent occurrence.

Feasibility Findings for Pouring Operators

The exposure profile in Table IV.4.8-E shows that the silica exposures of 50 percent of pouring operators in ferrous sand casting foundries are already 50 μg/m^3 or below. AFS reported that 67 percent of pouring operators already achieve the PEL, suggesting that OSHA may have underestimated the percentage of pouring operators whose exposures are currently below the PEL. Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for pouring operators when baseline and additional controls previously discussed are used.

OSHA finds that pouring operator exposure levels above 50 μg/m^3 are generally due to uncontrolled exposures in adjacent operations. For those pouring operators whose exposures might still be above 50 μg/m^3 after dust control for adjacent operations has been addressed, additional controls might be implemented. As discussed under the heading Additional Controls for Pouring Operators (Ferrous Sand Casting Foundries), such controls include isolation of the pouring operation, adjustment of air flow in the facility to prevent dusty air from being drawn into the pouring area, or use of booths and cabs to isolate operators from silica exposures.

Based on exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for most pouring operators when exposures in the rest of the foundry are adequately controlled.

Feasibility Findings for Shakeout Operators

The exposure profile in Table IV.4.8-E shows that the silica exposures for 43 percent of shakeout operators in ferrous sand casting foundries are already 50 μg/m^3 or below. AFS reported that 58 percent of its members' shakeout processes already achieve the final PEL, suggesting that OSHA may be overestimating baseline exposures. Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for shakeout operators when baseline and additional controls previously discussed are used.

By using additional controls, including enclosing operations, improving existing ventilation, or installing new systems, exposure levels can be reduced for most shakeout operators to levels of 50 μg/m^3 or less. For example, four shakeout operator exposure results were 41 μg/m^3 or less at three foundries that implemented various dust control measures in the shakeout area (e.g., shakeout enclosure added, ventilation system improved, rotary media mills installed, conveyors enclosed and ventilated) and made other systematic efforts to abate dust emissions (MI 1483 as cited in Document ID 1365, pp. 2-51 – 2-52). In its post hearing brief, the United Steelworkers commented:

> At a USW foundry, exposure monitoring of a shakeout operator was collected and trended from 1986 to 2013. This trend depicts a significant decline in exposure when the company began to utilize the hierarchy of controls and substitute the high silica content products with less concentrated products (Document ID 4214, p. 16).

While most shakeout operators' exposures will be controlled to the PEL of 50 μg/m^3 or below by using the controls described above, some operators (an estimated 5 percent of the total) will not be able to use the same methods to reach this level because the casting size or the need to manipulate castings will make it more difficult to enclose or ventilate the process (Document ID 1365, p. 2-47). For these operators, achieving exposures below 100 μg/m^3 using engineering controls is more realistic. Until engineering controls can be developed to manage silica concentrations in their work areas, employers will need to sample and to provide appropriate respiratory protection to protect these shakeout operators.

Finally, depending on the production process characteristics, substituting non-silica granular media that is less toxic than silica for silica sand in the molding and core making processes may be feasible in some operations. As discussed for the sand systems operator job category, these media are commercially available and are associated with silica exposure levels below the LOD for all job categories evaluated (Document ID 1365, p. 2-26; 1412, p. 10; 3733, pp. 2-3). However, because the ability to use substitutes depends on the processes involved, OSHA is not relying on substitution to support its technological feasibility finding.

Based on exposure data and the evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for most shakeout operators. The supplemental use of respirators may be necessary for the small percentage of shakeout operators who work on large castings in circumstances where substitution to non-silica granular media is not feasible.

Feasibility Findings for Knockout Operators

The exposure profile in Table IV.4.8-E shows that the silica exposures of 51 percent of knockout operators in ferrous sand casting foundries are already 50 μg/m^3 or below. Similarly, AFS reported that 52 percent of its members' knockout operations have exposures at or below 50 μg/m^3. These two independent data sets show that at least half of all knockout operations currently achieve the PEL under baseline conditions. Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for knockout operators when baseline and additional controls previously discussed are used.

OSHA thus finds that the remaining knockout operators with exposures above 50 μg/m^3 will require a combination of additional controls. As previously discussed, these include limiting the amount of sand loosely adhered to castings entering the knockout process, and LEV or ventilated tools in areas where excess sand and scrap metal are removed. Because loose sand is the greatest source of exposure to knockout operators who experience the highest silica concentrations, OSHA concludes that the silica exposure levels for even the most highly exposed operators can be reduced effectively when most of this sand is removed before the casting reaches the knockout area and without releasing silica dust into the work area air.

At a foundry in Michigan a combination of controls that included improved ventilation, better workstation enclosures (e.g., side shields and baffles), and new equipment to shake excess sand off castings (in a ventilated tunnel en route to the knockout area) reduced knockout operator exposures to levels of 30 and 50 μg/m^3 (Document 1409, pp. 9-11).

In addition, those operators who work on large castings will require LEV attached to hand tools to reduce exposures (discussed in cleaning/finishing operations). Using LEV-equipped hand tools on large castings where no other controls are feasible will reduce exposures below 100 μg/m^3, but might not reduce exposures below 50 μg/m^3 (Document ID 1365, pp. 2-59 – 2-60). Therefore, as with shakeout operators, OSHA concludes that results of under 100 μg/m^3 can be achieved for the approximately 5 percent of knockout operators working on very large castings, but information is insufficient to confirm that exposure levels for these workers can be reduced to levels of 50 μg/m^3 or less. The supplemental use of respirators may be necessary for the small percentage of knockout operators working on large castings after feasible engineering like LEV and work practice controls have been implemented.

Alternatively, as discussed for sand systems operators, foundries able to switch to non-silica granular media that is less toxic than silica sand can virtually eliminate the silica exposure of all knockout operators. However, because the ability to use substitutes depends on the processes involved, OSHA is not relying on substitution to support its technological feasibility finding.

Based on the exposure data and the evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for most knockout operators. The supplemental use of respirators may be necessary for the small percentage of knockout operators who work on large castings in circumstances where substitution to non-silica granular media is not feasible.

Feasibility Findings for Abrasive Blasting Operators

The exposure profile in Table IV.4.8-E shows that the silica exposures of 33 percent of abrasive blasting operations in ferrous sand casting foundries are already 50 μg/m^3 or below. AFS reported that 63 percent of its members' operations already achieve the PEL. OSHA attributes the difference to poor dust controls that included leaking ventilated booths and inefficient LEV in foundries visited by OSHA and NIOSH (Document ID 1365, pp. 2-61 – 2-65). The AFS survey data, however, suggests that OSHA may be underestimating baseline exposures. Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for abrasive blasting operators when baseline and additional controls previously discussed are used.

Because abrasive blasting operations are closed systems and minimize silica entering the general work area (see Additional Controls for Abrasive Blasting Operators (Ferrous Sand Casting Foundries)), OSHA has concluded that, unless the abrasive blasting enclosure is compromised, a portion of abrasive blaster's exposure levels above 50 μg/m^3 is due to uncontrolled exposures in adjacent operations (Document ID 1365, pp. 2-62 – 2-64). Where exposures remain above 50 μg/m^3, additional controls are available to address overexposures that occur if the equipment leaks, is damaged or needs maintenance. As seen earlier in this analysis, a gray ductile foundry made modifications that included a new blasting machine with LEV, enclosed and exhausted sand conveyors, adding an enclosure and LEV to the shakeout exit, and added LEV to the skip bucket enclosure. Over a period of almost two years, the foundry reduced operator silica results by 75 to 85 percent, to levels less than 50 μg/m^3 (Document ID 1365, pp. 2-63 – 2-64; 0128, pp. 16, 19, 24, 65, 72, 149-154). Another facility found an 88-percent exposure reduction to 51 μg/m^3 after workers started using automated, fully enclosed shot blasting for pre-cleaning castings (Document ID 1365, pp. 2-63 – 2-64; 0054, p. 8).

As noted in Additional Controls for Abrasive Blasting Operators (Ferrous Sand Casting Foundries), pre-cleaning small and medium-sized castings in automated shot blasting machines to reduce the amount of residual sand on the castings also provide a substantial reduction in exposures for these operators when the entire process cannot be accomplished using automated equipment.

For the largest castings, it may not be possible to perform blasting in ventilated blasting booths to limit exposure to other workers. An estimated five percent of abrasive blasting operators manually clean very large castings (the same percentage of shakeout operators are estimated to handle large castings) (Document ID 1365, pp. 2-53, 2-66). To the extent possible, these workers should perform this activity in ventilated blasting booths to limit exposure to other workers. Employers may consider a two-stage blasting process that includes pre-cleaning in a ventilated and enclosed booth. Many of these largest castings must be blasted manually because larger-sized pieces cannot be isolated within a blasting cabinet, thus necessitating other means of worker protection. As in the construction industry, wet abrasive blasting can offer exposure reductions during manual operations

(Document ID 1365, pp. 2-65 – 2-66). OSHA concludes that these controls will reduce exposures during blasting of these largest castings, but not necessarily to levels at or below the PEL.

Based on the exposure data and the evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for a majority of abrasive blasting operators by automating and enclosing abrasive blasting operations using properly ventilated equipment and following manufacturer's recommendations for abrasive blasting machine use and maintenance. This conclusion is based on the expectation that silica exposures from adjacent sources will be reduced when the exposure of adjacent workers in other job categories is controlled. Therefore, OSHA finds that compliance with the PEL for abrasive blasting operators is feasible. OSHA also finds, however, that for foundries that produce large castings, respirator use may be necessary.

Feasibility Findings for Cleaning/Finishing Operators

The exposure profile in Table IV.4.8-E shows that the silica exposures of 35 percent of cleaning/finishing operators in ferrous sand casting foundries are already 50 μg/m^3 or below. AFS reported that 62 percent of its members' cleaning and finishing operations already achieve levels of 50 μg/m^3 or less, suggesting that OSHA may be overestimating baseline exposures. Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for cleaning/finishing operators when baseline and additional controls previously discussed are used.

At one foundry, installation of a downdraft dust collection bench (LEV) for workers using handheld equipment to clean and finish castings reduced exposure levels to 20 μg/m^3 and 24 μg/m^3 (a reduction of 69 percent on average) (Document ID 1365, p. 2-73). At another foundry, pre-cleaning castings using a shot blast machine (prior to performing finishing operations using handheld and stationary grinding equipment) reduced exposures to 27 μg/m^3, 36 μg/m^3, and 40 μg/m^3) (Document ID 1365, p. 2-72; 0081, pp. 147-148).

OSHA expects that pre-cleaning castings will be as effective and possibly more effective when cleaning castings with larger quantities of adhered mold material. This expectation is based on the ability of pre-cleaning equipment to prepare castings equally well regardless of the initial quantity of mold material adhering to the castings' surface. For a typical casting, the shot blast machines, tumbling media mills, and related equipment (singly or in series) leave only the most ingrained mold material, so cleaning/finishing operators must grind only the trace volume of residual mold material, and the resulting silica exposures are minimized (Document ID 1695; 1692; 1148).

Since pre-cleaning and use of dust collection equipment are independent controls, OSHA estimates that foundries that pre-clean castings *and* install LEV can reduce the silica exposure of finishing operators using handheld equipment by a combined 90 percent (assuming the average exposure reduction for each control is achieved). For example, an exposure of 500 $\mu g/m^3$ conservatively can be reduced by 67 percent (the midpoint of the 57 to 77 percent range cited in Additional Controls for Cleaning/Finishing Operators (Ferrous Sand Casting Foundries)) to 165 $\mu g/m^3$ by thoroughly pre-cleaning castings, and can be further reduced on average by 69 percent, to 51 $\mu g/m^3$, by providing workers with LEV workstations (such as downdraft tables) (Document ID 0718, p. 357), for a total reduction approaching 90 percent.

OSHA finds that further dust management efforts can reduce exposures to lower levels. As noted in the section on additional controls for this job category, effective plant cleaning to remove sources of accumulated dust has been shown to reduce background respirable dust exposure levels by 60 to 80 percent (Document ID 1365, p. 2-75; 0511, p. 3).

OSHA further finds that eliminating the use of compressed air for cleaning will significantly reduce the exposure levels of many of the most highly exposed cleaning/finishing operators (those 11 percent with exposures currently exceeding 500 $\mu g/m^3$). ERG-G (2008) found that 26 cleaning/finishing results associated with compressed air for cleaning had a median of nearly 500 $\mu g/m^3$ (487 $\mu g/m^3$), compared with the median of 73 $\mu g/m^3$ for cleaning finishing operators as a whole (Document ID 1365, pp. 2-67, 2-70). OSHA estimates that by eliminating cleaning with compressed air, many of these workers will experience exposure levels closer to the median for the entire job category (i.e., substantially below 500 µg/m^3). At these reduced levels, these workers will benefit from the exposure control methods described in the previous paragraphs to the same extent as the other 89 percent of workers in this job category.

OSHA finds that the exposures for most of the remaining overexposed workers can be reduced to 50 µg/m^3 or less by using a combination of controls, including effectively pre-cleaning castings, using ventilated workstations, improving housekeeping, and eliminating the use of compressed air for cleaning and the use of wet methods. OSHA concludes that the 50 µg/m^3 PEL can be achieved for most cleaning/finishing operators most of the time.

Feasibility Findings for Material Handlers

The exposure profile in Table IV.4.8-E shows that the silica exposures of 50 percent of material handlers in ferrous sand casting foundries are already 50 µg/m^3 or below. AFS reported that 79 percent of its members' material handling operations already achieves exposure levels at or below 50 µg/m^3, suggesting that OSHA may be overestimating baseline exposures. Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for material handlers when baseline and additional controls previously discussed are used. OSHA thus finds that once foundries have controlled the exposures of workers in other job categories (which contribute the majority of the airborne silica to which material handlers are exposed), the exposures of the vast majority of the remaining overexposed material handlers also will be controlled to the same level.

Where material handlers' activities generate silica dust, exposures will be reduced through use of work practices that minimize dust release (minimizing the distance that sand falls during material handling and adding sand slowly to hoppers so that the hopper capacity is not exceeded). If exposures continue to exceed the PEL of 50 µg/m^3, foundries can install enclosed cabs on heavy material-handling equipment. While OSHA believes that material handlers who have exposures of 100 µg/m^3 or less can alter work practices to reduce their exposures, reductions might be insufficient to achieve exposures below 50 µg/m^3. Enclosed, ventilated cabs are associated with exposure reductions of 90 to 97 percent and can reduce even the highest material handler result to a level less than 50 μg/m^3 (Document ID 0719, p. 47; 0884, pp. 14, 20). AFS commented that OSHA's assumption that material handlers in U.S. foundries use forklifts is incorrect and asserts that using wheelbarrows to transport sand is common. However, AFS also indicates that the typical foundry may have 10 forklifts (Document ID 2379 Appendix 3, p. 21). Had AFS chosen to present some data about exposures associated with using wheelbarrows, OSHA could have factored this into the analysis.

As noted for other job categories, OSHA further finds that switching to alternate granular media that is less toxic than silica for molds and cores will essentially eliminate the silica exposures of material handlers. However, because the ability to use substitutes depends on the processes involved, OSHA is not relying on substitution to support its technological feasibility finding.

Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for most material handlers.

Feasibility Findings for Maintenance Operators

The exposure profile in Table IV.4.8-E shows that silica exposures of 46 percent of maintenance operators in ferrous sand casting foundries are already 50 μg/m^3 or below. AFS survey data indicate that OSHA may be significantly overestimating baseline exposures, as AFS reported that 74 percent of its members' maintenance activities already achieve the PEL. Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for maintenance operators when baseline and additional controls previously discussed are used.

OSHA thus finds that exposures below the 50 μg/m^3 PEL for maintenance operators are primarily achieved by using low-silica refractory materials where practical and implementing work practices that limit their exposures and activities to small-scale patching or repair tasks (Document ID 1365, pp. 2-89 – 2-90; 0121, pp. 7, 12, 10-21, 24).

Refractory repair is the primary source of silica exposure for these workers. While they might also encounter indirect exposure from the activities of workers in other job categories, maintenance operators' exposures from those sources will be eliminated when the other job categories are controlled. Maintenance operators can also encounter silica during upset conditions (Document ID 1365, p. 2-84).

OSHA has concluded that the exposure levels of many of the remaining operators (those with current exposure values of 250 $\mu g/m^3$ or less) can be reduced to levels of 50 $\mu g/m^3$ or less by using these same methods. This means that up to 80 percent of maintenance workers will achieve compliance with the PEL using these methods. A foundry that implemented a comprehensive exposure control program that included switching to low-silica refractory reduced exposure levels by 92 percent (Document ID 1365, p. 2-89; 0121, pp. 10-21, 24). The extent and the consistency of worker exposure reduction will depend on the silica content of the replacement materials and the proportions in which they are used compared with other refractory materials.

In foundries that cannot use reduced silica refractory patching products (because of incompatibility with production processes), additional control methods will be needed. OSHA finds that these facilities will be able to reduce maintenance operator exposure levels if they use a combination of chipping equipment fitted with LEV shrouds (or water spray when possible), work practices that limit exposure, and general exhaust ventilation that improves air circulation within the furnace during small-scale tasks (Document ID 1365, p. 2-89; 0862). However, the level of 50 $\mu g/m^3$ might not be achieved for all of these workers. NIOSH found that tool-mounted LEV when used with increased general ventilation reduced worker silica exposure levels by 78 percent in enclosed concrete mixer drums, but could not reliably maintain exposures to the level of the PEL (50 $\mu g/m^3$) (Document ID 1365, p. 2-74; 0862, pp. 10-13). OSHA acknowledges the need for maintenance workers to wear respiratory protection when patching refractories.

The exposure level of in-plant maintenance operators engaged in completely replacing refractory linings during overhaul activities also can be reduced using these controls, but to a somewhat lesser extent (to levels of 100 $\mu g/m^3$) because of the extent and duration of the project.[50] OSHA estimates that exposures during complete furnace replacements can be controlled by relying on a combination of controls that include LEV, automated or remotely operated equipment, the use of low silica-containing refractory materials, pre-wetting materials being removed, misting the air during removal, and high-moisture installation. These controls have been shown to reduce exposures during refractory repairs to levels of 50 µg/m^3 or less (see Section IV-4.19 – Refractory Repair). Based on the effectiveness of these controls described under the heading Additional Controls for Maintenance Operators (Ferrous Sand Casting Foundries), OSHA anticipates that using these controls during foundry-furnace repairs will reduce the exposure of most maintenance operators who maintain or replace refractory materials to levels below 50 µg/m^3.

Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 µg/m^3 PEL can be achieved for most maintenance operators most of the time. However, supplemental respiratory protection may be necessary for maintenance operators where reduced silica refractory patching products cannot be used.

Feasibility Findings for Housekeeping Workers

The exposure profile in Table IV.4.8-E shows that the silica exposures of 36 percent of housekeeping workers in ferrous sand casting foundries are already 50 µg/m^3 or below. AFS survey data indicate that OSHA may be significantly overestimating baseline exposures, as AFS reported that 72 percent of its members' housekeeping operations already achieve the PEL. Based on this and other information in the rulemaking record, OSHA finds that the standard is technologically feasible for housekeeping workers when baseline and additional controls previously discussed are used.

OSHA thus finds that the exposure levels of most overexposed housekeeping workers will be reduced to 50 µg/m^3 or less when the exposures of workers in other job categories

[50] Based on information reported by Refractory Products Supplier A (2010) (Document ID 1159) that 75 percent of facilities use a professional service for this work (suggesting that the remaining 25 percent perform it using their own workers), OSHA has determined that this group of maintenance operators is represented by the 21 percent shown in Table IV.C-16 who currently have exposures exceeding 250 µg/m^3. As noted previously, complete relining occurs only occasionally: monthly for some furnaces and annually (or every 3 years) for other furnaces.

also are controlled. If housekeepers in a foundry continue to experience elevated exposures after the silica levels associated with other job categories have been controlled, an initial thorough cleaning to remove residual accumulated silica can reduce exposure levels. A foundry reduced silica exposure in several job categories from levels of 200 μg/m^3 and higher to 50 μg/m^3 or lower by making a number of modifications, including a thorough cleaning with vacuuming and power washing to remove many years of silica dust accumulation (Document ID 1365, p. 2-94; 0752, p. 20).

Additional controls, such as using HEPA-filtered vacuums, using wet methods to clean up spilled sand (i.e., clean while the sand is still damp, using sweeping compounds) and eliminating use of compressed air, can further reduce exposures during those tasks performed by housekeeping workers that generate additional dust. OSHA concludes that with implementation of these control strategies, described in detail under the heading Additional Controls for Housekeeping Workers (Ferrous Sand Casting Foundries), all exposures for housekeeping workers can be reduced below 50 μg/m^3.

Based on the exposure data and evidence of effective controls, OSHA concludes that overall silica exposures in ferrous sand casting foundries will be significantly reduced as a result of the engineering controls provisions of the final rule. These overall exposure reductions will also reduce exposures to housekeeping workers. OSHA concludes that the 50 μg/m^3 PEL can be achieved for most housekeeping workers.

Ferrous Sand Casting Foundries—Overall Feasibility Finding

Based on the best available evidence, as presented above, OSHA finds that compliance with the PEL is technologically feasible in ferrous sand casting foundries in most operations most of the time. OSHA also concludes that engineering and administrative controls may sometimes not be sufficient to reduce exposures to 50 μg/m^3 or less, particularly for foundries that make large castings. In those instances, supplemental respiratory protection may be needed. OSHA thus finds that the final PEL of 50 μg/m^3 is technologically feasible for ferrous sand casting foundries.

4.8.2 Nonferrous Sand Casting Foundries

Description

The job categories, manufacturing processes, and equipment are essentially the same for ferrous and nonferrous sand casting foundries, as are the sources of silica exposure within these foundry types. Only the metal type of the material being cast differs. However, among all sand casting foundries, ferrous foundry workers typically have higher silica exposures than workers in other metal casting facilities. This is primarily due to the higher temperatures required for ferrous casting, causing molds that are hotter, drier, and hence dustier during shakeout operations (Document ID 1365, p. 2-95; 0926). For the same reasons, in nonferrous sand casting foundries, sand-handling and molding sand removal tasks, that is, knockout, abrasive blasting, and cleaning/finishing, contribute less dust exposure not only to these job categories but throughout the foundry. Some nonferrous metals are compatible with different casting materials than are typically used for ferrous casting. For example, historically, olivine sand (with very low silica content) was thought to produce better casting quality for aluminum than for iron, and thus is used more frequently in the aluminum casting sector (Document ID 1365, p. 2-95; 0683). AFS indicated that olivine sand was no longer available (Document ID 2379, Appendix 2, p. 5). Although there are other types of low silica content media available, the record does not reflect the extent to which these media can be used in the different processes (Document ID 3733, pp. 2-3). Regardless, based upon the studies reviewed above showing that there are feasible engineering and administrative controls that abate dust exposures in the ferrous sand casting foundries, the similarities among the tasks performed in ferrous and nonferrous sand casting, and the lower exposures discussed in more detail below, OSHA finds that exposures in nonferrous sand casting can be reduced to below the 50 μg/m^3 PEL without reliance on low silica media substitutes.

Because the same fundamental processes are used in nonferrous foundries as are used in ferrous foundries, the job categories are the same. The exposure sampling data available for this subsector aligns well with the job categories included in Table IV.4.8-F. The median, mean, and range of exposures of nonferrous sand casting workers are presented by job category in Table IV.4.8-F. Exposure results in these facilities are generally lower, though within the range of results reported for ferrous sand casting foundries. With one exception (the maximum result for cleaning/finishing workers), the medians and maximum exposure levels in every job category are lower for nonferrous foundries than for ferrous foundries.[51] However, the profile shows that there is the potential for elevated silica exposure among nonferrous sand casting foundry workers in all job categories.

Exposure Profile, Baseline Conditions, and Additional Controls for Nonferrous Sand Casting Foundries

For each job category, the following sections discuss the similarities and any relevant differences between nonferrous sand casting foundries and ferrous sand casting foundries as they apply to worker activities and exposure levels. The focus is primarily on the exposure levels because the processes and tasks performed are so similar between ferrous and nonferrous sand casting foundry workers. The discussion indicates whether the exposure control options and conclusions presented for ferrous sand casting foundries apply in nonferrous sand casting foundries.

The exposure profile in Table IV.4.8-F for nonferrous sand casting foundries includes 252 full-shift, PBZ samples of respirable crystalline silica. The median exposure is 16 μg/m^3, the mean is 38 μg/m^3, and the range is 10 μg/m^3 (LOD) to 1,915 μg/m^3. Of the 252 samples, 40 (15.9 percent) are above 50 μg/m^3; of which 7 (2.8 percent) exceed 100 μg/m^3, while 212 (84.1 percent) are at or below 50 μg/m^3. All job categories for which there are data show most workers with exposures at or below 50 μg/m^3. The samples were collected primarily by NIOSH and OSHA and include OIS data from more recent OSHA inspections. OSHA thus based the exposure profile on the best available evidence of worker exposure in this industry and considers it to reflect baseline conditions. The AFS did not submit exposure data on nonferrous foundries.

[51] The maximum value among the data available to OSHA for cleaning/finishing operators in nonferrous sand casting foundries (1,915 μg/mm^3) is 3 percent higher than the maximum for ferrous sand casting foundries (1,868 μg/m^3). However, this figure might not indicate increased potential for elevated exposures. Just 1 percent of the cleaning/finishing operators in nonferrous sand casting foundries experienced a result above 250 μg/m^3, while 22 percent of the exposure levels reported for workers in the same job category exceeded 250 μg/m^3 in the ferrous sand casting foundries (see Tables IV.4.8-F and IV.4.8-E).

4.8) Foundries (Metal Casting)

The affected job categories, worker duties, sources of exposure, and equipment in nonferrous sand casting foundries are the same as in the ferrous sand casting industry. Exposure levels in this industry tend to be lower than in ferrous sand casting foundries because the nonferrous metals are typically cast at lower temperatures than ferrous metals, resulting in less drying and fracturing of silica mold and core materials. Where additional controls are needed for nonferrous foundries, the same types of controls discussed above for ferrous foundries will be effective in controlling exposures. Therefore, as in the ferrous sand casting industry, OSHA finds that the silica exposures of most workers can be controlled to 50 $\mu g/m^3$ or less most of the time.

Table IV.4.8-F
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Nonferrous Sand Casting Foundries
(Parts of NAICS 331524, 331525, 331528, 331529)

	Exposure Summary			Exposure Range			Exposure Profile

<u>*Feasibility Finding for Nonferrous Foundries*</u>

Feasibility Finding for Nonferrous Sand Systems Operators

Processes and activities in nonferrous sand casting foundries are essentially the same as those found in ferrous sand casting foundries (Document ID 1365, p. 2-97). Both types of sand casting foundries use “green sand” (a moldable mixture of sand and clay) for their operations. Additionally, both types of foundries recycle molding sand using automated equipment to crush lumps and incorporate more clay (Document ID 1365, pp. 2-19 – 2-20). Ferrous and nonferrous foundries use the same types and configurations of molds. Ten results summarized in Table IV.4.8-F show exposures ranging from 13 to 78 μg/m^3, with a median of 20 μg/m^3.

The exposure profile in Table IV.4.8-F for sand system operators in nonferrous sand casting foundries includes 10 samples. The median exposure is 20 μg/m^3, the mean is 30 μg/m^3, and the range is 13 μg/m^3 (LOD) to 78 μg/m^3. Of the 10 samples, 8 (80 percent) are at 50 μg/m^3 or less. OSHA finds that additional controls will be necessary to achieve the PEL for the remaining 20 percent of workers who are overexposed. OSHA concludes that the controls and conclusions for sand systems operators in ferrous sand casting foundries also apply in nonferrous sand casting foundries because both types of foundries use the same equipment and sand in a similar manner and in similar processes (Document ID 1365, p. 2-95). Therefore, by implementing those controls as needed, nonferrous sand casting foundries will likely be able to reduce the exposure levels of most sand systems operators to levels of 50 μg/m^3 or less.

Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for sand system operators in nonferrous sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Finding for Nonferrous Molders

Molder activities in nonferrous sand casting foundries are the same as those in ferrous sand casting foundries. The molding equipment, sand type and quantities, and worker activities are nearly identical in both types of foundries (Document ID 1365, pp. 2-95 - 2-96).

The exposure profile in Table IV.4.8-F for molders in nonferrous sand casting foundries includes 61 samples. The median exposure is 20 μg/m^3, the mean is 35 μg/m^3, and the range is 12 μg/m^3 (LOD) to 441 μg/m^3. Of the 61 samples, 52 (85.2 percent) are at 50 μg/m^3 or less. OSHA finds that additional controls will be necessary to achieve the PEL for the remaining 15 percent of molders who are overexposed.

Because of the similarities in processes and materials, OSHA concludes that the controls for molders in ferrous sand casting foundries apply in nonferrous sand casting foundries as well. By implementing those controls as needed, nonferrous sand casting foundries will be able to reduce the exposure levels of all molders to levels of 50 μg/m^3 or less. Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for molders in nonferrous sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Finding for Nonferrous Core Makers

Core making is identical in nonferrous and ferrous sand casting foundries. In both types of foundries, core makers oversee transfer of the same type of sand and additives into automated core making equipment to make similar types of cores (Document ID 1365, pp. 2-95 - 2-96).

The exposure profile in Table IV.4.8-F for core makers includes 53 samples. The median exposure is 12 μg/m^3, the mean is 17 μg/m^3, and the range is 12 μg/m^3 (LOD) to 98 μg/m^3. Of the 53 samples, 51 (96.2 percent) are at 50 μg/m^3 or less. OSHA finds that additional controls to achieve the PEL will be necessary for the remaining 4 percent of core makers who are overexposed.

Because of the similarities in tasks and exposure sources, OSHA concludes that the controls for core makers in ferrous sand casting foundries apply in nonferrous sand casting foundries as well. By implementing those controls as needed, nonferrous sand casting foundries will be able to reduce the exposure levels of all core makers to levels of 50 μg/m^3 or less. Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for core makers in nonferrous sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Finding for Nonferrous Furnace Operators

Furnace operator functions are similar in nonferrous sand casting foundries and ferrous sand casting foundries. Although there are some variations in furnace types that are used for the various nonferrous metals, the furnace design is unlikely to affect operator silica exposure levels (Document ID 1365, p. 2-99).

The exposure profile in Table IV.4.8-F for furnace operators in nonferrous sand casting foundries includes 5 samples, all with exposure levels below the LODs (median exposure and mean are both 14 μg/m^3). These results are within the lowest end of the range reported for furnace operators in ferrous sand casting foundries.

OSHA concludes that furnace operator activities, such as controlling and monitoring the furnaces used to pour molten metal, are similar in both types of foundries. Based on the exposure profile, OSHA finds that the exposure levels of all furnace operators in nonferrous sand casting foundries are already at levels of 50 μg/m^3 or less, and additional controls are not necessary for this job category. OSHA recognizes that data are limited for furnace operators in the nonferrous sand casting industry. However, median exposures in both nonferrous and ferrous foundries are well below the final PEL of 50 μg/m^3, and indeed well below the action level of 25 μg/m^3. This supports the finding that the controls described for furnace operators in ferrous sand casting foundries apply to furnace operators in nonferrous sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for furnace operators in nonferrous sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Finding for Nonferrous Pouring Operators

Pouring operator activities are similar to those in ferrous sand casting foundries. Workers in both types of foundries transfer molten metal into a ladle or holding furnace, and then into molds (Document ID 1365, p. 2-99).

The exposure profile in Table IV.4.8-F for pouring operators in nonferrous sand casting foundries includes 8 samples, all with exposures below 17 μg/m^3 (median exposure and mean are both 14 μg/m^3). These results are within the lowest end of the range reported for furnace operators in ferrous sand casting foundries.

Based on the exposure profile, OSHA finds that the exposure levels of all pouring operators in nonferrous sand casting foundries are already at levels of 50 μg/m^3 or less, and additional controls are not necessary for this job category. As with the furnace operators, data are limited for pouring operators. Since median exposures in both types of foundries discussed are well below the final PEL of 50 μg/m^3 and indeed below the action level of 25 μg/m^3, OSHA concludes that the controls described for pouring operators in ferrous sand casting foundries apply to pouring operators in nonferrous sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for pouring operators in nonferrous sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Finding for Nonferrous Shakeout Operators

Shakeout operators perform the same functions and use the same equipment in nonferrous foundries as in ferrous sand casting foundries. In both types of foundries, these workers monitor equipment that separates castings from the same types of sand mold materials (Document ID 1365, p. 2-99).

The exposure profile in Table IV.4.8-F for shakeout operators in nonferrous sand casting foundries includes 31 samples. The median exposure is 35 μg/m^3, the mean is 52 μg/m^3, and the range is 12 μg/m^3 to 212 μg/m^3. Of the 31 samples, 20 (64.5 percent) are at 50 μg/m^3 or less.

OSHA finds that additional controls will be necessary for the remaining 35 percent of shakeout operators who are overexposed. OSHA finds that the controls described for this job category in ferrous sand casting foundries are the same for shakeout operators in nonferrous sand casting foundries; therefore, the remaining shakeout operators' exposures can be controlled to a similar extent by implementing those controls discussed for the equivalent group in the ferrous sand casting foundries. Although not suggested by the exposure profile in Table IV.4.8-F, it is possible that a few shakeout operators in these foundries might require respiratory protection under the same circumstances (i.e., very large castings) as for shakeout operators in ferrous sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for shakeout operators in nonferrous sand casting foundries, with the possible exception of those with very large castings (which is not reflected in the exposure profile of baseline conditions). The standard is therefore technologically feasible for this job category.

Feasibility Finding for Nonferrous Knockout Operators

Knockout operator functions are identical in ferrous and nonferrous sand casting foundries (Document ID 1365, p. 2-100). Operators in both types of foundries use hammers and saws to remove sprues, gates, and risers (i.e., the waste pieces of the metal casting that result from the molten metal passing through the fill tube for each mold) from castings. Although workers in both types of foundries also remove the same type of sand from castings, the lower casting temperatures in nonferrous sand foundries result in processes that are less dry and dusty (Document ID 1365, p. 2-95).

The exposure profile in Table IV.4.8-F for knockout operators in nonferrous sand casting foundries includes 26 samples. The median exposure is 24 μg/m^3, the mean is 29 μg/m^3, and the range is 10 μg/m^3 (LOD) to 84 μg/m^3. Table IV.4.8-F shows that, of the 26 samples, 22 (84.6 percent) are at 50 μg/m^3 or less.

OSHA finds that additional controls to achieve the final PEL of 50 μg/m^{3}will be necessary for the remaining 15 percent of knockout operators who are overexposed. OSHA concludes that the controls described for this job category in ferrous sand casting foundries are the same as those for knockout operators in nonferrous sand casting foundries. Therefore, OSHA finds that the remaining knockout operator exposures can be controlled to a similar extent by implementing those controls discussed for this job category in the ferrous sand casting foundries. Although not suggested by the exposure profile in Table IV.4.8-F, if extremely elevated exposures are encountered, it is possible that a few knockout operators in these foundries might require respiratory protection under the same circumstances (i.e., very large castings) as for the comparable group in ferrous sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for knockout operators in nonferrous sand casting foundries, with the possible exception of those with very large castings (which is not reflected in the exposure profile of baseline conditions). The standard is therefore technologically feasible for this job category.

Feasibility Finding for Nonferrous Abrasive Blasting Operators

The activities of abrasive blasting operators in nonferrous sand casting foundries are the same as in ferrous sand casting foundries. Blasters remove the same type of sand using enclosed systems, but lower casting temperatures in nonferrous foundries create conditions that are less dry and dusty than in ferrous sand foundries (Document ID 1365, pp. 2-95, 2-100).

The exposure profile in Table IV.4.8-F for abrasive blasters in nonferrous sand casting foundries includes 11 samples. The median exposure is 14 μg/m^3, the mean is 26 μg/m^3, and the range is 13 μg/m^3 to 58 μg/m^3. Of the 11 samples, 10 (90.9 percent) are at 50 μg/m^3 or less. Although 9 percent of the results exceed 50 μg/m^3, none exceeds 100 μg/m^3.

OSHA finds that additional control to achieve the final PEL of 50 μg/m^3 will be necessary for the remaining 9 percent of abrasive blasting operators who are overexposed. OSHA concludes that the controls described for this job category in ferrous sand casting foundries (including controlling exposures in the other job categories contributing to overall exposures) are the same as those for abrasive blasting operators in nonferrous sand casting foundries; therefore, the remaining abrasive blasting operators exposures can be controlled to a similar extent. Although not reflected in the exposure profile in Table IV.4.8-F, if extremely elevated exposures are encountered, it is possible that a few abrasive blasting operators in these foundries might require respiratory protection under the same circumstances (i.e., very large castings) as for this job category in ferrous sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 µg/m^3 PEL can be achieved for abrasive blasting operators in nonferrous sand casting foundries, with the possible exception of those with very large castings (which is not reflected in the exposure profile of baseline conditions). The standard is therefore technologically feasible for this job category.

Feasibility Finding for Nonferrous Cleaning/Finishing Operators

Cleaning/finishing operators perform the same activities in nonferrous sand casting foundries as in ferrous sand casting foundries. In both types of foundries, these workers use the same tools to grind out similarly constituted residual mold material and to finish the casting.

The exposure profile in Table IV.4.8-F for cleaning/finishing operators in nonferrous sand casting foundries includes 44 samples. The median exposure is 25 µg/m^3, the mean is 74 µg/m^3, and the range is 12 µg/m^3 to 1,915 µg/m^3. Of the 44 samples, 33 (75 percent) are at 50 µg/m^3 or less. OSHA finds that additional control to achieve the final PEL of 50 µg/m^3 will be necessary for the remaining 25 percent of cleaning/finishing operators who are overexposed. OSHA concludes that these workers require the same additional controls described for cleaning/finishing operators in ferrous sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 µg/m^3 PEL can be achieved for cleaning/finishing operators in nonferrous sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Finding for Nonferrous Material Handlers

The activities of material handlers in nonferrous sand casting foundries are the same as in ferrous sand casting foundries. They typically use powered material handling equipment to transport sand, castings, or other materials.

The exposure profile in Table IV.4.8-F for material handlers in nonferrous sanding casting foundries includes 2 samples. Both samples are below 50 µg/m^3 (16 µg/m^3 and 35 µg/m^3, with a median of 26 µg/m^3). Based on the exposure profile, OSHA finds that the exposure levels of all material handlers in nonferrous sand casting foundries are already at 50 μg/m^3 or less and additional controls are not necessary for this job category. Although the data available for material handlers are limited, the median exposure for material handlers in ferrous sand casting foundries is only 49 μg/m^3, and AFS reported that 79 percent of its members' material-handling operations in ferrous sand casting foundries already achieve the PEL. OSHA concludes that the controls described for material handlers in ferrous sand casting foundries apply to material handlers in nonferrous sand casting foundries in cases where exposures exceed the PEL.

Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for material handlers in nonferrous sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Finding for Nonferrous Maintenance Operators

In both nonferrous sand casting and ferrous sand casting foundries, maintenance operators repair and maintain foundry and sand-handling equipment, including refractory furnace linings. However, maintenance operators who repair nonferrous furnace linings might not need to perform this task as frequently since the lower melting temperatures of nonferrous metals potentially cause less damage to the linings (Document ID 1365, p. 2-101).

The exposure profile in Table IV.4.8-F for maintenance operators in ferrous sand casting foundries includes only 1 sample, which was an LOD value of 12 μg/m^3. While OSHA has only obtained one sample, this exposure is at the low end of the range of exposures for maintenance operators in ferrous sand casting foundries. Table IV.4.8-E shows that 46 percent of maintenance operators in ferrous sand casting foundries currently achieve the PEL, while AFS reported that 74 percent of its member's maintenance operations already achieve the PEL.

Since exposures for nonferrous sand casting foundries are generally expected to be lower, OSHA concludes that the final PEL of 50 μg/m^3 or less has already been achieved for maintenance operators in nonferrous sand casting foundries. Furthermore, refractory maintenance activities in nonferrous foundries are not likely to result in any greater exposure for maintenance operators than in ferrous foundries. The lower melting temperatures of some nonferrous metals, such as aluminum, are less destructive of furnace linings, which therefore require less frequent repair. In the event that elevated exposures do occur, OSHA finds that the controls for maintenance operators in ferrous sand casting foundries also apply in nonferrous sand casting foundries and that by implementing those controls as needed, nonferrous sand casting foundries will be able to reduce the exposure levels of all maintenance operators to levels of 50 µg/m^3 or less.

Based on the exposure data and evidence of effective controls, OSHA concludes that the 50 µg/m^3 PEL can be achieved for maintenance operators in nonferrous sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Finding for Nonferrous Housekeeping Workers

The activities of housekeeping workers in nonferrous sand casting foundries are the same as in ferrous sand casting foundries. In the PEA, OSHA presented a single result of 66 µg/m^3 that was obtained from a report on a nonferrous sand casting foundry in 1988.

OSHA has decided to exclude samples collected prior to 1990, and as a result OSHA has removed this sample from the exposure profile since the Agency has concluded that evidence from ferrous sand casting foundries for this job category is sufficient to characterize exposures for these workers in nonferrous sand casting foundries. Therefore, the exposure profile in Table IV.4.8-F contains no samples for housekeeping workers. However, the exposure profile in Table IV.4.8-E for housekeeping workers in ferrous sand casting foundries shows that 36 percent (4 out of 11 samples) of those workers currently achieve the PEL under baseline conditions, while AFS reported that 72 percent of its members' housekeeping activities already achieve the PEL.

Based on information presented above for other job categories (the major sources of silica exposure for housekeeping workers), OSHA concludes that silica exposure levels for this job category arise from the same sources in nonferrous sand casting foundries and are unlikely to exceed and are likely lower than the profile presented for housekeeping workers in the ferrous sand casting industry (Table IV.4.8-E). The controls for housekeeping workers in ferrous sand casting foundries also apply in nonferrous sand casting foundries. OSHA concludes that by implementing those controls as needed, nonferrous sand casting foundries will be able to reduce the exposure levels of all housekeeping workers to levels of 50 μg/m^3 or less.

Based on the exposure data for housekeeping workers in ferrous sand casting foundries and evidence of effective controls, OSHA concludes that the 50 μg/m^3 PEL can be achieved for housekeeping workers in nonferrous sand casting foundries. The standard is therefore technologically feasible for this job category.

Nonferrous Sand Casting Foundries—Overall Feasibility Findings

OSHA concludes that controls identified to reduce worker exposures in ferrous sand casting facilities also will reduce exposures to an equivalent extent in nonferrous sand casting facilities. This conclusion is based on evidence that the same casting methods involving sand are commonly used to cast most metals and that exposures in nonferrous sand casting foundries are generally comparatively lower. Therefore, based on the exposure data and availability of effective controls, OSHA finds that the 50 μg/m^3 PEL can be achieved for all job categories in nonferrous sand casting foundries, at least most of the time. The final PEL of 50 μg/m^3 is therefore technologically feasible for the nonferrous sand casting industry.

4.8.3 Non-Sand Casting Foundries (Ferrous and Nonferrous)

Description

Non-sand casting foundries include facilities that cast any metal primarily using methods other than bonded sand molds (sand bonded with clay or other additives). Casting methods include, but are not limited to, unbonded sand molding (e.g., lost foam), investment casting, casting with ceramic and plaster molds, and permanent mold casting (including centrifugal mold processes). Poured metal is shaped by a substance other than sand, typically a sturdy shell-like layer of refractory material, which can contain substantial amounts of quartz or cristobalite (Document ID 1365, p. 2-102). The refractory shell materials contain silica, and permanent molds are often washed with silica mold-release agents. Sand casting foundries sometimes use similar materials to line sand molds and cores, but non-sand casting foundries depend more heavily on these refractory substances in the molding process (Document ID 1365, p. 2-102).

Although sand is not the primary molding material, a reduced amount of sand might be involved in these casting methods. Some processes use loose, unbonded sand to fortify or provide structural support around the refractory mold. Additionally, sand cores might be inserted into any type of mold (Document ID 1365, p. 2-102; 1139).

In general, job categories are similar to those in ferrous sand casting foundries. With the exception of molders, which use non-silica molds, workers in non-sand casting foundries perform the same activities, have similar sources of exposure, and are exposed to similar levels of silica in both types of foundries (Document ID 1365, p. 2-102).

Non-sand Casting Foundries - Exposure Profile, Baseline Conditions, and Additional Controls

Table IV.4.8-G summarizes, by job category, the best available evidence of the full-shift PBZ silica exposure results for non-sand casting foundry workers. The exposure profile in Table IV.4.8-G shows that exposures of 50 μg/m^3 or less have already been achieved for the vast majority of workers in nine of the 11 job categories (molders, core makers, furnace operators, pouring operators, abrasive blasting operators, cleaning/finishing operators, material handlers, maintenance operators, and housekeeping workers). The exposure profile shows that only shakeout and knockout operations do not achieve exposures below the PEL most of the time under baseline conditions.

Considered overall, almost three-quarters of workers sampled in the non-sand casting foundries currently have exposures below the PEL. As discussed below, the job categories with higher exposures - the shakeout operators, knockout operators, abrasive blasting operators and cleaning/finishing operators - who can experience higher exposures due to the nature of their tasks, will benefit equally from the controls identified for these workers in ferrous sand casting foundries due to the similarity of the tasks performed.

For each job category, the following section discusses relevant differences between non-sand casting foundries and ferrous sand casting foundries as they apply to worker activities and exposure levels. The discussion indicates whether the exposure control options and conclusions presented for ferrous sand casting foundries apply in non-sand casting foundries. Where necessary, the section also describes required modifications to the controls. OSHA also provides its assessment of the feasibility of the PEL by job category and availability of exposure controls.

The exposure profile in Table IV.4.8-G for non-sand casting foundries includes 124 full-shift, PBZ samples. The median exposure is 16 μg/m^3, the mean is 71 μg/m^3, and the range is 8 μg/m^3 to 980 μg/m^3. Of the 124 samples, 92 (74.2 percent) are at or below the final PEL of 50 μg/m^3. OSHA finds that the additional controls identified for the different job categories in ferrous sand casting foundries will be necessary to achieve the PEL for the remaining 25.8 percent of workers in non-sand casting foundries. Based on the exposure profile and evidence of the effectiveness of these controls, the overall conclusion is that OSHA finds the standard to be technologically feasible for each of the job categories in non-sand casting foundries and for the non-sand casting foundry industry generally.

<u>*Non-sand Casting Foundries – Feasibility Finding*</u>

Feasibility Findings for Sand Systems Operators in Non-sand Casting Foundries

In non-sand casting foundries, the activities of sand systems operators are limited to mixing sand for cores in those facilities that use sand cores and to handling any un-bonded core sand returned from the shakeout process. Core sand and refractory materials are not typically reclaimed and reused in non-sand casting foundries. Thus, sand reclamation is less complicated and presumably less dusty than in ferrous sand casting foundries.

OSHA was not able to identify any exposure measurements for sand systems operators in non-sand casting foundries; however, the reduced use of sand and the modest exposure levels encountered for most job categories in these foundries suggest that exposure levels for this group would likely be in the lower end of the range reported for ferrous sand casting foundries. It is notable that in non-sand casting foundries, 74 percent of exposures in all job categories are already below the 50 μg/m^3 PEL. In 6 of 12 job categories in ferrous foundries, by contrast, more than 50 percent of the exposures exceed the 50 μg/m^3 PEL. For non-sand casting foundries only 2 of 12 job categories (shakeout and knockout operators) have more than half of the exposures in excess of the 50 μg/m^3 PEL. Because of the decreased amount of sand handling, fewer sand systems operators with lower exposures are likely to be employed in non-sand casting foundries than in sand casting foundries. In some cases, these duties are likely performed by a worker in another job category, such as core maker or molder. Their exposures are discussed below.

OSHA is unable to estimate what percentage of sand systems operators in non-sand casting foundries are currently below the PEL under baseline conditions. Based on the above information, however, the Agency concludes that for those workers in this industry who do have sand-handling duties, the available controls described for sand systems operators in ferrous sand casting foundries will be sufficient to control any exposures that occur in non-sand casting foundries as well. OSHA further concludes that by implementing those controls as needed, non-sand casting foundries will be able to reduce the exposure levels of all sand systems operators to levels of 50 μg/m^3 or less. Therefore, OSHA finds that the 50 µg/m^3 PEL can be achieved for sand system operators in non-sand casting foundries. The standard is thus technologically feasible for this job category.

Feasibility Findings for Molders

The silica exposures of molders in non-sand casting foundries originate from different mold materials than in sand casting foundries. Green and chemically bonded sand molding processes are non-existent in non-sand casting foundries. Instead, molders weigh and mix a slurry of refractory material (typically containing substantial quantities of silica as quartz or cristobalite, or both), then repeatedly dip expendable patterns (e.g., foam, wax) in the mold material to form a shell (Document ID 1365, p. 2-104; 0215). Some molders also pour the refractory investment material around a pattern set in a flask. Molders might also sift dry silica-containing sand over dipped patterns to fortify the mold shell as it forms. In foundries using permanent molds, molders spray or pour refractory material into the metal molds (Document ID 1365, p. 2-104; 0498; 1139). Molders oversee these typically semi-automated molding processes; however, molders might perform these processes manually for small runs or in a facility that performs one of these methods only occasionally.

The exposure profile in Table IV.4.8-G for molders in non-sand casting foundries includes 29 samples. The median exposure is 21 µg/m^3, the mean is 44 µg/m^3, and the range is 9 µg/m^3 (LOD) to 291 µg/m^3. Of the 29 samples, 22 (75.9 percent) are at the final PEL of 50 µg/m^3 or less. All samples are from SEP inspection reports and OSHA's OIS System.

One of the highest results (150 µg/m^3) was associated with a molder who cleaned permanent centrifugal molds (Document ID 1365, p. 2-105; 1175, pp. 2, 9). In a similar facility that also used permanent centrifugal molds, NIOSH noted that similar exposure levels were attributed to refractory mold release agents, which were applied to the interior of the permanent mold that forms products like iron pipes as the molten metal is poured into the mold while it spins. The agent is then brushed out of the mold after completion of the casting process. NIOSH noted significantly reduced exposures in a facility that switched from a silica flour mold release agent to a product containing less than 1.5 percent silica (Document ID 1365, p. 2-105; 0900, pp. 3-4, 14-15, (pdf) p. 24 Table 1).

Sequential sampling sessions show the effect of switching from silica sand to an alternate granular media even when the foundry uses molding methods other than green sand casting. OSHA obtained results of 50 $\mu g/m^3$ and 90 $\mu g/m^3$ for molders (compaction, compaction helper) at a steel investment[52] foundry that compacted un-bonded silica sand around lost-foam molds (Document ID 1365, p. 2-105; 0142, pp. 18-19, 133, 157). This facility replaced the silica sand with olivine, a low silica content alternative, and reduced exposures to below the LOD (less than or equal to 12 $\mu g/m^3$) (Document ID 0142, pp. 9, 10-14). These are among the lowest results reported for this job category.

Non-sand casting methods can involve refractory investment materials that contain cristobalite instead of, or in addition to, quartz. OSHA obtained a result for a molder that contained respirable cristobalite (129 $\mu g/m^3$) in addition to respirable quartz (162 $\mu g/m^3$), producing a combined respirable silica result of 291 $\mu g/m^3$. The molder manually emptied bags of silica-containing investment material into a bucket that included reaching in to stir the dry ingredients and break up clumps by hand (Document ID 1365, p. 2-104; 0498, pp, 46, 58-59). These results demonstrate the additive effect of quartz and cristobalite on the worker's overall silica result, as well as the risk of exposures above the PEL if appropriate controls are not used.

OSHA finds that the remaining 24 percent of workers exposed above the PEL will require additional controls. The controls described for ferrous sand casting foundries apply to non-sand casting foundries. As described in more detail in the earlier discussion of molders in ferrous sand casting foundries, specific controls include improved enclosures and ventilation on sand delivery systems, ventilated workstations, work practices that limit the spread of silica-dust, and substitution of non-silica containing materials where feasible.

[52] Investment refers to a liquid refractory or ceramic mixture that may contain silica that is poured into wax coated mold. Investment casting is used to produce small precision parts.

Non-sand casting foundries that mix refractory products require ventilated bag-dumping stations and mixing equipment. Workers who handle powdered silica materials, e.g., empty bags, weigh, and mix, can be exposed to dust when it is released from these processes, and when emptied bags are compressed for disposal. One control option involves bag-dumping stations with properly ventilated enclosures, which capture dust released during both bag emptying and bag disposal. One SEP report demonstrated the effectiveness of addressing bag dumping by enclosing and ventilating the container being filled with investment powder. In this case, exposures that were more than 400 μg/m^3 were reduced to less than 50 μg/m^3 (Document ID 0498, pp. 20-24). In addition, ERG obtained respirable quartz exposure monitoring data for workers using bag dumping stations to empty 50-pound bags of silica-containing materials into mixers at a paint manufacturing facility. The stations consisted of hoppers topped with grates that were enclosed by LEV hoods. This ventilation system automatically removed empty bags (by suction) and transferred them to an enclosed storage area. This technology reduced exposures from a level greater than 250 μg/m^3 to below the LOD. ERG obtained five full-shift PBZ silica exposure readings of less than or equal to 12 μg/m^3 (the LOD) for five workers who emptied bags of silica-containing material using the bag-dumping stations (Document ID 1365, p. 2-105; 0199).

ERG also obtained a full-shift PBZ exposure reading of 263 μg/m^3 for a worker at the same site who used a bag-dumping station equipped with an LEV system that failed to operate for approximately two hours (Document ID 1365, p. 2-106; 0199). Without the LEV system operating, the worker was required to manually stack and compress empty bags adjacent to the station, which generated visible dust. The difference between the elevated exposure readings obtained for the worker as compared with the low exposure readings when the LEV was working indicates the effectiveness of LEV-equipped bag-dumping stations.

NIOSH evaluated a second type of bag-dumping station equipped with an enclosure, empty bag compactor, bag disposal chute, and LEV system (Document ID 1365, p. 2-106; 1369). The LEV system ventilated both the enclosure and compactor. NIOSH evaluated the unit by measuring respirable dust levels with real-time aerosol monitors before and while workers emptied bags of crushed limestone into these hoppers. NIOSH determined that the unit effectively controlled respirable dust (Document ID 1369). Ventilated bag-dumping stations that include a ventilated compactor are readily available from commercial sources (Document ID 1224). OSHA concludes that ventilated bag-dumping stations would be equally effective in reducing silica exposures for molders in non-sand casting foundries.

Automated transfer equipment also can reduce dust released as hoppers are filled. Some of the lowest results (two 13 $\mu g/m^3$ [LODs], one 20 $\mu g/m^3$, and one 23 $\mu g/m^3$) were obtained by NIOSH and OSHA for four molders working in two ferrous sand casting foundries where pneumatic or enclosed conveyors were used to transport sand (Document ID 1365, p. 2-28; 0268, p. 4, 12; 0501, pp. 5, 63, 65, 67, 71-73). Non-sand casting foundries have systems that move much smaller amounts of silica-containing materials. OSHA expects that pneumatic and enclosed conveying of materials will be equally effective in non-sand casting foundries. Pneumatic and enclosed conveyors are also used in other industries. For example, OSHA inspected a structural clay facility and found an 86-percent reduction in silica exposures after the facility installed an enclosed, automated sand transfer system (Document ID 1365, p. 2-106; 0161). OSHA concludes that installing such a system could similarly reduce exposures to molders in non-sand casting foundries.

OSHA also concludes that for those facilities that clean refractory materials from permanent molds, vacuuming in lieu of using compressed air will reduce exposures. As discussed above, paragraph (h) of the standard for general industry and maritime prohibits the use of compressed air in cleaning clothing or surfaces where such activity could contribute to employee exposure to respirable crystalline silica except where the compressed air is used in conjunction with a ventilation system that effectively captures the dust cloud created by the compressed air, or where no alternative method is feasible. The use of compressed air and brushes is discussed at length in the Ferrous Sand Casting Foundries section above (Section IV-4.8.1) and is also applicable to non-sand casting foundries.

For these reasons, OSHA concludes that controls are available for reducing exposures such as improving or adding ventilation to bag-dumping stations, adding or improving ventilated bag compactors, as well as enclosing and ventilating mixing equipment. Based on the exposure profile and evidence of effective controls, OSHA finds that the 50 μg/m^3 PEL can be achieved for molders in non-sand casting foundries most of the time. The standard is therefore technologically feasible for this job category.

Feasibility Findings for Core Makers

Core makers work only in those facilities in non-sand casting foundries that produce or handle sand cores. These workers produce and handle sand cores that are essentially the same as cores produced and handled in other types of foundries (Document ID 1365, p. 2-102).

The exposure profile in Table IV.4.8-G for core makers in non-sand casting foundries includes 3 samples, which constitute the best available evidence of these workers' exposures. The three results were all LOD values, well below the final PEL of 50 μg/m^3 and the action level of 25 μg/m^3. Therefore, OSHA concludes that core makers will rarely need additional controls. Due to the similarity of the tasks and dust sources, however, the controls and conclusions described for core makers in ferrous and nonferrous sand casting foundries can be used to achieve the PEL for core makers in non-sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA finds that the 50 μg/m^3 PEL can be achieved for core makers in non-sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Findings for Furnace Operators

Furnace operator functions are the same in non-sand casting foundries as in other foundries. The exposure profile in Table IV.4.8-G for furnace operators in non-sand casting foundries includes 4 samples, which constitute the best available evidence of these workers' exposures. The four results are all below the final PEL of 50 μg/m^3 and three are below the action level of 25 μg/m^3. Therefore, OSHA concludes that furnace operators will rarely need additional controls. However, if overexposures do occur, the controls and conclusions described for furnace operators in ferrous and nonferrous sand casting foundries apply equally in non-sand casting foundries due to the similarity of operator functions.

Based on the exposure data and evidence of effective controls, OSHA finds that the 50 μg/m^3 PEL can be achieved for furnace operators in non-sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Findings for Pouring Operators

Pouring operator functions in non-sand foundries are the same as those in ferrous sand casting foundries; however, the equipment and materials differ. Pouring operators in non-sand casting foundries use a variety of mold types, including permanent molds for metals such as aluminum (made of a metal with a higher melting temperature) and investment molds described above. Pouring operators using permanent molds can be exposed to silica when molders who work in close proximity apply or remove refractory coating from the molds (Document ID 1365, p. 108).

The exposure profile in Table IV.4.8-G for pouring operators in non-sand casting foundries includes 7 samples, which constitute the best available evidence of these workers' exposures. The median exposure is 12 μg/m^3, the mean is 33 μg/m^3, and the range is 10 μg/m^3 (LOD) to 150 μg/m^3. Of the 7 samples, 6 (85.7 percent) are at the final PEL of 50 μg/m^3 or less. OSHA attributes the one exposure that exceeded the PEL to stagnant air and lack of ventilation (Document ID 1175, p. 9).

The silica content of mold release agents can influence the exposure levels of workers in the pouring area. Two of the available results for this job category, 36 μg/m^3 and 150 μg/m^3, were obtained for pouring operators at two foundries where workers (molders or pouring operators) applied and removed refractory mold release agents on permanent centrifugal molds (Document ID 1365, p. 2-108; 0900, (pdf) p. 24, Table 1; 1175, (pdf) p. 9, Table E-2). The lower of these results (36 μg/m^3) was associated with a "low silica parting compound" used as the mold release agent (Document ID 0900, p. 4). OSHA expects that similar exposure reduction for the higher exposure (150 μg/m^3) can be achieved by using a low silica mold release agent. Additionally, the study associated with the higher sampling result noted that the area was poorly ventilated (Document ID 1175, (pdf) p. 1). Additional general ventilation and LEV for mold cleaning activities could effectively reduce the exposures from this source.

Based on the exposure data and evidence of effective controls, OSHA finds that the 50 μg/m^3 PEL can be achieved for pouring operators in non-sand casting foundries when exposures in the rest of the foundry are adequately controlled. The standard is therefore technologically feasible for this job category.

Feasibility Findings for Shakeout Operators

Shakeout operator functions are generally similar to those in ferrous sand casting foundries. However, in sand casting foundries, manual processes for removing mold and core materials are consolidated into this operation (despite worker job titles associated with knockout operations), while sprue and riser removal are consolidated under the knockout operations.

The exposure profile in Table IV.4.8-G for shakeout operators in non-sand casting foundries includes 7 samples, which constitute the best available evidence of these workers' exposures. The median exposure is 220 μg/m^3, the mean is 183 μg/m^3, and the range is 10 μg/m^3 (LOD) to 420 μg/m^3. Of the 7 samples, 2 (28.6 percent) are at the final PEL of 50 μg/m^3 or less.

Three of the seven samples (all from one steel investment foundry) contained cristobalite only (no quartz detected) at exposure levels of 222 μg/m^3, 283 μg/m^3, and 420 μg/m^3, while one sample result of 100 μg/m^3 from the same foundry included equal parts quartz and cristobalite (Document ID 1365, pp. 2-108 – 2-109; 0078, pp. 89, 91, 101, 103, 106, 108). The shakeout operations in this foundry were quite primitive and included removing sand and refractory materials in enclosed areas with no controls in place. The inspection report notes poor ventilation as well as the use of compressed air for blowing contamination from workers' clothing and dry sweeping (Document ID 0078, p. 54). The 220 μg/m^3 exposure measurement was collected in a lost foam casting operation in which the employee was removing sand from the casting using a jackhammer and chipping hammer with inadequate ventilation (Document ID 0134, pp. 14, 34).

The exposure profile in Table IV.4.8-G shows that exposure levels of 50 μg/m^3 or less have already been achieved for 29 percent of shakeout operators. The remaining overexposed workers will require additional controls. Because of the lack of controls present and the use of poor work practices (the use of compressed air and dry sweeping) under baseline conditions, OSHA concludes that significant reductions in exposures are possible using the control methods described above for Shakeout Operators in Section IV-4.8.1 – Ferrous Sand Casting Foundries and that those methods will be effective in reducing exposures to the 50 μg/m^3 PEL. Because the tasks and dust sources are similar, OSHA expects that controls like enclosed and ventilated shakeout equipment, combined with other dust control measures such as local exhaust ventilation, and the use of vacuums rather than compressed air and dry sweeping (Document ID 0078, p. 54; 0134, p. 14) will control shakeout operator exposures in non-sand casting foundries.

Based on the ability of controls in ferrous sand casting foundries to reduce exposures to levels of the PEL or below and the similarity in the nature of the shakeout processes, OSHA finds that those controls will be similarly effective for shakeout operations in non-sand casting foundries. Therefore, based on the exposure data and evidence of effective controls, OSHA finds that the 50 μg/m^3 PEL can be achieved for most shakeout operators in non-sand casting foundries. As in ferrous casting foundries for shakeout operators, OSHA expects that the supplemental use of respirators may be necessary for the small percentage of shakeout operators who work on large castings in circumstances where substitution to non-silica granular media is not feasible. The standard is therefore technologically feasible for this job category.

Feasibility Findings for Knockout Operators

Knockout operator functions are generally the same as in ferrous sand casting foundries. However, as stated earlier, manual processes for removing mold and core materials are consolidated into the shakeout process. Sprue and riser removal activities are consolidated under the knockout operations.

The exposure profile in Table IV.4.8-G for knockout operators in non-sand casting foundries includes 15 samples. The median exposure is 56 μg/m^3, the mean is 140 μg/m^3, and the range is 9 μg/m^3 (LOD) to 614 μg/m^3. Of the 15 samples, 7 (46.7 percent) are at the final PEL of 50 μg/m^3 or less. As with the other results in the exposure profile, these samples are the best available evidence of these workers' exposures. One of the highest results (598 μg/m^3) was from an investment casting foundry and contained cristobalite but no detectable quartz (Document ID 1365, p. 2-109). (OSHA has little information about the conditions that lead to the highest exposure level, 614 μg/m^3.)

OSHA finds that additional controls will be necessary to achieve the PEL for the remaining 53 percent of knockout operators who are overexposed. Based on the similarities between knockout operator tasks in this and other types of foundries, OSHA concludes that additional controls for knockout operators in ferrous sand casting foundries apply equally effectively in non-sand casting foundries. Similar to ferrous foundries, a small percentage of knockout operators in these foundries might require respiratory protection under the same circumstances (i.e., very large castings) as mentioned for shakeout operators in ferrous sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA concludes that compliance with the 50 μg/m^3 PEL can be achieved for knockout operators in non-sand casting foundries most of the time. As in ferrous casting foundries, the supplemental use of respirators may be necessary for the small percentage of knockout operators who work on large castings in circumstances where substitution to non-silica granular media is not feasible. The standard is therefore technologically feasible for this job category.

Feasibility Findings for Abrasive Blasting Operators

Abrasive blasting is used in non-sand casting foundries to remove silica-containing investment materials or mold washes from the castings. Activities of abrasive blasting operators in non-sand casting foundries are the same as in ferrous sand casting foundries. The exposure profile in Table IV.4.8-G for abrasive blasters in non-sand casting foundries includes 13 samples from a variety of inspection reports and industry studies, representing the best available evidence of these workers' exposures. The median exposure is 14 μg/m^3, the mean is 138 μg/m^3, and the range is 10 μg/m^3 (LOD) to 980 μg/m^3. Of the 13 samples, 8 (61.5 percent) are at the final PEL of 50 μg/m^3 or less.

OSHA finds that additional controls will be necessary to achieve the PEL for the remaining 39 percent of abrasive blasting operators who are overexposed. Due to the similarity in the tasks and dust sources, OSHA concludes that the controls for abrasive blasting operators in ferrous sand casting foundries to control respirable silica dust released while removing green sand molding materials using enclosed blasting systems will work as effectively in non-sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA finds that the 50 μg/m^3 PEL can be achieved for abrasive blasting operators in non-sand casting foundries most of the time. As for abrasive blasting in ferrous casting foundries, respirator use may be necessary for foundries that produce large castings. The standard is therefore technologically feasible for this job category.

Feasibility Findings for Cleaning/Finishing Operators

Cleaning/finishing operators perform the same activities in non-sand casting foundries as in ferrous sand casting foundries. As noted above, silica mold materials and washes can remain adhered to castings using non-sand casting methods just as they do in sand casting foundries, although the quantity might be lower, because the washes are thinly applied coatings (Document ID 1287, p. 25). For example, mold washes are typically used in small quantities as release agents, to capture more details from the pattern, or to increase mold life (protect it), on permanent molds, lost foam, and investment casting patterns. Where they are used, these agents remain present as trace contaminants on the finished casting rather than as large chunks or deeply embedded veins in the metal. Regardless of the casting or mold release material used, however, cleaning/finishing operators use the same tools and processes to clean the castings (Document ID 1365, 2-110; 0900, pp. 4, 14; 1287, pp. 23-27).

The exposure profile in Table IV.4.8-G for cleaning/finishing operators in non-sand casting foundries includes 34 samples (combined quartz and cristobalite). The median exposure is 16 µg/m^3, the mean is 54 µg/m^3, and the range is 8 µg/m^3 (LOD) to 820 µg/m^3. Of the 34 samples, 29 (85.3 percent) are at or below the final PEL of 50 µg/m^3.

OSHA finds that additional controls will be necessary to achieve the PEL for the remaining 15 percent of abrasive blasting operators who are overexposed. Because of the similarities between cleaning/finishing operator activities in this and other types of foundries, OSHA concludes that the controls provided for cleaning/finishing operators in ferrous sand casting foundries are equally effective in non-sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA finds that the 50 µg/m^3 PEL can be achieved for cleaning/finishing operators in non-sand casting foundries. In the event that exposure levels of a few operators still remain above 50 µg/m^3, respiratory protection will be necessary for those workers. The standard is therefore technologically feasible for this job category.

Feasibility Findings for Material Handlers

Material handlers in non-sand casting foundries perform the same types of tasks as material handlers working in ferrous sand casting foundries. The exposure profile in Table IV.4.8-G for material handlers in non-sand casting foundries includes 3 samples, which are the best available evidence of these workers' exposures. The median exposure is 8 µg/m^3, the mean is 41 µg/m^3, and the range is 8 µg/m^3 (LOD) to 107 µg/m^3. Two of the three samples are below the 25 µg/m^3 action level. The sample with the high exposure level was obtained in a foundry that had few controls for an employee whose job duties included shoveling sand in the basement. OSHA recommended improvements in ventilation and the use of vacuums for clean-up rather than dry sweeping and using compressed air (Document ID 0134, pp. 14, 58-59). These recommendations are similar to the controls that OSHA describes above for Material Handlers (in Section IV-4.8.1 – Ferrous Sand Casting Foundries), where OSHA concluded that enclosed, ventilated cabs are associated with exposure reductions of 90 to 97 percent and can reduce even the highest material handler result to a level less than 50 µg/m^3 (Document ID 0719, p. 47; 0884, pp. 14, 20).

OSHA finds that additional controls will be necessary to achieve the final PEL of 50 µg/m^3 for any material handlers in non-sand casting foundries who are overexposed. Because the work activities of material handlers are the same within both types of foundries, OSHA concludes that the controls for those workers in ferrous sand casting foundries are equally effective in non-sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA finds that the 50 µg/m^3 PEL can be achieved for material handlers in non-sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Findings for Maintenance Operators

Maintenance operators in non-sand casting foundries perform the same types of tasks as they perform in other types of foundries that cast the same metals. These tasks include refractory repairs. For example, a report on a non-sand casting foundry included four sampling results of maintenance operators performing refractory repair work in a cast iron foundry.

The exposure profile in Table IV.4.8-G for maintenance operators in non-sand casting foundries includes 4 samples, which are the best available evidence of these workers' exposures. The median exposure is 12 µg/m^3, the mean is 14 µg/m^3, and the range is 12 µg/m^3 (LOD) to 20 µg/m^3.

OSHA concludes that because the exposure levels of all (100 percent) maintenance operators in non-sand casting foundries are already below the final PEL of 50 µg/m^3 (all 4 results were below the action level of 25 µg/m^3), additional controls are not likely to be necessary for this job category. However, OSHA acknowledges that the available data might underestimate exposure for maintenance operators in non-sand casting foundries, who have the potential for exposure at the same levels encountered by workers performing the same refractory repair tasks at ferrous sand casting foundries. OSHA finds that, if elevated exposures do occur, additional controls will be necessary to achieve the PEL for any maintenance worker who is overexposed, and expects that the controls described for maintenance operators in ferrous sand casting foundries will be equally effective to control the dust exposures of maintenance operators in non-sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA finds that the 50 μg/m^3 PEL can be achieved for material handlers in non-sand casting foundries. The standard is therefore technologically feasible for this job category.

Feasibility Findings for Housekeeping Workers

The work activities of housekeeping workers in non-sand casting foundries are the same as those of the equivalent job category in ferrous sand casting foundries. The exposure profile in Table IV.4.8-G for housekeeping workers in non-sand casting foundries includes 2 samples, which were obtained from a report on a non-sand casting foundry. Both samples were less than or equal to the LOD (12 μg/m^3 and 14 μg/m^3) (median of 13 μg/m^3). These best available results are within the range reported for ferrous sand casting foundries (Document ID 1365, p. 2-111; 0017). OSHA concludes that the exposure levels of all (100 percent) housekeeping workers in non-sand casting foundries are already below the final PEL of 50 μg/m^3. Therefore, additional controls are not likely to be necessary for this job category. OSHA further concludes that, if elevated exposures do occur, the controls for housekeeping workers in ferrous sand casting foundries should be equally effective to achieve exposures of 50 μg/m^3 or less for housekeeping workers in non-sand casting foundries.

Based on the exposure data and evidence of effective controls, OSHA finds that the 50 μg/m^3 PEL can be achieved for housekeeping in non-sand casting foundries. The standard is therefore technologically feasible for this job category.

Non-Sand Casting Foundries—Overall Feasibility Finding

OSHA finds that controls identified to reduce worker exposures in ferrous sand casting foundries also will reduce exposures to an equivalent extent in non-sand casting foundries. This finding is based on evidence that although non-sand casting foundries use sand and other materials that contain silica in casting processes, for example, in cores or to pack investment molds, that result in dust from sources similar to those in the ferrous sand casting foundries, the amount of silica-containing materials used is much less. Therefore, OSHA finds that the controls discussed for ferrous sand casting foundries will be at least as effective to reduce dust emissions in non-sand foundries. Where production methods diverge (e.g., the use of mold release agents on permanent molds), additional controls are available as described above.

Based on the exposure levels reported for this industry in Table IV.4.8-G and the availability of effective controls for most working conditions, OSHA finds that exposure levels of 50 μg/m^3 or less can be achieved for most operations, most of the time, in non-sand casting foundries. Therefore, the final PEL of 50 μg/m^3 is technologically feasible for non-sand casting foundries.

4.8.4 Captive Foundries

Captive Foundries Description

Captive foundries are foundries based within the facilities of another non-foundry industry. They cast metal using the same range of processes that are found in the foundry industry. A captive foundry might cast any metal in any quantity, use any molding process, clean castings, and process and reclaim sand using the same range of methods and equipment used by ferrous sand casting, nonferrous sand casting, or non-sand casting foundries (Document ID 1365, p. 2-111). Furthermore, the job categories found in captive foundries mirror those found in other foundries. For example, a state industrial commission reviewed data collected from a captive gray iron foundry that produces large truck brake drums. Job categories sampled included those found in ferrous sand casting foundries. As another example, OSHA inspected sand casting foundries (both ferrous and nonferrous) belonging to an enameled iron and metal products manufacturer and sampled shakeout operators (Document ID 1365, p. 2-112; 0168). In addition, the UAW submitted descriptions of some of the job categories in a captive foundry owned by Caterpillar, a manufacturer of farm machinery, that are the same as those addressed in the ferrous and non-ferrous sand casting foundries and the non-sand casting foundries. The specific activities noted by UAW for the job categories they list are similar to the activities noted by OSHA for the foundry sector (Document ID 2282, Attachment 3, pp. 9-10).

The difference between a captive foundry and other foundries involves the business relationship between the foundry and the organization it supplies, rather than a fundamental difference in the metal casting process. Captive foundries fill specific requirements of their parent companies, whether the need is for large numbers of identical pieces, a small number of customized items, or specialty handling of a wide range of castings. As such, a captive foundry operation is incorporated into the larger manufacturing process of the parent operation.[53]

[53] OSHA notes that information contained in some documents does not permit the facilities to be classified as captive or independent foundries. As a result, some information on facilities that are actually captive foundries might appear in the analysis for other foundry types. Table IV.4.8-H summarizes data from facilities known to be captive foundries at the time the samples were collected.

Table IV.4.8-H
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Captive Foundries

	Exposure Summary			Exposure Range		Exposure Profile				
Captive Foundries	**N**	**Mean (µg/m³)**	**Median (µg/m³)**	**Min (µg/m³)**	**Max (µg/m³)**	**<25 (µg/m³)**	**≥25 and ≤50 (µg/m³)**	**>50 and ≤100 (µg/m³)**	**>100 and ≤250 (µg/m³)**	**>250 (µg/m³)**

Notes: All samples summarized are personal breathing zone (PBZ) results representing 8-hour time-weighted average exposures.
Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility.
Percentages may not add to 100 percent due to rounding.

Sources: Document ID 1720; 3958; 0152; 0168; 0171.

Captive Foundries—Exposure Profile, Additional Controls, and Overall Feasibility Findings

The exposure profile in Table IV.4.8-H includes 53 full-shift, PBZ samples for captive foundries. These samples are the best available evidence of worker exposures in captive foundries. The median exposure is 28 μg/m^3, the mean is 134 μg/m^3, and the range 12 μg/m^3 to 1,456 μg/m^3. Eight of nine job categories (all but shakeout operator) already experience exposures below the PEL. No sample exposures were available for three operations (sand system operator, pouring operator, and material handler).

Of the nine job categories for which Table IV.4.8-H has data, five (furnace operator, shakeout operator, abrasive blasting operator, cleaning/finishing operator, and maintenance operator) show some exposures under baseline conditions over the final PEL of 50 μg/m^3, ranging from 20 percent (2 out of 10 samples for cleaning/finishing operator) to 61.6 percent (8 out of 13 samples for shakeout operator). The two highest samples (1,330 μg/m^3 and 1,456 μg/m^3) were in abrasive blasting and maintenance operations, respectively. Based on these data, OSHA finds that additional controls will be necessary to achieve the final PEL of 50 μg/m^3 for the remaining workers in the various job categories who are overexposed. OSHA concludes that the casting processes, tasks performed, and dust sources in captive foundries are comparable to those discussed with respect to non-captive foundries. Therefore, where overexposures exist, OSHA concludes that the controls discussed for ferrous sand casting foundries will be equally effective in reducing exposures in each of the job categories in captive foundries.

Based on these exposure data and evidence of effective controls, OSHA finds that the 50 μg/m^3 PEL can be achieved for most operations in captive foundries most of the time. Therefore, the standard is technologically feasible in captive foundries.

4.9 GLASS PRODUCTS

4.9.1 Description

Silica sand is the main raw material used in the manufacture of glass products, including flat glass, container glass, and fibrous glass (Document ID 1365, p. 7-1). Industries that manufacture glass products are classified primarily in the following six-digit North American Industry Classification System (NAICS) codes: 327211, Flat Glass Manufacturing; 327212, Other Pressed and Blown Glass and Glassware Manufacturing; and 327213, Glass Container Manufacturing. This section also includes facilities in NAICS 327993, Mineral Wool Manufacturing, that produce fibrous glass and glass wool insulation products directly from sand.

Depending on the facility and type of glass production, operations might be highly mechanized or involve manual operations. Mass production glasses (such as flat glass, container glass, and fiberglass) involve automated raw materials handling processes and continuous, enclosed melting processes. These production processes require large amounts of sand or cullet.[54] Small-run glass manufacture, such as manufacture of specialty glass and art glass, however, involves intermittent production that can utilize a combination of automated and manual operations (Document ID 1365, p. 7-2).

The potential for silica exposures is limited to the so-called “hot end” of the process, where sand, cullet, and other raw materials are unloaded, transferred, and mixed prior to melting. Once melted, the silica in the sand is converted to amorphous silica and no longer presents a significant exposure hazard to workers downstream of the melting stage.

The two job categories with the potential for silica exposure in the glass products industry are raw material handlers and batch operators (and associated workers), who are the only glass product manufacture workers who work at the "hot end" of the manufacturing

[54] Cullet is waste and scrap glass (Document ID 1365, p. 7-6). Since glass, including cullet, is in the amorphous state, cullet is not a significant source of crystalline silica dust (Document ID 1720, p. IV-205).

process. Table IV.4.9-A provides information on these job categories and their sources of exposure.

Table IV.4.9-A Job Categories, Major Activities, and Sources of Exposure of Workers in the Glass Products Industry (NAICS 327211, 327212, 327213, 327993)	
Job Category*	**Major Activities and Sources of Exposure**
Material Handler	Overseeing the delivery of sand and other raw materials. • Dust from automatic or manual transfer of sand.
Batch Operators and Associated Workers	Transferring raw materials to weigh stations, mixers, and furnaces; performing housekeeping/maintenance in the vicinity of such operations. • Dust from automatic or manual transfer of sand. • Re-suspension of settled dust during housekeeping/maintenance activities.
*Job categories are intended to represent job functions; actual job titles may differ and responsibilities may be allocated differently, depending on the facility. Source: Document ID 1720, p. IV-205.	

4.9.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.9-B includes 14 full-shift personal breathing zone samples of respirable crystalline silica for the Glass Products Industry. It shows a median exposure of 71 μg/m^3, a mean of 110 μg/m^3, and a range from 12 μg/m^3 to 350 μg/m. Table IV.4.9-B shows that, of the 14 samples, 9 (64 percent) are above 50 μg/m^3 and 5 (36 percent) exceed 100 μg/m^3. To obtain the exposure profile, OSHA reviewed exposure monitoring data for the Glass Products Industry from two NIOSH reports of site visits to large flat glass manufacturing facilities and from an OSHA Special Emphasis Program (SEP) inspection report of a large glass products facility (Document ID 0085; 0221; 0886). OSHA inspection data submitted to the rulemaking record from OSHA's Information System (OIS) provide two additional sample results from two recent inspections that OSHA has added to this analysis (Document ID 3958). No additional exposure data for the glass industry is in the rulemaking record. Glass Association of North America (GANA) indicated that some employees are exposed over the PEL and that there was not enough data to support that all of the flat glass will be able to meet the final PEL (Document ID 2215, pp. 4-5). GANA did not provide any exposure data to support this statement. Therefore, OSHA did not add any additional data to the profile. However, OSHA's exposure profile is consistent with GANA's statement and indicates that the majority of the exposures are above the final PEL. These exposures represent current baseline conditions.

Exposure Profile and Baseline Conditions for Material Handlers

The exposure profile in Table IV.4.9-B includes 6 samples for material handlers in the Glass Industry. It shows a median exposure of 130 μg/m^3, a mean of 156 μg/m^3, and a range from 46 μg/m^3 to 350 μg/m^3. Five of the six samples (83 percent) are above 50 μg/m^3. “Hot-end” material handlers primarily work outdoors to oversee the delivery of sand and other raw materials to the facility. These materials are transported primarily via rail car or truck, with the exception of certain small-run specialty glass producers, which receive sand in smaller containers such as bags or fiber drums. Sand is typically unloaded and transported to storage units by automated equipment, such as pneumatic or gravity conveyors, which material handlers set up and operate. Material handlers may not be required to remain at the unloading site for their entire shift (Document ID 1365, p. 7-3).

No additional data were identified for material handlers beyond that presented in the PEA, in which OSHA reviewed the exposure results for six workers from one OSHA SEP inspection report and two NIOSH reports (Document ID 1720, pp. IV-205 – IV-206). Details on conditions that led to the highest exposure were not provided.

Exposure Profile and Baseline Conditions for Batch Operators and Associated Workers

The exposure profile Table IV.4.9-B includes 8 samples for batch operators and associated workers in the Glass Industry. It shows a median exposure of 40 μg/m^3, a mean of 75 μg/m^3, and a range of 12 μg/m^3 to 262 μg/m^3. Four of the eight samples are above 50 μg/m^3. Batch operators and associated workers are responsible for transferring raw materials to weigh stations, mixers, and furnaces. Depending on the size and type of glass production facility, the batching systems can be fully automated or can involve manual operations. OSHA estimates that up to 10 percent of batch operations involve manual charging of mixers and furnaces (Document ID 1365, p. 7-9).

Other workers in the batch area may inspect equipment and perform maintenance operations or housekeeping activities. Based on the available literature and personal communications with representatives of glass products manufacturers, OSHA estimates that, while few facilities have implemented engineering controls to minimize exposures associated with maintenance operations, 75 percent of facilities use dust suppressants, high-efficiency particulate air (HEPA)-filtered vacuums, or industrial-scale portable vacuum systems to control exposures during housekeeping activities (Document ID 0085, p. 14; 0221, p. 6; 1365, p. 7-10; 0698, p. 1).

The six samples previously reported in the PEA for batch operators, which were derived from one OSHA SEP inspection report and one NIOSH report. Two additional sample results were obtained from OIS inspection data, having values of 12 $\mu g/m^3$and 140 $\mu g/m^3$, and added to the exposure profile for this industry (Document ID 1720; 3958, Rows 264, 382).

Table IV.4.9-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Glass Products Industry
(NAICS 327211, 327212, 327213, 327993)

	Exposure Summary			Exposure Range			Exposure Profile				
Glass Industry	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**		**<25 (μg/m³)**	**≥25 and ≤50 (μg/m³)**	**>50 and ≤100 (μg/m³)**	**>100 and ≤250 (μg/m³)**	**>250 (μg/m³)**

Supplemental Data and Supporting Information Submitted to the Record

The North American Insulation Manufacturers Association (NAIMA) submitted as post-hearing evidence a summary of exposure data from glass industry plants producing insulation products (Document ID 3999). The summary data provided no individual sample results so these data could not be added to the exposure profile for this industry. For rock and slag wool manufacturing, all reported exposures were below the final rule's action level of 25 μg/m^3. For glass wool manufacturing, mean exposures for "routine manufacturing" were all below the action level (arithmetic mean 15 μg/m^3, geometric mean (which is a mathematical representation of the median) 12 μg/m^3, maximum value of 93 μg/m^3). For "non-routine" glass wool manufacturing, arithmetic mean exposures were 34 μg/m^3 (geometric mean 17 μg/m^3), well below the revised PEL, although a maximum value of 340 μg/m^3 was reported (Document ID 3999, Attachment 1, pp. 3-4). Information on the working conditions associated with these exposure results was not provided, so it is not possible to determine what work activities or exposure conditions were associated with those exposures that exceeded the final rule's PEL of 50 μg/m^3.[55]

These NAIMA data portray exposures in the rock and slag wool manufacturing industry as being lower than those summarized in the exposure profile for the glass manufacturing industry as a whole (Table IV.4.9-B). OSHA's exposure profile relies heavily on data drawn from OSHA inspections (SEP and OIS data), which tend to measure the most highly exposed workers, and might overestimate median exposures (Document ID 0085; 3958; 0677, p. 146). Thus, OSHA concludes that current worker exposures in this industry are no higher than those presented in the exposure profile (Table IV.4.9-B) and likely to be lower. Overall, the NAIMA data support OSHA's finding that the final rule's PEL is feasible for routine day-to-day operations in glass manufacture because the majority of sample results provided were well below 50 μg/m^3 TWA.

[55] NAIMA described non-routine tasks as "involving infrequent routine maintenance tasks, such as cleaning the batch house, where raw material is fed into a furnace, which is done several times per year, and changing baghouse bags, which is done approximately annually" (Document ID 3999, p. 2). However, OSHA was unable to determine which of these tasks were associated with the exposure samples.

Commenters from the glass manufacturing industry did not question the feasibility of complying with the final rule's PEL for routine operations; to the contrary, testimony from industry representatives included statements and data supporting the revised PEL. In hearing testimony, Mr. Steve Smith of Verallia, a glass container manufacturer, stated that "[w]orkers performing daily activities already meet the proposed standard" (Document ID 3584, Tr. 2846). Mr. Robert Stone, Director of OSHA's Office of Regulatory Analysis, asked Mr. Smith: "other than for maintenance and upset conditions or malfunctions, do you have any other types of overexposures with silica in your operations?" Mr. Smith replied that "the answer to that question is no. [In] our day-to-day operations, we can meet this standard" (Document ID 3584, Tr. 2864).

In written comments, NAIMA acknowledged that, in the rock and slag wool manufacturing industry, "according to OSHA's count and NAIMA's data, relatively few workers face exposure levels that equal or exceed the proposed PEL — and then only for a small fraction of their total work period each year" (Document ID 2348, Attachment 1, p. 27). NAIMA explained that the following controls have been implemented by the mineral wool industry:

- Baghouses or bin vents on silos, mixing operations, and receiving tanks.
- Baghouse monitoring (*e.g.*, differential pressure monitoring, bag break detection) for emissions control.
- Clean, climate-controlled control rooms both in the batch house and in the furnace deck area. In some facilities the batch house control room is remote and not located in the batch house.
- Fully enclosed conveyors and transfer points used in sand handling.
- Capturing fugitive emissions from furnaces and melters.
- Use of wetting screws at the point of batch delivery into the furnace or melter.
- Use of central vacuuming systems, and/or use of outside industrial vacuum trucks for cleaning (Document ID 2348, Attachment 1, p. 21).

NAIMA noted that, on average, mineral wool industry workers' exposure to silica does not exceed 50 μg/m^3, and often does not exceed 25 μg/m^3. However, NAIMA argued that those average exposure levels "do not prove that current engineering controls alone are feasible in all plants for all workers at all times" (Document ID 2348, Attachment 1, p. 27). Technological feasibility has been interpreted to mean that a typical firm will reasonably be able to implement engineering and work practice controls sufficient to reduce exposures to or below the PEL in most operations most of the time. See discussion of technological feasibility in Section II, Pertinent Legal Authority section of the preamble.

NAIMA also noted that no mineral wool products manufacturing data was used in preparing OSHA's Preliminary Economic Analysis of the glass products manufacturing sector (Document ID 2348, pp. 18-19). OSHA appreciates NAIMA's contribution to the rulemaking record and the steps plants have already taken to reduce workers' exposures. While no sample data were available for inclusion in the exposure profile from mineral wool products facilities, OSHA has considered information in the record regarding processes and exposure controls in the manufacture of fiberglass, a type of mineral wool. Based on an interview (conducted by OSHA contractor ERG) with a fiberglass manufacturer, OSHA concludes that the nature of the operations in mineral wool manufacturing is sufficiently similar to the glass industry as a whole to rely on the baseline conditions and exposure profile laid out in the PEA (Document ID 0699). In addition, NAIMA's data clearly indicate that workers in glass mineral wool manufacturing are already exposed below 50 μg/m^3; therefore, it is likely that OSHA has overestimated the costs and controls needed for glass mineral wool manufacturing (Document ID 3999, Attachment 1, pp. 3-4).

4.9.3 Additional Controls

Additional Controls for Material Handlers

The exposure profile in Table IV.4.9-B shows that 17 percent (1 out of 6) of material handlers have exposures below 50 μg/m^3 under baseline working conditions. Therefore, OSHA finds that the remaining 83 percent will need additional controls to reduce exposures to below the final PEL of 50 μg/m^3. Control options include using sized and washed sand containing fewer fine particles (when permitted by final product properties), which is widely available from sand suppliers; fully enclosing and ventilating all conveyors and transfer points used in sand handling; implementing general dust control measures to minimize dusty conditions that exacerbate exposure levels; and educating workers on protective work practices (Document ID 1365, p. 7-10; 0703, p. 1).

A glass product manufacturing facility with an actively enforced silica control program reported that only one in a thousand PBZ air samples exceeded the ACGIH TLV of 50 μg/m^3 when the following practices were followed: purchase pre-washed, size-selected sand which exceeds respirable size; fully ventilate with negative pressure all dry sand conveying equipment; perform preventive maintenance; automate sand handling where possible; and train workers and enforce work practices that control silica release. This facility also noted that many larger manufacturers add moisture to the batch mixer for process reasons, which has an additional hygiene benefit of reducing dust in air and therefore reducing silica exposures (Document ID 0703).[56]

When a fine sand particle size must be used for production purposes (e.g., glass fiber production), another facility has achieved low silica exposures by using a pneumatic sand conveyance system instead of conveyor belts (Document ID 0699, p. 1). This fiberglass manufacturer attributes low exposure levels (typically below the limit of detection (LOD)) to good facility design, using sealed pneumatic pipes for all transport, and good work practices. In addition, this facility trains workers to watch for and respond appropriately to leaks and uses careful clean-up methods (Document ID 0699, p. 2).

Additional Controls for Batch Operators and Associated Workers

The exposure profile in Table IV.4.9-B shows that 50 percent (4 of 8) of batch operators and associated workers have exposures above the final PEL of 50 μg/m^3, and the other 50 percent have exposures below 25 μg/m^3, the final rule's action level. For the workers with exposures above the PEL, additional controls will be required to achieve the PEL. The same control methods described previously for material handlers also will benefit workers in the batch area. At the two facilities described above, these practices resulted in

[56] No individual sampling results relating to this facility's estimate were actually provided to the rulemaking record, and thus could not be included in the exposure profile for this sector.

silica exposure levels generally well below 50 μg/m^3 for workers, including workers in batch areas.

Two of the sample results included in the exposure profile (Table IV.4.9-B) represent batch operators at a large glass products facility who operated automated equipment to weigh materials and transfer them to mixers; these individuals had exposure results of 14 μg/m^3 and 60 μg/m^3 (Document ID 1720, p. IV-209; 0085, pp. 33-36).[57] Further exposure reductions could be achieved by fully enclosing and ventilating all conveyors and transfer points, and isolating batch operators in enclosed, ventilated control booths. Facilities with manual batch operations could reduce exposures by installing automated batch handling equipment.

Exposures to workers engaged in batch area-related maintenance and housekeeping tasks also can be controlled below 50 μg/m^3. Reduction of dust leakage, spillage, and other sources of silica material in the batch area (as described above) should serve to generally reduce dust levels. Diligent, routine housekeeping in batch areas is required to reduce dust accumulation and limit the potential for exposure to re-suspended dust. Using HEPA-filtered vacuums and dust suppressant during housekeeping activities, rather than dry sweeping and using compressed air, also will reduce exposures.[58] OSHA has determined that housekeeping activities can be performed efficiently when engineering controls are fully implemented and maintained on sand handling equipment since there will be fewer fugitive emissions of dust to clean up (Document ID 1540, pp. 209-210).

Glass industry comments submitted to the record described several other types of control options that have been found to be feasible and effective in reducing exposures. William Mann, VP of Health and Safety for Verallia, testified about Verallia's use of central

[57] These workers had total respirable dust exposures of 0.204 mg/m^3 and 0.83 mg/m^3, with percent silica values in these samples of 6.8 percent and 7.2 percent, respectively (Document ID 0085, pp. 33-36). The silica exposure is determined as follows: 0.204 mg/m^3 x 1000 μg/mg x .068 = 13.9 μg/m^3. Likewise, 0.83 mg/m^3 x 1000 μg/mg x .072 = 59.8 μg/m^3.

[58] In hearing testimony, Dr. Paul Schulte recommended "...vacuum systems, portable or centralized" as an alternative to dry sweeping. (Document ID 3579, Tr. 142). Portable vacuum systems are recommended, described, and illustrated in the NIOSH Dust Control Handbook for Industrial Minerals (Document ID 1540, pp. 207 – 209).

vacuum systems for housekeeping (Document ID 3584, Tr. 2860). GANA, the Glass Packaging Institute (GPI), and NAIMA also described using central vacuum systems to reduce silica exposures for workers performing housekeeping activities in glass manufacturing plants (Document ID 2215, Attachment 1, p. 4; 2290, p. 5; 2348, Attachment 1, p. 21). William Yanek, Executive Vice President of GANA, described wet sweeping as a means of reducing exposures during housekeeping as well (Document ID 2215, Attachment 1, p. 9). In hearing testimony, Mr. Steve Smith and Mr. William Mann of Verallia discussed the use of vibrating pipes as an effective means of reducing the frequency of pipe clogs in materials transfer equipment which would otherwise require workers to open a pipe to clear a jam, and can lead to high silica exposures (Document ID 3584, Tr. 2856-2857).

Oral testimony and written comments from the glass manufacturing industry focused on a few specific concerns regarding feasibility. Industry representatives expressed concern about the feasibility of controlling exposures during upset conditions, such as malfunctions or response to batch leaks, without reliance on respiratory protection, "because the type and level of maintenance malfunction events are essentially endless." (Document ID 3584, Tr. 2834-2836; 2290, Attachment 1, p. 2; 2215, Attachment 1, p. 4). OSHA recognizes that upset conditions, such as unforeseeable failure of engineering controls or failure of process equipment that can only be accessed by removing or disabling containment controls, are a potential exposure concern that poses special challenges. These types of situations are discussed more fully in Section IV-1 – Introduction, earlier in this technological feasibility chapter.

Industry representatives challenged the feasibility of controlling exposures during maintenance activities (Document ID 3584, Tr. 2844 - 2851; 3581, Tr. 1725; 2290, Attachment 1, p. 2). In hearing testimony, Mr. Smith of Verallia, described air filter changes as a maintenance activity where exposure control without respiratory protection would not be feasible (Document ID 3584, Tr. 2849 – 2851). OSHA notes, however, that as an alternative to respiratory protection in controlling exposures during air filter changes, some industries use bag-out style filters to encapsulate contaminated filters (Document ID 3883, p. 8-38). Such bag-out techniques could be adopted to reduce reliance on respirators in the glass industry. Respirators may be needed where these other controls do not reduce exposures below the PEL.

In written comments, NAIMA stated that its sampling data showed the following categories of job tasks "which have at least one sample that exceeds the proposed [silica] PEL… where respiratory protection is needed":

- Hot end repair/mechanic (involves maintenance and repair projects; sample results range from 4 $\mu g/m^3$ to 84 $\mu g/m^3$).
- Batch house cleaning (involves cleaning spilled materials in batch house and unloading area, an infrequent maintenance task performed several times per year, which may use vacuuming, wet or other dust suppressant methods, dry sweeping and compressed air; sample results range from 22 $\mu g/m^3$ to 170 $\mu g/m^3$).
- Baghouse maintenance (involves replacing baghouse bags, performed annually, sample results range from 3.6 $\mu g/m^3$ to 76 $\mu g/m^3$) (Document ID 2348, Attachment 1, pp. 16 - 17).

Based on this testimony and experience in analogous situations in other industries, OSHA expects that engineering controls can be implemented for many maintenance activities.

For example, portable exhaust ventilation systems are often used as an engineering control where fixed, permanent local exhaust is not practical or feasible, such as in welding or spray painting. These systems are mounted on a wheeled cart and include particulate filters and flexible exhaust hoses that can be positioned at the point of contaminant generation (Document ID 3658, pp. 2-168 – 2-169; 3659, p. 3-36). In the case of batch house cleaning, additional reductions in silica exposures can likely be achieved by reducing reliance on dry sweeping and use of compressed air, and replacing these dust generating practices with more appropriate controls, such as HEPA-vacuuming and wet or other dust suppressant methods. The Agency has also acknowledged that for very short-term, infrequent activities such as maintenance of engineering controls or servicing of sand handling machinery that is normally enclosed, use of respiratory protection may be appropriate.

Some industry representatives commented that it is not feasible to eliminate the use of compressed air for cleaning in all cases, such as when cleaning tight spaces or hard-to-reach crevices (Document ID 3584, Tr. 2837; 2215, Attachment 1, p. 9; 2348, Attachment 1, p. 37). For example, in hearing testimony, Mr. Steve Smith, VP of Environmental and Regulatory Affairs for Verallia, explained that it would be very difficult to clean a batch scale without relying on compressed air cleaning (Document ID 3584, Tr. 2852). OSHA concludes, however, that the need for such cleaning can be reduced through improved ventilation at the scale and/or enclosure of sand handling equipment, which should minimize the need for cleaning the scales. Additionally, crevice tools are commercially available accessories that can be fitted to standard 35 mm or 1-1/2” diameter vacuum hoses in order to clean hard-to-reach crevices (Document ID 3998, Attachment 10, pp. 32 and 43). It may also be possible in some cases to more fully enclose or seal off hard-to-reach areas so that dust cannot accumulate in them, thus eliminating the need for cleaning.

In some limited circumstances, compressed air cleaning may be the only feasible method of cleaning. In this situation, care must be taken to ensure the use of compressed air does not contribute to airborne silica exposures in the workers’ breathing zone. One way to reduce employee exposure in this situation would be to use a longer compressed air wand to create a separation between the worker’s breathing zone and any airborne respirable silica disturbed by compressed air cleaning activities.[59] Use of longer handled-tools to reduce breathing zone exposures to airborne contaminants is a standard approach under the hierarchy of controls. For example, in an assessment of dowel drilling (NIOSH EPHB report 347-15a), NIOSH recommended use of a long-handled tool to reduce exposures to airborne silica when marking pavement (Document ID 4153, pp. 18-19, 31). It may also be possible to use portable local exhaust in combination with compressed air cleaning, which would capture any dust disturbed by compressed air cleaning before it can enter a worker’s breathing zone. OSHA has previously determined that the set-up of compressed air combined with LEV is permissible when other options such as wet methods or

[59] Wands are already used with compressed air, as observed by NIOSH in a foundry assessment, although the length of the wands used were not actually described (Document ID 0233, pp. 6, 9).

vacuuming are not feasible (e.g., Cadmium and Lead in Construction standards, 29 CFR 1910.1027(k)(6); 1926.62(h)(5)) and as such, has allowed compressed air to be used in conjunction with a ventilation system.

Regarding specific exposure controls, industry commented that use of specific controls should not be mandated, because, while they have been implemented effectively in many circumstances, they are not feasible in all cases. These include use of cullet (Document ID 2215, Attachment 1, p. 5; 2348, Attachment 1, p. 9), prewashed sand or sand of specified grain sizes (Document ID 2215, Attachment 1, p. 5; 2348, Attachment 1, pp. 22-23), and pneumatic conveyance systems (Document ID 2348, Attachment 1, pp. 23-24; 2215, Attachment 1, p. 7). The respirable crystalline silica standard for general industry is performance-oriented, and does not mandate the use of any specific controls. Alternative controls exist, such as implementation of enclosed, ventilated conveyance systems and transfer points; enclosed, ventilated operator control booths; automated batch handling equipment; HEPA-filtered vacuums; dust suppressants during housekeeping activities; general dust control measures; and educating workers on adequate work practices. Employers are free to use any combination of these and other control strategies to meet the PEL in the final rule.

4.9.4 Feasibility Finding

Feasibility Finding for Material Handlers

Based on the exposure profile in Table IV.4.9-B, which shows that, 83.3 percent of material handlers currently have exposures above the final PEL, OSHA expects that additional controls to achieve silica levels of 50 μg/m^3 or less will be required for these overexposed workers. Other information in the record, including communication with a fiberglass manufacturing facility, however, indicates that by using a combination of control methods, all glass manufacturing facilities can achieve levels below 50 μg/m^3 on a regular basis for all workers, including material handlers (Document ID 0699, pp. 1-2; 1365, p. 7-13). Appropriate engineering controls include automated and ventilated equipment for unloading raw materials from shipping containers and transferring them to storage units. Other modifications include fully enclosing and ventilating all sand conveyance devices (including the transfer points) and implementing administrative controls such as improved housekeeping and active dust management procedures.

OSHA concludes that implementation of the control methods described in this section will reduce exposure levels for most material handlers to 50 μg/m^3 or below. Therefore, OSHA finds that the standard is feasible for material handlers in the glass industry.

Feasibility Finding for Batch Operators and Associated Workers

Based on the exposure profile in Table IV.4.9-B, which shows that half of batch operators and associated workers currently have exposures over the final PEL, OSHA concludes that additional controls will be required for these overexposed workers. Employers can reduce exposures to 50 μg/m^3 for those batch area and associated workers using the same combination of engineering and administrative controls described for material handlers. Such controls include automated and ventilated equipment for transferring raw materials to mixers and furnaces, and administrative procedures for managing released sand. OSHA acknowledges that respirator use by batch area workers may be necessary in limited situations when engineering controls cannot be feasibly implemented, such as during certain maintenance activities or upset conditions.

OSHA concludes that implementation of the control methods described in this section, including the occasional use of respirators where engineering and work practice controls alone are insufficient, will reduce exposure levels to 50 μg/m^3 or lower for most batch operators and associated workers in the batch areas of glass product manufacturing. Therefore, OSHA finds that the standard is feasible for batch operators and associated workers in the glass industry.

Overall Feasibility Finding for the Glass Industry

OSHA concludes that, based on the exposure profile and evidence in the record, effective control measures can be implemented to achieve compliance with the final PEL of 50 μg/m^3 for most operations, most of the time, in the Glass Industry. Therefore, OSHA finds that the final PEL of 50 μg/m^3 is technologically feasible for the Glass Products Industry.

4.10 JEWELRY

4.10.1 Description

The jewelry manufacturing industry uses silica-containing materials in casting and finishing operations. Worker exposure to silica can occur during investment casting[60] involving the use of investment casting compounds, which are powdered refractory materials that often contain quartz or cristobalite (Document ID 1370). Workers in this industry also perform abrasive blasting using silica sand as abrasive media for cleaning the investment material from castings, which can result in worker exposure (Document ID 1365, p. 8-1). Workers performing lapidary operations (cutting, polishing, and engraving precious stones) are potentially exposed to silica generated by gemstones (such as agate, amethyst, aventurine, jasper, and quartz crystal) and by abrasives used for grinding and polishing jewelry products (Document ID 1402). Jewelers typically perform small-scale, bench-top operations, using relatively small amounts of silica-containing materials (Document ID 1365, p. 8-1). Facilities manufacturing jewelry are classified in the 2007 six-digit North American Industry Classification System (NAICS) codes: 339911, Jewelry (except costume) Manufacturing; 339913, Jewelers' Material and Lapidary Work Manufacturing; and 339914, Costume Jewelry and Novelty Manufacturing[61] (Document ID 1365, p. 8-1).

Table IV.4.10-A summarizes the major activities and sources of exposure for jewelers, the single job category with potential exposure to silica in this industry.

[60] "Investment casting" is a form of metal casting that involves enclosing a three-dimensional pattern in a heat-resistant ceramic mold called "investment material." Lost-wax casting is an example of a type of investment casting commonly used in jewelry production facilities and dental laboratories (Document ID 0201, p. 3-5).

[61] The applicable 2012 NAICS code is 33910, Jewelry and Silverware Manufacturing.

Table IV.4.10-A Job Category, Major Activities, and Sources of Exposure of Workers in the Jewelry Industry (2007 NAICS 339911, 339913, 339914)	
Job Category*	**Major Activities and Sources of Exposure**
Jeweler	Mix investment material and cast jewelry products. • Dust released during manual transfer and mixing of silica-containing investment material. • Dust generated while separating castings from investment material. Cleaning and abrasive blasting of jewelry. • Dust from abrasive blasting operations involving silica-containing media and/or castings coated with silica-containing investment material. Cutting, grinding, and/or polishing of jewelry. • Dust from grinding or polishing of jewelry with silica-containing abrasives. • Dust from cutting, grinding, or polishing of gemstones containing silica.
*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility. Source: Document ID 1365, pp. 8-2 – 8-3.	

4.10.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.10-B includes 11 personal breathing zone (PBZ) samples of respirable crystalline silica, for the jewelry industry. The median exposure is 12 μg/m^3, mean of 120 μg/m^3, and the range is 4 μg/m^3 to 565 μg/m^3. Table IV.4.10-B shows that, of the 11 samples, 4 (36.4 percent) are above 50 μg/m^3, while 7 (63.6 percent), are below 25 μg/m^3.

As described in the Preliminary Economic Analysis (PEA), OSHA identified two PBZ respirable quartz exposure samples for jewelers from two OSHA Special Emphasis Program (SEP) inspection reports (Document ID 0150, p. 40; 0145, p. 21). The exposure monitoring data presented in these reports were not collected over full work shifts; however, the reports indicate that activities associated with potential exposure were infrequent and not performed during the unsampled portions of the workers' shifts (see, e.g., Document ID 0145, p. 71 (sandblasting occurs "maybe once every two weeks")). As a result, OSHA contractor ERG calculated 8-hour time-weighted average (TWA) exposures based on the reported data and assuming no exposure during the unsampled period. In this manner, ERG calculated an 8-hour TWA of 15 micrograms per cubic meter (μg/m^3) for a jeweler who, under these realistic assumptions, performed abrasive blasting of gold and silver using an unventilated glovebox blasting cabinet and silica sand media (originally 21 μg/m^3 for a 349 minute sample) (Document ID 1365, pp. 8-4 - 8-5;

0150, p. 40). According to the inspection report, visible airborne dust leaked from the cabinet while it was in operation (Document ID 0150, p. 57). The worker performed abrasive blasting operations for approximately 5 to 20 percent of each 8-hour shift (i.e., roughly 30 to 100 minutes per shift) (Document ID 1365, p. 8-5).

For a jeweler at the second site who performed abrasive blasting of metallic medals for approximately 15 percent of the shift, the exposure was less than the limit of detection (12 µg/m^3 as an 8-hour TWA, less than or equal to 77 µg/m^3 for the 76 minute sampling period[62]). The jeweler used garnet media (a substitute abrasive blasting media that contains less than 0.5 percent silica) in an unventilated glovebox cabinet (Document ID 1365, p. 8-5; 0145). The cabinet leaked blast media through holes during the abrasive blasting operation and released visible airborne dust when opened by the worker to remove or reposition the medals. The room had open windows, and the jeweler used a floor fan for comfort.[63]

In addition to the two SEP inspection results detailed above, and because so few suitably documented data were available for the jewelry application group, OSHA considered supplemental PBZ data reported in OSHA's Integrated Management Information System (IMIS) (Document ID 1698; 4185) as well as adding the OSHA Information System (OIS) sample results (Document ID 3958).[64]

The only additional IMIS sample result, collected in 2009, was below the limit of detection. Because information on sample volume is not available for IMIS results, it is

[62] The elevated LOD (less than or equal to 77 µg/m^3) is a function of the extremely short sample duration (76 minutes).

[63] Two additional results from a New Jersey Department of Health (NJDOH) report and a NIOSH report, are excluded from the exposure profile (Document ID 1365, p. 8-5). Both results are reported as below the LOD, but supporting information is insufficient to determine the LOD. In addition, the NIOSH sample covered only some of the worker's potential sources of silica exposure and likely does not represent total exposure for that day. One jeweler conducted polishing inside a booth equipped with LEV, while the other jeweler worked without ventilation (Document ID 1365, pp. 8-4 – 8-5).

[64] Table IV.4.10-B contains IMIS sampling results associated with Standard Industrial Classification (SIC) codes 3911 (Jewelry, Precious Metal), 3915 (Jewelers' Findings and Materials, and Lapidary Work), and 3961 (Costume Jewelry and Costume Novelties, Except Precious Metal).

not possible to determine the sample limit of detection, and thus OSHA could not include such results in the exposure profile presented in Table IV.4.10-B.

The OIS data provided three additional sample results that OSHA has added to this analysis (Document ID 3958). All three OIS data points are from a single inspection, and involved tasks such as casting operations and model making. All three sampled employees were described as using local exhaust ventilation, and all three sample results were below 25 μg/m^3.

In addition, OSHA has updated the exposure profiles contained in the PEA to include only those IMIS samples collected after 1990 (see Section IV-2 – Methodology), resulting in the removal of 10 sample results (Document ID 1698). A total of five IMIS samples collected after 1990 were below the limit of detection and have been excluded from Table IV.4.10-B as well.[65] While it is likely that exclusion of so many non-detect values (31 percent of all sample results) would lead to an overestimate of the distribution of exposures in this application group, the data presented in Table IV.4.10-B do indicate that elevated exposures can occur in this industry when controls are not in place while workers perform abrasive blasting. Results as high as 565 μg/m^3 were reported in IMIS in this application group as recently as 1997. Since 2000, exposure levels reported in this application group have been less than 25 μg/m^3.

No other data or comments were submitted to the rulemaking record relating to technological feasibility in the jewelry manufacturing sector. Based on the available information in the record, baseline controls for this sector include either LEV for finishing operations or use of substitute media for abrasive blasting operations (generally only a single control is in place). Facilities commonly use unventilated glovebox abrasive

[65] In the PEA, which included IMIS samples for the period 1979 through 2002, a total of 34 results were available for the jewelry sector, with sixteen results having detectable silica, and 18 results (52 percent) as non-detects or below the LOD, and thus excluded from the exposure profile. Among the sixteen samples with detectable silica, 56 percent were below 50 μg/m^3. Results ranged from 4 μg/m^3 to 565 μg/m^3, with a median of 39 μg/m^3 and a mean of 108 μg/m^3. Seven results (43 percent) exceeded 50 μg/m^3, and 5 results (31 percent) exceeded 100 μg/m^3.

blasting cabinets. Activities associated with silica exposure are often performed for less than 20 percent of each shift.

OSHA did not receive any evidence contradicting or supplementing OSHA's preliminary analysis of current conditions in the jewelry industry. Therefore, the Agency considers the Table IV.4.10-B to be representative of baseline exposures and conditions.

Table IV.4.10-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Jewelry Industry (NAICS 339911, 339913, 339914)

	Exposure Summary			Exposure Range			Exposure Profile

4.10.3 Additional Controls

The exposure profile in Table IV.4.10-B shows that a little over 36 percent (4 of 11 samples) of jewelry workers have exposures over the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Although OSHA concludes that adequate controls are widely used, where necessary, as evidenced by the nearly 64 percent (7 out of 11) of sampled jewelers in the exposure profile who have exposures below 25 μg/m^3. These additional controls include:

- Covered containers and LEV during investment mixing.
- Wet methods and/or LEV when separating investment material from castings (e.g., breaking molds under a water stream or mist).
- Properly designed and ventilated abrasive blasting cabinets.
- Alternative low-silica or silica-free blast media.
- Clean blast media for each session (to avoid recycling media contaminated with refractory material unless it can be cleaned).
- Improved work practices (such as allowing the blasting cabinet ventilation to clear the equipment of dust before opening the cabinet).
- Wet methods and/or LEV during finishing operations.
- Improved housekeeping (such as use of a high-efficiency particulate air (HEPA)-filtered vacuum, daily where necessary).

Although no information is available quantifying the effectiveness of each individual method in reducing silica exposures specifically within the jewelry industry, these are standard, time-tested approaches that have been effectively used in many industries to control occupational exposures to a variety of hazardous particulates, including silica. Jewelers employing at least one control typically achieved levels of silica below 25 μg/m^3 (the earlier discussion of baseline conditions for this industry describes use of either LEV for finishing operations or use of substitute media for abrasive blasting operations; also, facilities commonly use unventilated glovebox abrasive blasting cabinets (Document ID 1365, p. 8-7; 0145; 0150; 3958)). In addition, dental laboratory technicians who perform work similar to that of jewelers (mixing investment material, casting precious and semi-precious metals, cleaning and finishing small castings, and abrasive blasting in cabinets) have reduced silica exposures by using several similar exposure controls that should be equally effective in the jewelry industry (see Section IV-4.6 – Dental Laboratories). The effectiveness of these controls is demonstrated by silica exposure levels below the LOD (10 μg/m^3 in this case) obtained for all workers in a dental laboratory that used sealed mixers, wet methods for grinding and divesting castings, benchtop local exhaust ventilation, and an abrasive blasting cabinet when performing small-scale metal casting, finishing, and abrasive blasting processes that were nearly identical to those used in jewelry manufacturing (Document ID 0201). Based on the similarity of the tasks and the scale of these operations in these two industries, and having received no comments concluding otherwise, OSHA concludes that control options available in dental laboratories will be just as effective in jewelry manufacturing facilities. Comments received regarding dental laboratories indicated that ventilation controls and substitute blasting media are feasible and effective in reducing exposures, and that leaks from unvented gloveboxes can contribute to exposure (Document ID 3585, Tr. 3128-3129; 1763, pp. 2-3). To the extent commenters expressed concerns about OSHA's assessments of the control options available to dental laboratories, OSHA's responses in that section also apply to the use of those controls with respect to manufacturing jewelry.

At one dental laboratory, technicians used a covered and sealed mixer to blend water with powdered silica investment materials (containing 70 percent silica). After casting, the investment mold was cracked and castings removed (called "divesting") under a stream of water to suppress dust. Workers also used water-fed and ventilated grinding equipment, performed abrasive blasting with new (clean) media in a ventilated cabinet, and worked at benches fitted with LEV (Document ID 0201, pp. 11 - 15). Three dental technicians working with these controls had exposures below the limit of detection (10 μg/m^3 in this case).

The two samples described in the OSHA SEP inspection reports noted visible dust escaping from unvented abrasive blasting cabinets, indicating the potential for silica-containing dust to escape from the cabinets (Document ID 1365, p. 8-5; 0150; 0145).[66] While unvented blasting cabinets are often sufficient in jewelry or dental laboratories where they are used in small facilities for only a portion of the work shift, unvented cabinets, with open ports for the arms, may not be sufficient when used for a full shift, or when a number of blasting cabinets are in simultaneous use. Mr. John Adams, Vice President of the American Federation of Government Employees (AFGE) Local 2778, representing dental laboratory workers at the Atlanta Veterans Administration hospital, noted that:

> Leaks in a blasting box can cause exposure. Exposure is also caused by opening the door to the blasting box before the dust had settled. Dust in a blasting box must be removed by a dust collection system to prevent dental lab workers from being exposed to silica (Document ID 1763, p. 2).

Where silica exposures above 50 μg/m^3 are associated with use of unvented blasting cabinets, OSHA notes that, in accordance with the hierarchy of controls, equipping such units with HEPA-filtered local exhaust ventilation, and ensuring proper use and maintenance of blasting cabinets, would be effective control measures.

Due to the similarity in work processes and controls between the dental laboratory and jewelry sectors, and the evidence of those types of exposures in the two OSHA SEP inspection reports for the jewelry sector, OSHA has determined that this comment from Mr. Adams is equally applicable to jewelry manufacture. Overall, dental laboratory industry data suggest that jewelers who perform similar tasks using similar controls are unlikely to experience exposure levels above 50 μg/m^3 or even the action level. Baseline controls in use in dental labs, namely local exhaust ventilation, including ventilated blasting gloveboxes and other enclosures, are such that exposures for 97 percent of sampled dental lab workers are already below 50 μg/m^3, with 55 percent below the LOD (as summarized in exposure profile Table IV.4.6-B in Section IV-4.6 – Dental Laboratories in this technological feasibility analysis). Based on these data from a closely

[66] While the measured exposures did not exceed 50 μg/m^3 in these relatively short term samples, the detectable silica in the exposure sample for the worker performing silica sandblasting underscores the importance of ensuring proper functioning of containment devices such as a blasting cabinet.

analogous process and industry, OSHA expects that use of these same controls in the jewelry sector will eliminate exposures exceeding 50 μg/m^3.

4.10.4 Feasibility Finding

Based on the exposure profile in Table IV.4.10-B and other record evidence discussed above, OSHA finds that the standard is technologically feasible for most jewelry workers most of the time when baseline and additional controls previously discussed are used. Many jewelry manufacturing facilities already achieve respirable crystalline silica levels of 50 μg/m^3 or less for most of their workers. Based on information summarized in Table IV.4.10-B, OSHA finds that *at least* 63.6 percent of jewelers' exposures are already below 50 μg/m^3. This percentage likely underestimates the number of jewelers with exposures less than 50 μg/m^3 because nondetectable results were excluded from the IMIS data summarized in Table IV.4.10-B.

For the nearly 36 percent of jewelers with exposures above 50 μg/m^3, OSHA expects that exposures below 50 μg/m^3 will be achieved if properly ventilated abrasive blasting cabinets are used. Employers may also be able to achieve the same result by implementing one or more of the other controls identified above. This finding is based on the similarities between the processes used by dental laboratory technicians and those performed by jewelers, the evidence of similar types of exposures between the dental labs and jewelry manufacturers, and the absence of comments disputing OSHA's estimates in the PEA or the comparison between dental labs and jewelry manufacture. Controls that can reduce silica exposure during jewelry manufacturing include LEV for mixing and finishing operations, sealed equipment or wet methods for handling silica-containing investment casting materials, ventilated abrasive blasting cabinets, and alternative (low- or non-silica) abrasive blasting media.

Therefore, OSHA finds that the final PEL of 50 μg/m^3 is technologically feasible for the Jewelry industry.

4.11 LANDSCAPING SERVICES

4.11.1 Description

Landscape companies are primarily engaged in providing landscape care and maintenance services, including the installation of trees, shrubs, plants, lawns, and gardens. As part of their services, some landscape companies also construct walkways, retaining walls, patios, fences, ponds, or similar structures (hardscape). Establishments providing landscaping services are classified in the six-digit North American Industry Classification System (NAICS) code 561730, Landscaping Services (Document ID 1365, p. 18-1).

In Chapter IV of the Preliminary Economic Analysis (PEA), OSHA preliminarily concluded that only landscape and horticultural service workers performing masonry-related activities have the potential for silica exposure (Document ID 1720, p. IV–218). Several commenters disagreed, stating that other tasks associated with landscaping services had a potential for exposure to respirable crystalline silica. For example, the Construction Industry Safety Coalition (CISC) and the Interlocking Concrete Paving Institute (ICPI) stated that OSHA omitted the following activities from its preliminary analysis:

- Placing and compacting aggregate base;
- Placing bedding sand;
- Compacting pavers;
- Sweeping joint sand into paver joints; and
- Compacting joint sand.

Additionally, CISC listed the “demolition of concrete and masonry structures” and “installing erosion control” (Document ID 2319, Attachment 1, p. 20), and the ICPI added “excavating” and “removing dust off surfaces” (Document ID 2246, p. 8).

These views were supported by the National Association of Home Builders (NAHB) and the Associated Builders and Contractors, Inc. (ABC) who also listed “moving soil” (Document ID 2296, p. 35) and the “handling of paving stones and compaction of interlocking pavers" (Document ID 2289, p. 3) as landscaping activities that could contribute to exposure.

These industry comments convinced OSHA to expand upon its preliminary analysis of the landscaping services industry and to include in its final analysis activities related to the following activities: movement of sand, gravel, and soil; excavation of soil; placing of the sand or aggregate base; compaction of the sand or aggregate base; and sweeping sand into joints. OSHA has concluded based on this further analysis that these activities have the potential to expose workers to respirable silica and that they should therefore be included in the Final Economic Analysis (FEA).

While CISC listed "handling and installing pavers, and cleaning and preparing surfaces for sealing" as potential silica-generating activities, the ICPI excluded them from their list of silica-generating tasks (although it included these activities as part of the process) (Document ID 2246, p. 8; 2319, Attachment 1, p. 20). OSHA agrees with the ICPI that these activities are not likely to contribute to exposures above the PEL and therefore has decided not to include these tasks in its analysis of technological feasibility for the industry.

Based on the comments and supporting material in the docket, the Agency has determined that landscaping services consist of three major activities: 1) lawn maintenance services; 2) cutting silica-containing materials when installing "hardscapes" like retaining walls, patios, and walkways; and 3) moving and compacting sand, gravel, and soil.

Lawn Maintenance Services: In the PEA, OSHA determined that workers engaged primarily in lawn maintenance services, e.g., mowing, trimming, planting, mulching, fertilizing, leaf removal, are not routinely exposed to silica. The Agency did not, therefore, address these workers in the preliminary analysis (Document ID 1720, IV-218). This assumption was not disputed in any of the submitted comments; accordingly, OSHA has not included these workers in its final analysis of landscaping services.

Cutting Silica-Containing Landscaping Materials: OSHA also preliminarily determined that activities related to cutting brick, concrete, stone, and pavers with masonry saws did have exposure to silica. Although the quantity of this work varies with the operation and nature of the firm's services, OSHA has determined that, overall, these activities represent a relatively minor portion of the industry's labor time and only a small share of the industry is engaged routinely in installation of hardscapes where block and brick cutting operations occur (Document ID 1365, p. 18-2). OSHA assumed that if a firm generates a majority of its revenues from this type of activity, the firm is classified as a construction firm and not as a landscaper (Document ID 1720, IV-218). This assumption was not disputed in any of the submitted comments.

Because OSHA has determined that respirable crystalline silica exposures of landscape workers using masonry saws can be well controlled by the controls described in Sections IV-5.6 – Masonry and Concrete Cutters Using Portable Saws and IV-5.7 – Masonry Cutters Using Stationary Saws, and in particular Table 1, the Agency has not included a detailed exposure profile for these workers in this section. This approach differs from the PEA, which addressed only exposures from masonry saws for landscape workers. The controls for masonry saws, however, which are not discussed further in this section, would have the indirect effect of lowering background and secondary exposures of other workers in the work area. In addition to the controls described in Sections IV.5.6 and IV.5.7 relating to portable and stationary masonry saws of this Final Economic Analysis (FEA), this section on Landscaping Services describes silica dust reduction controls that are applicable to the installation of pavers, patios and walkways.

Movement and Compaction of Sand, Gravel, and Soil: Although the quantity of work involving the movement and compaction of sand, gravel and soil varies with the operation and nature of the firm's services, OSHA has determined that, overall, these activities represent a relatively minor portion of the industry's labor time as the vast majority of workers are engaged primarily in lawn and tree maintenance services. Only a small share of the landscaping services industry is engaged routinely in the movement and compaction of sand, gravel, and soil and experiences exposures to silica (Document ID 1365, p. 18-2; 2246, pp. 8-11; 2289, p. 3; 2296, pp. 6-7; 2319).

Final Industry Description

For the final technological feasibility analysis, OSHA has determined that landscaping service workers with potential silica exposure are those workers performing activities related to the movement and compaction of sand, gravel, and soil such as installing erosion control, placing aggregate base and bedding sand, compacting sand and soil, and sweeping joint sand into paver joints. In addition, OSHA has excluded masonry cutting that sometimes occurs in but is not typically characteristic of this industry. For exposures and controls relating to masonry cutting, refer to Sections IV-5.6 – Masonry and Concrete Cutters Using Portable Saws and IV-5.7 – Masonry Cutters Using Stationary Saws.

Sources of exposure for these workers come directly from the dust generated by the movement of the soil, sand, and aggregate. Table IV.4.11-A describes the major activities and sources of exposure of these workers.

Table IV.4.11-A
Job Category, Major Activities, and Sources of Exposure of Workers in the Landscaping Services Industry (NAICS 561730)

Job Category*	Major Activities and Sources of Exposure
Landscape Worker	Moving aggregate and sand; installing erosion control; placing aggregate base and bedding sand; compacting sand and soil; and sweeping joint sand into paver joints. • Dust generated by the movement of the material

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the landscaping employer.

4.11.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.11-B includes 7 full-shift personal breathing zone (PBZ) respirable crystalline silica samples for landscape workers who are involved in manual labor including hardscape installation and sand moving. The median exposure is 33 μg/m^3, the mean is 34 μg/m^3, and the range is 6 μg/m^3 to 66 μg/m^3. Of the 7 samples, 2 (28.6 percent) exceed 50 μg/m^3.

The sampling data OSHA has consist of two samples for landscape workers from the OSHA Information System (OIS) with 8-hour time weighted averages (TWA) of 12[67] and 17 μg/m^3, and one 303-minute sample from the 2000 Shield's database for a worker on a sidewalk project, with an 8-hour TWA of 66 μg/m^3 (Document ID 1143; 3958, Rows 731-732).[68] This worker spent the shift laying pavers and sweeping sand into the joints of pavers while another worker on site performed concrete sidewalk cutting using a masonry saw (Document ID 1143). OSHA also identified four additional samples from OSHA's Integrated Management Information System (IMIS) database that OSHA has included in Table IV.4.11-B because of the limited data available through other sources (Document ID 4185). These four samples came from four workers performing landscape activities.[69] The highest exposure of 66 μg/m^3 came from a worker classified as a paver. A second paver on the same site had an exposure of 33 μg/m^3. A hardscape installer had an exposure of 6 μg/m^3 and a worker listed as a landscaper had the second highest exposure of 59 μg/m^3. No further detail about the tasks these workers were doing while sampling occurred is known.

In the PEA, OSHA was not able to identify any data on the silica exposures of landscape workers who did not use saws. OSHA therefore relied on data from similar activities in other industries, that is, masonry workers using saws outdoors, a subcategory of the exposure profile for Section IV-5.6 – Masonry and Concrete Cutters Using Portable Saws, a construction application group, in developing the preliminary exposure profile (Document ID 1720, p. IV-219). Because OSHA was subsequently able during the

[67] Results reported as "zero" or "non-detect" are assigned a value equal to the limit of detection (LOD)(12 in the sample referred to above). The LOD is determined individually for each sample based on the volume of air sampled and the method used to analyze the sample, therefore, the limit of detection varies between samples. See Section IV-2–Methodology for additional information on LODs.

[68] Because the sample from the Shields database was collected for less than 360 minutes and assumed a zero exposure for the unsampled portion of the shift, OSHA recalculated the TWA consistent with Section IV-2–Methodology regarding the handling of General Industry data and assumed there was a continuous exposure during the unsampled portion of the shift in order to obtain an 8-hrhour TWA of 67 μg/m^3. The sample value for this worker was reported by the OSHA compliance officer as 42 μg/m^3.

[69] These data are difficult to interpret because information regarding specific worker activities, workplace conditions, engineering controls, personal protective equipment, and sample duration is not available. However, the IMIS data represent the only other source of current information to date for this analysis.

rulemaking to identify sampling data for the landscape industry which are more representative, it has removed the construction data points used in the PEA for the Final Exposure Profile for this industry.

No studies directly relating to worker exposures while installing hardscapes or conducting landscape activities were submitted to the docket. Several analyses discuss exposures during soil moving activities and demolition clean-up, activities arguably similar to those that may be performed during hardscape installations. As discussed further below, although the analyses provide some useful comparisons, the working conditions described, which include the use of power tools by other workers not classified as moving materials or cleaning-up and the materials being moved like concrete, are dissimilar to those conditions most often experienced by landscape workers. These analyses, therefore, in some ways instructive, do not undermine the Final Exposure Profile.

A literature review by Beaudry et al. (2013) analyzed construction workers exposure to silica dust during the "manual moving of small rocks, soil, etc." done by unskilled laborers with shovels, brooms and occasionally motorized tools, utilizing data collected in Canada, France, and the United States (Document ID 3797, p. 19).[70] While the exposure results in this study are somewhat higher than the exposure profile in Table IV.4.11-B (range of zero to 350 μg/m^3), the study does not provide information on which power tools or dust controls, if any, were in use during sampling and how much of the material contained concrete debris and therefore, OSHA is unable to gauge their effect on the results (Document ID 3797 p. 83). [71] More pertinent to landscape workers, is the comparison in Beaudry, Appendix 6, which compared silica exposure levels for workers

[70] The focus of the literature review was to identify exposure information applicable to the work environment in Quebec, Canada; therefore, Beaudry, et al., eliminated data points that were not relevant to the work environment in Quebec.

[71] Significant differences exist between OSHA's data and the dataset used by Beaudry, et al. OSHA's exposure profile relies on exposure results obtained for workers in the United States and does not incorporate international data because working conditions may differ from those typically found in the United States. Additionally, when data was available only in summary form (e.g., eight exposure results described only by their mean in the source document), OSHA discussed this information separately, rather than including it in the exposure profile calculations.

based on the substrate. This comparison reflects significantly lower exposures for employees working with soil (Document ID 3797, p. 87). Sampling of workers working with soil ranged from 0 to 170 μg/m^3, had a median of 20 μg/m^3 and geometric mean of 30 μg/m^3. With sand, the range was 10 to 530 μg/m^3 with a median of 60 μg/m^3 and a geometric mean of 80 μg/m^3. With brick and concrete blocks, the range was 0 to 960 μg/m^3 with a median of 210 μg/m^3 and a geometric mean of 160 μg/m^3 (Document ID 3797, p. 87). Based on this comparison of silica exposure and substrate, OSHA has determined that landscape workers who move soil have significantly lower exposures than those workers involved in the cleanup of worksite and demolition materials containing concrete.

The sample data reviewed in Beaudry et al. demonstrate that exposures to silica when working with soil are lower than when working with brick and block (mean of 30 μg/m^3 compared to 160 μg/m^3). In addition, the mean exposure for soil is consistent with OSHA's exposure profile. Beaudry et al. (2013) included, however, some exposures significantly higher than those identified in the exposure profile. Because the report evaluated clean-up of materials including concrete in the construction industry, OSHA is unable to determine if these elevated exposures were the result of construction tools not typically used by landscape workers and, therefore, not likely to occur regularly in the landscape industry.

In a 2006 study, Flanagan et al., compiled construction site silica-monitoring data for U.S.-based workers from various sources.[72] This study reported 49 samples for workers using a broom and /or shovel with a geometric mean of 30 μg/m^3 and 61 samples for clean-up workers with a geometric mean of 50 μg/m^3 (Document ID 0677, p. 147). The findings for workers using brooms and shovels are consistent with the exposures identified in the profile for landscape workers while the exposure reported for clean-up workers are slightly higher.

[72] Beaudry, et al., note a significant (20 percent) contribution from the Flanagan dataset (Document ID 3797, p. i; Document ID 0677). Because neither dataset were made available to OSHA, the Agency cannot determine the amount over overlap in samples between the two reports.

The workplace conditions and control methods in place for most of these workers is unknown. Flanagan et al. did not capture information on the materials worked with in this study; however, a large portion of the samples were taken on new construction projects, during building renovations and demolition projects where materials commonly worked with would contain silica concentration higher than soil (Document ID 0677, Attachment 2). Again, because landscape workers do not work with concrete and silica-containing materials on a regular basis, OSHA judges that their exposures will be more typical of the results in the final exposure profile.

The ICPI provided descriptive information on the tasks where exposure is likely to occur during the installation of hardscapes. Charles McGrath of ICPI stated that “Seventy-eight percent of our industry is residential” and that work is not typically done using mechanical equipment, which is usually reserved for large jobs like ports and parking lots (Document ID 3589, Tr. 4407). However in his written comments, he stated that “compacting pavers into the bedding sand is probably the second largest generator of silica dust on any paver project” and this is done using a mechanized plate compactor (Document ID 2246, p. 10). He further explained that while a rubber mallet and hammer can be used instead of a compactor, it increases the installation time significantly (Document ID 2246, p. 10).

Vibrating machines are used during the filling of paver joints with sand as well. According to the ICPI, the traditional method is to repeatedly sweep dry sand containing polymers over the surface into the joints and then vibrate the pavers to ensure they are filled (Document ID 2246, p. 10). However, Warren Quinn with the American Nursery and Landscape Association stated that most landscapers do not use sand when laying paving brick; instead they use stone dust (Document ID 0961).

During the public hearing, the ICPI agreed with others that excavating is not a significant source of silica exposure and generally does not present a risk when installing pavers, stating, “For the purpose of installing paver system, workers do not have to excavate deep into the earth. If the soil is very dry, there may be dust; but in most cases the soil is damp beneath the surface of the earth producing little dust” (Document ID 3589, Tr. 4397). The

ICPI did state that in the case where a surface, such as a concrete patio or walkway, has to be demolished before the installation of the hardscape, the dust from the concrete could contribute to exposures (Document ID 3589, Tr. 4397-4398). The Agency does not disagree with ICIP about the potential for elevated exposures during demolition activities. Based on the studies OSHA reviewed in this section and a review of the databases described, however, demolition does not appear to be a typical source of exposure for landscape workers (no landscaping work/activities are associated with demolition in these large industry studies of construction tasks). Moreover, the demolition of concrete structures, which typically involves tools such as jackhammers, concrete saws and drills, is work performed primarily by employers in the construction industry. And, these activities, the equipment, and available controls are addressed in the pertinent construction sections.

With respect to the installation of pavers and paving brick, and cleanup activities associated with that work, Warren Quinn, with the American Nursery and Landscape Association, clarified that sand cleanup activities are typically done with mechanized blowers and vacuums rather than push brooms (Document ID 0961).

As previously noted, the Agency has not included a detailed exposure profile for landscape workers cutting masonry products during the installation of hardscapes in the final exposure analysis. OSHA, however, did obtain one sample of the silica exposure of landscaper who cut masonry products. This worker had an exposure of 181 $\mu g/m^3$ and was cutting pavers outdoors without any dust controls in place. It is unknown what type of saw the worker was using (portable or stationary) and whether any other workers were using mechanized tools in the area. Due to the limited data received, OSHA does not have enough information to draw a conclusive analysis for landscape workers who cut silica-containing products; however, OSHA expects that the profile for these workers would be similar to the exposures experienced by workers using masonry saws outdoors. Section IV-5.6 – Masonry and Concrete Cutters Using Portable Saws reported a mean exposure of 200 $\mu g/m^3$ and median of 150 $\mu g/m^3$ for workers outdoors with no controls in place, consistent with the exposure for the landscape worker reported above. OSHA also concludes that implementation of the controls described in Sections IV-5.6 – Masonry and Concrete Cutters Using Portable Saws and IV.5-7 – Masonry Cutters Using Stationary Saws will control these workers' exposures.

Based on the information discussed above, OSHA has determined that landscape workers are exposed to silica dust during the movement and compaction of sand, gravel, and soil, such as moving soil, installing erosion control; placing aggregate base and bedding sand; compacting sand and soil; and sweeping joint sand into paver joints, using brooms, shovels, and occasionally using mechanized machinery. OSHA has determined that these activities are not used by the landscape industry on a frequent basis but when performed, the majority of workers are not using controls to reduce exposures.

Because a wide variety of conditions exist in the landscape industry, OSHA has determined that the baseline conditions are best represented by the median for all exposure levels for this job category, as summarized in Table IV.4.11-B. OSHA finds that the results represented in Table IV.4.11-B offer the best available evidence of existing exposure levels. Thus, the exposure level associated with baseline conditions for landscape workers is represented by a median of 33 $\mu g/m^3$.

Table IV.4.11-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Landscaping Services Industry (NAICS 561730)

	Exposure Summary			Exposure Range			Exposure Profile				
Landscaping Services Industry	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**		**< 25 (μg/m³)**	**≥ 25 and ≤ 50 (μg/m³)**	**> 50 and ≤ 100 (μg/m³)**	**> 100 and ≤ 250 (μg/m³)**	**> 250 (μg/m³)**

4.11.3 Additional Controls for Landscape Workers

The exposure profile in Table IV.4.11-B shows that 2 of 7 samples (28.6 percent) of landscape workers have exposures above the final PEL of 50 μg/m^3. OSHA finds that additional controls will be necessary for any overexposed landscape worker, and that the majority of these workers will likely achieve the PEL when effective controls are implemented to reduce silica dust generated by the movement of material. As shown in Table IV.4.11-B, the highest result sampled was 66 μg/m^3. Based on this information, OSHA concludes that even a modest improvement in dust management will result in exposure levels less than the PEL of 50 μg/m^3 for most landscape workers most of the time.

The primary control for workers performing activities that could generate silica dust in the landscape industry is the implementation of wet methods. In a few instances workers may be able to use vacuums to clean up excess material; however, OSHA was unable to find information in the docket explaining the practicality of implementing this control due to the mobile nature of the industry.

Additionally, exposures will be reduced by the implementation of outdoor work practices such as positioning the workers away from or downwind from dust sources.

Wet Methods

Wet methods for dust control during landscape work include spraying silica-containing materials with water before moving them with shovels, brooms, rakes or other hand tools; adding water sprays to mechanized equipment such as plate compactors; wetting material when equipment is used; and ensuring sand, soil and aggregate remain damp while working with it. Wetting the material reduces exposure to respirable crystalline silica by preventing the fine particles mixed with the aggregate from becoming airborne (Document ID 1365, pp. 3-10, 13-19, 19-22). As discussed below, OSHA expects that wet methods can control silica dust exposures for most landscaping activities like sweeping, excavating soil, and compacting aggregates and similar products with minimal water usage.

In a study on using water for dust control in the mineral processing and mining industry, NIOSH discusses the use of water spray systems, explaining that when using sprays, one of the primary considerations is the droplet size and for optimal dust capture, the particle and water droplet sizes should be roughly equivalent. NIOSH explains that when wetting bulk material to achieve airborne dust prevention, droplet sizes above 100 micrometers (μm) (preferably 200 to 500 μm) should be used. However, for airborne dust suppression, where the goal is to knock down existing dust in the air, the water droplets should be in similar size ranges to the dust particles. To achieve this, droplets in the range of 10 to 150 μm have been shown to be most effective. For dust particles in the respirable range this equates to a finely atomized water spray ranging from a thin fog to a mist (Document ID 1540, pp. 63-64). This is confirmed by industry representatives for dust suppression, Bartell and Jett, who state that wet methods where droplet size matches the diameter of the respirable dust is the most effective use of sprays and results in minimal water usage (Document ID 0548, pp. 1-2). Bartell and Jett further explain that droplet size is important because too large droplets can lead to over wetting, resulting in problems with material consistency and equipment without improving dust capture efficiency (Document ID 0548, pp. 1-2).

In its discussion of wet spray systems, NIOSH states that in most cases, a properly designed spray system using finely atomized water sprays will not exceed 0.1 percent moisture application. NIOSH does note that systems that address prevention over larger areas with larger droplet sprays may add up to 1.5 percent moisture to the process (Document ID 1540, p. 61). While this study addresses dust control on a larger scale than that typically seen during landscape work, due to the similar properties of the material, the same concept can be applied to these worksites. Hoses and sprays which optimize dust capture will result in minimal water consumption and added weight to the materials while being moved. In addition, OSHA has determined that using wet methods during the unloading of bulk materials (i.e., decorative gravel, crushed granite and sand) at the jobsite will help control the exposures of workers present by minimizing fugitive dust.

Nij et al. (2009) studied dust control measures in the construction industry in the Netherlands for activities similar to the movement of material often done by landscape workers. The study included six workers who were sweeping and clearing rubble on the work site (Document ID 2347, Attachment 5). A total of 12 PBZ respirable silica samples were collected for 6 workers with sample durations of 6.5 hours or more. The samples ranged in value from 1.6 μg/m^3 to 97 μg/m^3 and had an arithmetic mean of 32 μg/m^3 and a geometric mean of 17 μg/m^3 (Document ID 2347, Attachment 5, p. 214). Nij found that the effect of spraying water to control respirable dust varied widely when sweeping, resulting in total respirable dust reductions of 12 to 99 percent (Document ID 2347, Attachment 5, p. 215), and determined that wet dust suppression during sweeping required proper wetting in order to be the most effective.

The tools and methods used for site cleanup and clearing rubble on construction sites in the Nij study are similar to tasks in the landscape industry involving the movement of material. In both industries, workers sweep, shovel, and scoop material to relocate it; however, in landscaping, workers may additionally use these tools to place and spread materials over large areas. Although it is not certain how much of the work involved the movement of sand, rock, and soil in the Nij study, workers on site were using power tools to cut, chip, drill, and saw concrete, lime sandstone, breeze block, and mortar, all of which contain silica. OSHA assumes therefore that laborers onsite were working with those materials as well (Document ID 2347, Attachment 5, pp. 212, 214).[73] OSHA concludes that the exposures in the Nij study would be equivalent to or higher than those experienced by a typical landscape worker due to the higher silica content of the materials (concrete, lime sandstone, breeze block, and mortar) described in the study when compared to the material generally found in landscaping.

Beaudry et al. (2013) also noted the importance of using wet methods when sweeping, transporting and handling materials to reduce exposures (Document ID 3797, p. 25). In light of the lower levels of silica found in soil, OSHA also expects that the controls Nij et al., studied for reducing the silica exposure for these workers would have similar results

[73] Breeze block is a highly cellular material made form quartzite, lime, and water (Document ID 2347, Attachment 5, p. 212).

in controlling exposures in landscaping if properly implemented, reducing levels to below the PEL (Document ID 3797, p. 87).

Before hardscapes can be installed, the ground must be properly prepared to prevent settling and to minimize cracking and deterioration of the structure. Preparation typically involves excavation of soil to ensure the surface is level, the placing of sand or aggregate base, and the compaction of the sand or aggregate base to ensure a stable foundation for the hardscape. However, as explained above in the Exposure Profile and Baseline Conditions section, soil excavating will usually be done with damp soil which results in less airborne dust (Document ID 3589, Tr. 4397).

The next step in the process, placing and compacting aggregates, is typically done with plate compactors of varying sizes. The amount of silica dust created can be controlled by wetting the aggregate. Care must be taken, however, to assure that the water added does not exceed the optimum moisture content for compacting aggregate and make it impossible to achieve the necessary density level required for a stable base required by many construction specifications as well the ICPI recommendations (Document ID 2246, p. 9). Placing bedding sand would be similar to placing aggregate, and water could be used to help control dust so long as the bedding sand does not become too wet, making it unworkable (Document ID 2246, p. 9).

Based on the information in this analysis, OSHA concludes that when properly implemented, water is an effective control to reduce silica dust exposure when compacting aggregate; however, employers will need to adjust the flow of water and droplet size based on the specifications of the project. In addition, employers will need to train workers to observe dust release and adjust the flow rate or spray direction to maximize visible dust control and minimize dust. Workers must also be trained to observe the spray quality (its effect on visible dust) and stop work to clean or replace a nozzle that becomes clogged.

As explained above, to optimize the effectiveness of water sprays, water droplets the same size as the dust particles should be sprayed at the dust emission point. With this approach, the least amount of water possible can be used while remaining effective, and allow proper management of the water supplied and eliminated (Document ID 3797, p. 23).

Brouwer et al. (2004), conducted a field study to investigate the effectiveness of the atomization of water as a method for dust control during the use of plate compactors while compacting soil. The study was conducted using two types of compactor: a light weight, flat plate compactor and heavy weight, V-plate type (Document ID 4157, p. 70). Thirty-minute samples were taken with and without automated water sprays while soil was compacted in an enclosed hall (Document ID 4157, p. 70). Both compactors were equipped with flat spray nozzles on each side (4 total) and the water flow rate was set at 1 liter per minute (L/min), resulting in approximately 0.23 L/min going to each spray nozzle (Document ID 4157, p. 70). The study was performed on six separate days over four weeks with a total of 16 samples taken. Exposures for the light weight compactor range from an 8-hour TWA of 150 μg/m^3 to 790 μg/m^3 without the use of the automated water sprays, and below the limit of quantification (LOQ) of 20 μg/m^3 to 169 μg/m^3 with atomization (Document ID 4157, p. 70). For the heavyweight plate compactor, exposures range from 110 μg/m^3 to 400 μg/m^3 without automated water sprays and 80 μg/m^3 to 250 μg/m^3 with the addition of water sprays (Document ID 4157, p. 70).

The researchers attribute the elevated uncontrolled exposures on the light weight type compactor to the operator's location, which was closer to the device compared to the heavy weight compactor. In addition, the light weight compactor had a higher beat frequency (heavy beat frequency 1300-2100 b/min versus light beat frequency of 3000 b/min), which generated more dust (Document ID 4157, p. 72). Switching the atomization resulted in a significant reduction of silica concentrations for the light weight contractor but not for the heavy weight type. Visual observations during the study revealed a higher coverage of the spray generated by the nozzles located at the front of the light weight type compactor compared to that of the heavy weight type (Document ID 4157, p. 72). The authors note that the atomization devices used in this study were prototypes and the location of the spray nozzles needed to be optimized (Document ID 4157, p. 73). OSHA concludes that adjustments to the location of the nozzles, droplet sizes, and initial velocity of the droplets generated might increase effectiveness of the atomization, resulting in exposure levels below PEL.

Unlike the Brouwer study conditions, which were conducted inside, in landscaping, compacting is done outdoors (Document ID 4157, p. 70). Outdoors, the air movement allows natural dispersion of the silica dust and lower exposures. Based on the Brouwer study demonstrating exposure reductions of up to 88 percent when compacting soil indoors, likely improvements in water atomization as well as additional available control measures like equipment-mounted local exhaust ventilation (LEV), OSHA concludes that silica-dust exposures can be feasibly reduced during most compacting activities to below the PEL most of the time.

OSHA acknowledges, however, that there are landscaping activities like installing certain types of paver systems where wet methods are not available. The ICPI stated that many paver system projects use joint sand stabilizers to help secure the sand in the paver joints so neither adding water or a dust reducing sweeping compound are options (Document ID 2246, p. 10). David Smith on behalf of ICPI explained that these stabilizers are generally polymer substances in the acrylics family that are activated with water (Document ID 3598, Tr. 4400-4401). The pavers are laid and then sand, together with a polymer substance, is swept into the joints. A very light spray of water on the surface activates the polymer materials causing the sand to stiffen. This is done to prevent erosion of the sand from between the pavers. He further explained that it is not possible to dampen the sand-polymer mixture before sweeping it into the paver joints because the material becomes sticky and adheres to the surface (Document ID 3598, Tr. 4400-4401). In his written comment, Charles McGrath with the ICPI stated that preparing a paver surface for hydrating joint sand is typically done by blowing dust off the surface using a leaf blower (Document ID 2246, p. 10).

OSHA acknowledges the concern ICPI has with wetting sand and understands that there are instances when wet methods for reducing silica dust exposure may not be implemented. Based on the frequency and duration of those tasks, the Agency believes that there are alternate control exposures that can be implemented to reduce exposures to below the PEL through the use of ventilation and/or work practice controls as discussed under the headings Ventilation and Work Practice Controls and Alternate Processes, below in this subsection.

Ventilation

Beaudry suggests that in cases where water cannot be used due to operational considerations, or when cracked materials or rough surfaces are present, the use of an industrial vacuum with a high efficiency filter for clean-up can reduce exposures (Document ID 3797, p. 25). Nij showed that the use of vacuums in lieu of sweeping resulted in total respirable dust exposure reductions of 84 to 99 percent (Document ID 2347, Attachment 5, p. 215). OSHA anticipates that respirable silica dust would be comparably reduced as well. LEV in the Landscaping Services industry would primarily consist of vacuums to clean up dirt and debris from the worksite instead of sweeping. Vacuuming collects dust particles before they become airborne while using compressed air or blowers causes these particles to become airborne, increasing the potential for greater exposures.

In their written comments, the ICPI stated that "[s]ome tasks such as compacting pavers cannot use vacuum devices to reduce exposures." He explained that vacuuming the sand is not an option as it typically removes the sand from the joints with the dust from the surface (Document ID 2246, p. 10). As previously noted, Warren Quinn with the American Nursery and Landscape Association stated that sand cleanup activities are typically done with mechanized blowers and vacuums rather than push brooms (Document ID 0961). OSHA acknowledges that vacuums may not be feasible under the circumstances described, but where this option can be implemented; its use can effectively reduce exposures.

Work Practice Controls and Alternate Processes

Work practices such as limiting the number and location of workers around the movement of material or when compacting sand and aggregate can reduce exposures to workers during these activities. OSHA expects that work practice controls can be implemented in all but the most challenging circumstances. Good work practice controls include training workers to stay upwind of dust sources and avoid dust clouds, which may indicate the presence of airborne respirable silica dust. Workers should move around the work site and position themselves away from the dust source. Although no quantitative exposure reduction data exist regarding worker positioning in relation to dust created by landscape activities, OSHA concludes based on general industrial hygiene principles that exposures will be reduced when workers do not position themselves within or downstream of silica-containing dust clouds.

Another control for reducing exposure to silica during the installation of hardscapes is the use of layouts and designs that do not require or that minimize cutting, and the use of mechanical splitters to score and snap pavers. In addition to reducing exposures for those workers who operate the saws, this control reduces dust emissions on the worksite, lowering the secondary exposures of other workers in the area.[74] Curb blocks and pavers used in the landscape industry are available in a variety of shapes and dimensions, and patterns can be chosen that eliminate the need for cutting. Manufactured half blocks or closure units can be used in place of cut block and smaller blocks can be used to fill in spaces around obstacles or edges (Document ID 3756, Attachment 6, pp. 4 and 7). Mechanical block splitters are available for snapping pavers, and they do not create excessive dust (Document ID 3756, Attachment 6, p. 6). Mechanical block splitters do not require the use of water for dust suppression, which may make them easier to use on remote locations or in subfreezing temperatures. Some block splitters may not accommodate larger pavers or flag stones used in hardscape installation, and saws with water for dust suppression will still be necessary (Document ID 3756, Attachment 6, p. 8).

4.11.4 Feasibility Finding

Based on the exposure profile in Table IV.4.11-B and other record evidence discussed above, OSHA finds that the standard is technologically feasible for most landscape workers most of the time when baseline and additional controls previously discussed are

[74] Controlling exposures for those workers who use saws to cut brick, block and pavers through the use of wet methods and local exhaust ventilation (LEV) is discussed in Sections IV-5.6–Masonry Cutters Using Potable Saws and IV-5.7–Masonry Cutters Using Stationary Saws.

used. As previously noted, workers cutting silica-containing landscaping materials when installing hardscapes such as retaining walls, patios, and walkways make up a minor portion of the industry's labor time; only a small share of the industry is engaged routinely in the installation of hardscapes where block and brick cutting operations occur. OSHA determined that firms that generate a majority of their revenue from this type of work are classified as construction, and this determination was not disputed. Moreover, and importantly, the exposures from block and brick cutting are well controlled by the controls described in Section IV-5.6 – Masonry and Concrete Cutters Using Portable Saws. A further discussion of the processes, exposure levels, conditions, and silica dust control options available for workers performing these activities are discussed in that section.

Accordingly, OSHA concludes that most of the workers in the landscaping services industry already experience exposures lower than the PEL of 50 μg/m^3, most of the time. OSHA has determined that landscape service workers face less frequent exposures than workers engaged in construction activities involving the movement of concrete rubble, stones, sand, and other materials. This is due in part to the generally low silica content of soil, the smaller scale of the jobs using less mechanized machinery than similar tasks in the other industries, and the infrequent nature of landscaping work that produces respirable silica.

Where workers currently experience exposure levels above 50 μg/m^3, additional controls to reduce exposures below the PEL include increased attention to the rate and position of water used for wet dust suppression; using work practices that position the worker away from the dust; and controlling silica exposure from adjacent sources. While the use of vacuums might reduce silica exposures substantially, OSHA acknowledges that currently they have limited applicability in the landscape industry.

Davis Landscape commented that they believe it would be "exponentially more difficult to meet the proposed PEL of 50 μg/m^3" (Document ID 2383, Attachment 4). OSHA does not agree. The exposure information available to the Agency demonstrates that the majority of workers are already experiencing exposures below 50 μg/m^3. As demonstrated in this section for the few remaining workers with higher exposures, there are available controls that if implemented will result in material reductions in exposures.

The exposure profile in Table IV.4.11-B shows 72 percent (5 out of 7 samples) of samples already at or below the PEL of 50 $\mu g/m^3$. No evidence contradicting or supplementing these data were entered into the rulemaking record. Accordingly, OSHA concludes that most landscape workers are currently exposed to silica levels below 50 $\mu g/m^3$. For workers who are currently exposed above 50 $\mu g/m^3$, the engineering and work practice controls described in this section can be implemented to reduce silica exposure levels to 50 $\mu g/m^3$ or less in most operations, most of the time. Therefore, OSHA finds that the final PEL of 50 $\mu g/m^3$ is technologically feasible for the Landscaping Services industry.

4.12 MINERAL PROCESSING

4.12.1 Description

The nonmetallic mineral processing industry includes those establishments that are primarily engaged in the processing of minerals, including clays, ceramic and refractory minerals, barite, slag, roofing granules, sand, and other nonmetallic minerals. These processes include calcining (processed by burning or incinerating), dead burning (calcining (as a carbonate rock) at a higher temperature and for a longer time), or otherwise post-mining processing beyond beneficiation, as defined by the North American Industry Classification System (NAICS) 327992, Ground or Treated Mineral and Earth Manufacturing and 327999, All Other Miscellaneous Mineral Products.[75] This industry includes facilities that batch, blend, extrude, and package dry and de-aired moist clays. Many of the raw materials processed by this industry contain varying amounts of naturally occurring silica and include nonmetallic minerals such as clay, diatomaceous earth, graphite, and mica (Document ID 1365, p. 20-1).

Similar processes occur infrequently in other industries besides nonmetallic mineral processing such as 325314, Fertilizer (Mixing Only) Manufacturing and 339999, All Miscellaneous Manufacturing. However, OSHA has determined that these types of activities are limited in occurrence and the potential for exposure to respirable crystalline silica in these industries is uncommon. Nonetheless, samples from NAICS codes 325314, Fertilizer (Mixing Only) Manufacturing, and 339999, All Miscellaneous Manufacturing, were included in the exposure profile for the mineral processing industry because OSHA determined that, at the time of sampling, the workers were performing tasks that were very similar to the tasks performed in the this industry (Document ID 3958).

[75] Beneficiation is the process whereby the extracted material is reduced to particles that can be separated into mineral and waste; it is considered a mining activity and is, therefore, not regulated by this rule (Document ID 1720, p. IV-225).

The nonmetallic mineral processing industry produces intermediate or finished products from mined or quarried nonmetallic minerals.[76] Depending on the specific establishment, production workers might perform one or more jobs with the potential for exposure to respirable crystalline silica, including loader/material handler; operator of equipment like the crusher, screener, batch, mixer, and dryer; bagger; laborer; or housekeeper. The activities and equipment used by workers also can vary by facility depending on whether operations are performed manually or by fully automated systems. Consequently, job function and associated exposure to silica varies by establishment (Document ID 1365, pp. 20-2 – 20-4). Table IV.4.12-A presents a summary of the primary activities associated with silica exposure of workers in this industry.

Several stakeholders and trade associations, including the National Industrial Sand Association (NISA), International Diatomite Producers Association (IDPA), Industrial Minerals Association - North America (IMA-NA), National Stone, Sand & Gravel Association (NSSGA), and SMI, stated that most of their facilities fall under the jurisdiction of the Mine Safety and Health Administration (MSHA) and not OSHA, with OSHA only having jurisdiction over a small number of facilities involved in the blending, product assembly, and packaging of minerals (Document ID 3577, Tr. 560, 618; 3583, Tr. 2287; 2101, p. 3; 2179, p. 1; 2294; 2312, p. 1; 2377, pp. 1-2). As stated in a footnote on MSHA jurisdiction (see previous page), OSHA recognizes that those mining and extraction operations are regulated by MSHA, and this OSHA standard only applies to post-mining operations within the nonmetallic mineral processing industry over which MSHA does not exercise jurisdiction.

[76] The Mine Safety and Health Administration (MSHA) has jurisdiction, which it has exercised, over the mining and extraction of nonmetallic minerals, up to and including beneficiation. Consequently, pursuant to 29 U.S.C. 653(b)(1), OSHA does not have jurisdiction over those operations. This rule applies only to operations within the nonmetallic mineral processing industry that are outside MSHA's exercise of jurisdiction.

Table IV.4.12-A Job Category, Major Activities, and Sources of Exposure of Workers in the Mineral Processing Industry (NAICS 327992, 327999)	
Job Category*	**Major Activities and Sources of Exposure**
Production Worker	Dumping dry materials. • Dust generated during manual breaking and dumping of dry materials. • Dust generated by disposal of empty bags. Transferring, mixing, and packaging dry materials. • Dust from transferring or processing dry materials (e.g., with conveyors, elevators, mixers, blenders, screeners). • Dust from manual mixing or packaging of dry materials. Performing housekeeping duties. • Dust raised by using inappropriate cleaning methods (e.g., dry sweeping, shoveling).

4.12.2 Exposure Profile and Baseline Conditions

Exposure Profile and Baseline Conditions for Production Workers

The exposure profile in Table IV.4.12-B incudes 33 full-shift, personal breathing zone (PBZ) exposure samples for production workers in the general industry category of mineral processing. The median exposure is 26 μg/m^3, the mean is 39 μg/m^3, and the range is 12 μg/m^3 to 221 μg/m^3. Table IV.4.12-B shows that, of the 33 samples, 7 (21.3 percent) exceed 50 μg/m^3, and 2 (6.1 percent) exceed 100 μg/m^3.

The samples included in Table IV.4.12-B come from two sources: an OSHA Special Emphasis Program (SEP) inspection report on a facility using mineral raw materials to mix the clays it provides to the pottery industry (Document ID 0108) and a NIOSH Health Hazard Evaluation (HHE) report on a manufacturer producing mineral granules for eventual use by the roofing tile industry (Document ID 1377). Additionally, OSHA Information System (OIS) health sampling data were submitted to the rulemaking record for inclusion in the exposure profile (Document ID 3958). The data and information from these sources provide the basis for the final exposure profile for mineral processing production workers.

The highest exposure of 221 μg/m^3 in Table IV.4.12-B is from an OSHA SEP inspection of a clay manufacturing company for ceramic and pottery clay products where there were noted several issues with dust control. A worker who spent a portion of the shift dumping bags of dry silica-containing material at this station, and spent the remaining portion dry sweeping, experienced the exposure. During the inspection, the dustiest operation OSHA observed was breaking and dumping bags of raw materials into a hopper on an elevated work platform. Although the hopper was partially enclosed and ventilated, the task produced substantial amounts of dust (Document ID 1365, p. 20-7; 0108, pp. 45-49, 64-83).

Two additional workers near the bag dumping station had exposure levels of 80 μg/m^3 and 83 μg/m^3. These workers ran the clay batch operation, which involved dry sweeping, packaging dry product, and moving bags of raw material with an open lift truck. OSHA also noted that product bag-filling areas did not have local exhaust ventilation (LEV) during the inspection, but that mixing and blending containers, and material conveyors and elevators, were enclosed (Document ID 0108, pp. 45-49, 64-83; 1365, p. 20-7).

Following the inspection, the facility made several improvements to its engineering controls including: the installation of ventilated bag-disposal hoppers; a new LEV system with a commercially available dust collector for dry batch operations; improvements to existing LEV ductwork and hoods to improve capture efficiency and exhaust flow; and the addition of high-efficiency particulate air (HEPA) after-filters for two existing dust collectors (Document ID 0108, pp. 137-139, 155-165). After the engineering improvements were completed, three full-shift PBZ follow-up exposure levels were reported at less than 31 μg/m^3 (limit of detection (LOD)), 26 μg/m^3 and 44 μg/m^3 (Document ID 0108, pp. 155-165; 1365, p. 20-8).

NIOSH conducted an HHE at a company that produces roofing granules from nepheline-syenite[77]. The facility processes the raw material into uniform-sized granules by using a system of crushers and production screeners. The granules are then transported by

[77] Although NIOSH indicated that nepheline-syenite is reported to not contain silica, two bulk samples collected during the course of the NIOSH investigation contained 1 to 2 percent silica (as cristobalite). Cristobalite had an existing PEL of 50 μg/m^3.

conveyor to the coloring department where the product is colored, heat cured, and transferred to storage silos (Document ID 1365, pp. 20-2 – 20-3; 1377, p. 2). Six full-shift PBZ samples were collected during the initial visit. Three of those six samples exceeded 50 μg/m^3.[78] A helper in the crushing and screening department who performed general cleaning within the department and assisted with screen changing had the highest exposure at 111 μg/m^3. Two other workers in the crushing and screening department experienced exposures of 58 μg/m^3 (Document ID 1377, pp. 3, 10, PDF 62; 1365, pp. 20-7 - 20-10; 1720, p. IV-227).

Although most processes and conveyors were enclosed, NIOSH investigators observed process leaks and poor housekeeping practices (e.g., piles of dust located throughout the facility) that could expose workers to silica-containing dusts. NIOSH also noted that its monitoring data might not be representative of typical worker exposures at the plant because of upset conditions created by a power failure. Plant management reported that dust concentrations were higher than normal (Document ID 1377, p. 11; 1365, pp. 20-10 - 20-11).

Documents submitted to the rulemaking record indicate that this industry recognizes the need for and uses controls to reduce silica exposures. NISA submitted a copy of its Silicosis Prevention Program (SPP) Guide (Document ID 2195, Appendix A). The guide outlines the seven steps set forth in NISA's SPP to eliminate silicosis among its workforce, including implementation of dust control equipment or processes. During the public hearings, Andrew O'Brien with Unimin Corporation, a NISA member company, stated that "the SPP encourages NISA member companies to undertake a program to anticipate, recognize, evaluate, and control hazardous dust exposures, and to continually monitor the effectiveness of control strategies. It emphasizes that the control of hazards from exposures to respirable crystalline silica and the elimination of silicosis is the primary and single most important reason for developing a comprehensive silicosis prevention program" (Document ID 3577, Tr. 571). NISA

[78] All of the samples which exceeded 50 μg/m^3 contained cristobalite, a type of RCS which forms at the high temperatures associated with mineral processing. When cristobalite was identified in a sample, values were added to the quartz levels to create a total silica result.

recommends that its members implement and manage a comprehensive SPP (Document ID 2195, p. 5). It has received a formal commitment to do so from 15 of its 31 member companies (Document ID 2195, pp. 10-11 n. 12).

The NSSGA submitted a copy of its Occupational Health Program, including the Silica & Dust Control module, to the docket (Document ID 2195, Appendix B). The contents of the silica module include: General Approaches to Silica Exposure Control; Engineering Controls; Work Task Controls; Administrative Controls; Personal Protective Equipment; and Web and Print Resources (Document ID 4026, p. 3). The NSSGA stated that many of its members have been successfully using the Occupational Health Program for decades to measure and control silica exposures (Document ID 2327, Attachment 1, p. 3).

Additionally, the IDPA submitted a copy of the IDPA's Safe Handling Guide to the docket (Document ID 4002, Attachment 3), which provides guidance to diatomite distributors and end users regarding the benefits of engineered ventilation controls, safe work practices, and respiratory protection programs for reducing exposure (Document ID 3577, Tr. 617-619). Although the guide is very general in nature, it shows that the industry recognizes the importance of effective controls for reducing exposure and it supports OSHA's conclusions that these controls are available and can be used to describe baseline conditions in the industry.

Several commenters explained that there is an increasing trend toward automation "of processes that historically were conducted manually" (Document ID 2195, p. 20). Stated another way, "It is not uncommon now * * * for a handful of employees working in a central control room (with a conditioned environment) to perform the tasks previously undertaken by a large crew that was deployed across vast operating areas" (Document ID 2327, Attachment 1, p. 7). Commenters stated that viewing equipment and production processes from a control room, along with automated conveyor systems and mechanical screen vibrators, reduce human intervention and potential dust exposures (Document ID 2327, Attachment 1, p. 7).

Michael Johnson with NSSGA stated, "With respect to the trend of increasing automation in aggregates facilities, the more modern conveying and screening equipment includes designs to reduce maintenance requirements in general and the time it takes to perform maintenance operations. These improvements reduce the opportunity for dust exposures among maintenance and other plant employees" (Document ID 4026, pp. 3-4).

Although not included in the exposure profile because working conditions were not described, the Sorptive Mineral Institute submitted sampling results from 23 production facilities[79] to the rulemaking record (Document ID 4010, pp. 12-18).[80] These samples were taken during MSHA inspections between 2009 and 2014 in accordance with MSHA protocol. The samples were reported using 8-hour time weighted averages (TWA) (Document ID 4010, p. 3). Appendix 2, beginning on page 12, contains 54 samples for Bagging/Packaging workers, with an average exposure of 34 μg/m^3; 11 of those samples were above 50 μg/m^3. There were 32 samples for Kiln/Dryer operators, with an average exposure of 20 μg/m^3; only one sample of 228 μg/m^3 was above the PEL (Document ID 4010, pp. 3, 12-18). While these samples were taken at processing facilities on mine sites, which are not under the jurisdiction of OSHA and sorptive minerals are outside the scope of this final standard, the processes are similar to those in non-mining operations with the scope of the standard. Accordingly, the Agency finds that these data support the conclusion that the PEL of 50 μg/m^3 TWA can be achieved for mineral processing production workers most of the time and can be viewed as showing a representative range of baseline exposures.

During the public hearings, Andrew O'Brien from the Unimin Corporation discussed current exposure among NISA companies and controlling worker exposure to levels below 50 μg/m^3 TWA. Mr. O'Brien stated that "within Unimin, we have an internal target of 50 μg/m^3 for a time-weighted average. And we control to at least below that in order to ensure the lowest likelihood of exceeding 100" (Document ID 3577, Tr. 597). When there is a single exposure above 50 μg/m^3, it conducts a root cause analysis "to

---

[79] The Sorptive Mineral Institute (SMI) submitted two separate post hearing briefs to the docket (Document ID 4230; 4010). Appendix 2 of Document ID 4010 included an Excel spreadsheet containing sample data for 23 facilities identified by separate Mine IDs assigned by MSHA. Conflicting information was included in Document ID 4230 on page 8 where SMI states data were collected by 36 SMI mining and processing facilities.

[80] Note that sorptive clays are not included in the scope of this rulemaking, as stated in the regulatory text.

identify what may or may not have contributed to that exposure and to determine whether any corrective actions can be taken to bring exposures back down below the 50" (Document ID 3577, Tr. 598-599). He further added that current exposures are "well below the PEL (of 100 µg/m^3). In fact, well below 50 µg/m^3" (Document ID 3577, Tr. 605).

Mark Ellis, representing the IMA-NA and NISA, stated that "by and large, the members have to control below 50 µg to reliably be below 100 µg where the existing PEL is" (Document ID 3583, Tr. 2322), indicating that many facilities already experience exposures below 50 µg/m^3.

Changes to the Exposure Profile

OSHA made a number of revisions to the exposure profile for Mineral Processing production workers that was presented in the PEA, resulting in the final exposure profile shown in Table IV.4.12-B.

OSHA removed 22 PBZ samples included in NIOSH HETA 91-0091-2418. NIOSH had reported these samples as below the NIOSH recommended exposure limit (REL) of 50 µg/m^3 as an 8-hour TWA. Although NIOSH noted that "most" exposures were below LOD of 20 µg/m^3, the report did not specify how many (Document ID 1377 (p. 10 of Report); 1720, p. IV-227). For all 22 NIOSH samples removed, OSHA had taken the most conservative approach and used an exposure of 50 µg/m^3 in the PEA exposure profile (Document ID 1720, p. IV-227). In the final exposure profile, the Agency has decided to rely on the more precise sample results provided for this industry by OIS.

OSHA added 21 samples from the OIS database to the exposure profile with a range of 12 µg/m^3 to 63 µg/m^3. Nine of the samples added to the profile were below the LOD and were assigned a value of 12 µg/m^3 as described in Section IV-2 – Methodology. Only one sample, which was for a worker in the mixing room of an abrasive product plant, had a result over 50 µg/m^3. General ventilation was used, but no other controls were in place. Worker job titles for the additional OIS data include bagger/blender, mixer/mixing room operator, grinder, soil worker, and maintenance and forklift operator (Document ID 3958).

Nine of the 21 samples came from NAICS codes that are not described as nonmetallic mineral processing. Five samples came from NAICS 325314, Fertilizer (Mixing Only) Manufacturing and the remaining 4 came from 339999, All Miscellaneous Manufacturing. OSHA has included these samples in the exposure profile for Mineral Processing because at the time of sampling, these workers were performing tasks similar to those performed by workers in the mineral processing industry, including blending, bagging, and moving sand (Document ID 3958).

No additional exposure sampling data containing sufficient information as outlined in Section IV-2 – Methodology, were submitted to OSHA for inclusion into the final technological feasibility analysis for mineral processing production workers.

The removal of the 22 NIOSH data points and the addition of the 21 OIS data points resulted in no change to the range of exposures for nonmetallic mineral processing production workers, which remain from 12 μg/m^3 to 221 μg/m^3. The mean exposure declined from 50 μg/m^3 to 39 μg/m^3 and the median declined from 50 μg/m^3 to 26 μg/m^3. In the final exposure profile for this industry, 78.8 percent of the samples (26 out of 33) are below 50 μg/m^3; of the 21.2 percent of samples (7 out of 33), 5 (15.2 percent) are between 50 μg/m^3 and 100 μg/m^3 and 2 (6.1 percent) are over 100 μg/m^3 but below 250 μg/m^3.[81]

Exposure Profile and Baseline Conditions

Based on a review of the available information in the record, OSHA finds that while some facilities may have automated operations and facilities, many do not. Although often the inspector performing the OIS inspection indicated whether there was general and local exhaust ventilation, there were no references to automation. OSHA therefore assumes that automatic controls are not represented in the final exposure profile. Baseline conditions at typical facilities therefore include some form of exhaust ventilation and process enclosures, although these controls might be inadequately maintained and function inefficiently. OSHA concludes that the exposure profile in Table IV.4.12-B is

[81] Without the data OSHA included from NAICS codes 325314 and 339999, the exposure profile would have a mean of 65 μg/m^3. The range of exposure would remain unchanged.

based on the best available data and best represents baseline conditions for production workers in the mineral processing sector of general industry (i.e., excluding mines covered by the Mine Act).

Table IV.4.12-B Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Mineral Processing Industry (NAICS 325314, 327992, 327999, 339999)											
	Exposure Summary			Exposure Range			Exposure Profile				
Mineral Processing Industry	**N**	**Mean (µg/m^3)**	**Median (µg/m^3)**	**Min (µg/m^3)**	**Max (µg/m^3)**		**<25 (µg/m^3)**	**≥25 and ≤50 (µg/m^3)**	**>50 and ≤100 (µg/m^3)**	**>100 and ≤250 (µg/m^3)**	**>250 (µg/m^3)**
Production Worker (Before engineering improvements)	18	42	22	12	221		10 (55.6%)	4 (22.2%)	3 (16.7%)	1 (5.6%)	0 (0%)
Production Worker (With engineering controls)	9	21	15	12	44		6 (66.7%)	3 (33.3%)	0 (0%)	0 (0%)	0 (0%)

4.12.3 Additional Controls

The exposure profile in Table IV.4.12-B shows that 21 percent (7 out of 33 samples) of production workers in general industry mineral processing facilities have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Appropriate control options include equipping existing bag-dumping stations with well-ventilated enclosures and ventilated bag-disposal equipment; modifying and/or improving maintenance to existing process equipment enclosures and LEV to ensure optimal dust control; and using more diligent housekeeping, in association with low dust producing cleaning methods (i.e., HEPA-filtered vacuuming and wet methods), to reduce dust accumulation.

Local Exhaust Ventilation

The highest exposure level in the industry profile (221 μg/m^3) is associated with bag-dumping and disposal operations at a ceramic and pottery supply company (clay manufacturer). Exposure was reduced by about 80 percent to 44 μg/m^3 after this establishment made engineering improvements to its dry batch operations (Document ID 1365, pp. 20-3—20-8; 0108, pp.137-147, 155-165). Exposure levels for two other workers in the production area of the clay manufacturer were also reduced after the engineering improvements. Full-shift PBZ exposure results for the two workers were initially 80 μg/m^3 and 83 μg/m^3. After improvements were made to control dust from the bag-dumping station and other dry batch process equipment, exposure levels were less than the LOD (in this case 31 μg/m^3) and 26 μg/m^3 (Document ID 1365, pp. 20-5—20-9; 0108, pp. 157-163).

For those facilities with exposures above 50 μg/m^3, LEV that can effectively control dust released during bag opening, emptying, and disposal as reflected above, will need to be installed. This includes ventilated bag disposal hoppers and ventilation systems with dust collectors that service the bag dumping and disposal hoppers, and other dry batch processing equipment (blenders and elevators) (Document ID 1365, pp. 20-15—20-16).

Where further reductions are needed, the addition of HEPA after-filters to dust collectors may improve capture efficiency and exhaust flow, further reducing exposures.

Additionally, installing wet dust collectors intended to remove particles from ventilated air, and internal water sprays, have been shown to reduce exposure (Document ID 1365, pp. 20-15—20-16).

Process Enclosure and Maintenance

Properly enclosed, ventilated, and maintained process equipment (e.g., conveyors, elevators, mixers, blenders, screeners) is necessary to ensure low exposures to silica-containing dusts during material transfer and other process-related operations. OSHA has determined that proper process enclosure and maintenance include (1) implementing a preventive maintenance program to ensure that potential process-related leakage points are inspected and repaired before significant dust emissions occur; (2) designing and testing LEV systems to ensure they are functioning effectively; and (3) replacing process enclosures that are removed for inspection or maintenance purposes as soon as the work is completed to prevent significant (and unnecessary) releases of silica-containing dust into the workplace (Document ID 1365, pp. 20-16—20-18; 1720, p. IV-226).

Housekeeping

Poor housekeeping can contribute substantially to a worker's exposure levels. OSHA has determined that control options for production workers also include performing more diligent housekeeping and using low dust producing cleaning methods such as:

1) Implementing vacuuming as a cleaning method (as opposed to dust producing methods such as dry sweeping and shoveling). Sweeping with hand brooms has been observed to produce noticeable clouds of dust so the use of vacuums with HEPA filters is helpful in reducing dust levels generated during cleaning (Document ID 1365, p. 20-18);

2) Wet sweeping in areas where vacuuming is not practical. Wet sweeping includes the addition of moisture in the form of water or other suitable substances to help minimize the release of dust during cleaning (Document ID 1365, p. 20-20);

3) Implementing procedures that require routine cleaning of all surfaces, including floors, storage bins, and process equipment, and developing and enforcing a program to correctly handle product, contain spills, and perform clean-up (Document ID 1365, pp. 20-18—20-20).

NISA stated that sweeping is widely employed in the aggregates industry for cleaning durable surfaces such as roads, buildings, shop floors, and offices and that sweeping outside of buildings often requires wet-vac sweepers, although this is not always the case. It further acknowledge that sweeping is an important housekeeping activity that helps to maintain a safe working environment (Document ID 2327, Attachment 1, pp. 9-10). OSHA agrees that housekeeping is an important factor in reducing and maintaining lower exposures. Where dust accumulations are prevalent, a thorough cleaning in association with improved housekeeping procedures such as wet methods or vacuum cleaning, as discussed above, may be needed to reduce exposures (Document ID 1365, p. 20-18).

Comments Regarding Additional Controls for Production Workers

Several commenters expressed concern regarding the availability of controls and control implementation.

SMI felt that it was “unclear whether it is technologically feasible for the covered SMI facilities to comply with the Proposed Regulation. SMI members' preliminary analysis suggests that engineering controls may not be available to consistently reduce exposures to * * * the PEL and Action Level set forth in OSHA's Proposal” (Document ID 2377, p. 11). However, SMI did not provide any further detail on why the kinds of controls identified in the PEA would not be technologically feasible. OSHA, therefore, continues to believe that the best available evidence, including the previously described voluntary safe handling guidelines for large segments of the mineral processing industry, demonstrates the feasibility of the standard in this industry.

The National Mining Association (NMA) stressed the importance of properly designing, installing, and maintaining controls stating, “No matter how well you design and install a system, if it is not properly and adequately operated and maintained over time it is as unreliable as a poorly worn respirator” (Document ID 2211, p. 7). NISA stated, “Every work environment is unique so the most effective controls (singularly and combined) are often those designed specifically for the space, machinery, process flow, work schedule and other variables that differ from one work environment to the next.” NISA companies “continually monitor the effectiveness of control strategies” (Document ID 2195,

Appendix A, p. 12). OSHA concurs with both the NMA and NISA that controls must be properly installed in each individual workplace and then continually maintained to ensure their effectiveness in reducing exposures.

The NSSGA expressed concern regarding the introduction of new hazards into the workplace through the implementation of wet methods to the process. It commented, "Using water as a dust suppressant inside of structures such as a maintenance shops could increase electrical safety hazards and potentially violate OSHA electrical safety standards" (Document ID 2327, Attachment 1, p. 11). OSHA acknowledges that additional precautions, such as GFCI in accordance with 29 CFR 1910.304(b)(3) when needed to provide protection for employees, may be necessary when using wet methods around electrical equipment.

4.12.4 Feasibility Finding

Based on the exposure profile in Table IV.4.12-B, OSHA concludes that a substantial majority of the production workers in this industry (78.8 percent) already achieve exposure levels of 50 μg/m^3 or less through the use of process enclosures and ventilation and that the remaining 21.2 percent of workers who are overexposed will require additional controls to reach this level. Based on the other record evidence discussed above, however, OSHA finds that the standard is technologically feasible for most production workers in mineral processing facilities most of the time when baseline and additional controls previously discussed are used.

Evidence submitted to the docket shows that a significant number of facilities already routinely achieve exposures of 50 μg/m^3 or less through the use of engineering controls and work practices, including properly designed and maintained LEV and enclosures, and good housekeeping practices. In fact, the data show that where engineering controls are used the highest exposures experienced is 44 μg/m^3 versus 111 μg/m^3 during upset conditions (a power failure) when engineering controls were not operational.

OSHA received two comments regarding the feasibility of the PEL for the nonmetallic mineral processing industry. Michael Sheahan with Front Range Aggregates stated, "OSHA has underestimated the feasibility, achievability and economics associated with the proposed rule" (Document ID 2225, p. 2). NISA expressed support of the American Chemistry Council's (ACC) position that the proposed standard with a PEL of 50 μg/m^3 is not technologically feasible (Document ID 4208, pp. 3-4).

However, no data or specific information explaining why the rule was not technologically feasible for the mineral processing industry was provided by the ACC, NISA, or Front Range Aggregates. In fact, NISA and its members stated their ability to achieve exposures below 50 μg/m^3 on a consistent basis (Document ID 3577, Tr. 597, 605; 3583, Tr. 2322-2323).

For the reasons stated above, OSHA does not agree that worker exposure to less than 50 μg/m^3 is technologically infeasible for nonmetallic mineral processing facilities. The record evidence relied on by OSHA cited in this section demonstrates that, through the use of LEV, process enclosure and maintenance, and good housekeeping measures, exposures below 50 μg/m^3 can be regularly achieved. Industry data and evidence submitted to the docket support this finding.

Thus, OSHA concludes that most production workers at mineral processing facilities are currently exposed to silica levels below 50 μg/m^3. For workers who are currently exposed above 50 μg/m^3, the engineering and work practice controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or less in most operations, most of the time. Therefore, OSHA finds that the final PEL of 50 μg/m^3 is technologically feasible for the Mineral Processing industry.

4.13 PAINT AND COATINGS

4.13.1 Description

During the manufacturing of paints and similar products such as stains, powder coatings, glazing compounds, and vitreous enamels; ground quartz and cristobalite are often added for pigment and as a filler component. These products are manufactured by establishments classified in the six-digit North American Industry Classification System (NAICS) code 325510, Paint and Coating Manufacturing. Although the production of specialized vitreous coatings are described in Sections IV-4.14 – Porcelain Enameling and IV-4.15 – Pottery, specialized forms of coatings, glaze and enamels are relevant to the paint-manufacturing industry (Document ID 1720, pp. IV-233, IV-239 – 250, IV-251 – 274). OSHA estimates that one-third of this industry uses silica during paint manufacturing with less than 10 percent of the industry using silica in the form of cristobalite (Document ID 1720, p. IV-233).

OSHA finds that material handlers and mixer operators are the two job categories with the highest potential of exposure in this industry. OSHA's findings are based upon two OSHA Special Emphasis Program (SEP) inspection reports, records associated with two OSHA inspections reported in OSHA's Information System (OIS), and a site visit (Document ID 0105; 0199; 0943; 3958). The handling of powdered silica components, including mixing operations and housekeeping, are believed to create the greatest worker exposures. Table IV.4.13-A summarizes the job categories, major activities, and primary sources of silica exposure of workers in this industry.

There is no evidence of exposure for both material handlers and mixer operators once end products are packaged because they are in a liquid form. The American Coatings Association (ACA) noted in written comments that "[o]nce added to the finished paint or coating product, crystalline silica becomes part of a 'wetted mixture' of resin, pigment and solvent and would not, in and of itself, be considered 'respirable crystalline silica'" (Document ID 2239, Attachment 1, p. 1 (quotations in original)).

Table IV.4.13-A Job Categories, Major Activities, and Sources of Exposure of Workers in the Paint and Coatings Industry (NAICS 325510)	
Job Category*	**Major Activities and Sources of Exposure**
Material Handler	Oversee delivery of raw materials and their transportation through the facility. • Dust from open transferring of silica-containing raw materials (such as sand and clay) manually or by lift truck. • Dust from manual weighing of silica-containing materials. • Dust from sweeping, brushing (housekeeping).
Mixer Operator	Add wet and dry ingredients to milling, mixing, and dispersion equipment. • Dust from opening and manually emptying bags of silica-containing materials into hoppers. • Dust from manual weighing of silica-containing materials. • Dust from sweeping, brushing (housekeeping).
*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility. Source: Document ID 1365, Table 9-3 on p. 9-4.	

4.13.2 Exposure Profile and Baseline Conditions

Exposure Profile and Baseline Conditions for Material Handlers

The exposure profile in Table IV.4.13-B includes 11 full-shift personal breathing zone (PB) samples of respirable crystalline silica for material handlers in the paint and coatings industry. All 11 results for material handlers are below 25 μg/m³ (the median exposure is 12 μg/m³, the mean is 12 μg/m³, and the range is 10 μg/m³ to 13 μg/m³). The 11 samples come from 1 air sample result from an OSHA SEP Inspection, 3 results from OSHA OIS files, and 7 analytical results as part of a site visit conducted by the OSHA contractor Eastern Research Group (ERG). OSHA concludes that this exposure profile represents the baseline exposure for material handlers in facilities that use crystalline silica in this industry (Document ID 1365, pp. 9-6 – 9-8; 1720, Table IV.C-30 on p. IV-236; 3958).

Baseline conditions for material handlers include considerable manual handling of packaged and bulk raw materials, including powdered products. Manual handling of silica-containing materials can increase the exposure risk to material handlers but are mitigated by local exhaust ventilation (LEV). Exposure results were less than 12 μg/m³ (the limit of detection) when LEV was used to mitigate material handler exposure at a coatings manufacturing facility identified during the review of OSHA OIS files (Document ID 3958).

Exposure Profile and Baseline Conditions for Mixer Operators

The exposure profile in Table IV.4.13-B includes 12 full-shift PBZ samples for mixer operators in the paint and coatings industry. The median exposure is 13 µg/m³, the mean exposure is 89 µg/m³, and the range is 12 µg/m³ to 413 µg/m³. Table IV.4.13-B shows that, of the 12 samples, 3 (25 percent) are above 50 µg/m³, and those 3 also exceed 100 µg/m³. For the original exposure profile presented in the PEA, OSHA reviewed a total of 10 analytical results: 3 from two OSHA SEP Inspections and 7 air sample results as part of an ERG site visit (Document ID 1720, pp. IV-234-235). To produce the exposure profile in this FEA, OSHA added an additional 2 sample results for mixer operators from OSHA's OIS files (Document ID 3958).

One result of 263 µg/m³ is from a 447-minute sample associated with a mixer operator manually transferring raw materials (emptying 50-pound bags) during a period of ventilation system failure. At that manufacturing site, the plant-wide combination LEV and bag disposal system worked well for the first shift monitored but became clogged (reduced or no airflow) during the subsequent shift during which ERG obtained the elevated result. The other six results from this site were collected while the ventilation system was still functioning and resulted in exposure levels below 25 µg/m³ (Document ID 0199, pp. 6, 8-11).

In 2014, OSHA conducted an inspection of another paint manufacturer, obtaining two personal sampling results for mixer operators who added "sand and other particulate to paint during a mixing process" without the benefit of LEV. This basic information about the plant conditions (general dilution ventilation) surrounding these two sample results are described in OSHA's OIS. One of these two results was greater than 200 µg/m³, indicating that mixer operators in paint plants continue to experience exposure levels more than twice the previous PEL when LEV is absent (Document ID 3958, Rows 237-239).[82]

[82] Lines 237 and 238 were consecutive samples collected on a single employee during a single work shift.

Based on the information in the ERG site visit report, OSHA determined that exposures are due primarily to airborne dust generated when: 1) bags are opened, 2) materials are transferred into hoppers, and 3) empty bags are compressed for disposal; and that exposures are significantly higher when LEV is not available or fails (Document ID 0199, pp. 9-10). Two additional sample results from OIS support this determination regarding the value of LEV (see discussion above, Document ID 3958).

Detailed information on housekeeping practices at the paint manufacturing facility visited by ERG indicate that a mixer operator used a brush to dry sweep into the tank any silica powder that accumulated on tank rims near the bag dumping stations. Another operator at this facility used a hose to wash away powder spilled on the floor. Floors at this facility were also cleaned using a wet vacuum truck that was operated by workers in the material handler job category (Document ID 0199, pp. 4, 9, 12). Workers performing these activities during a shift when the exhaust ventilation system was functioning were among those who experienced exposure levels of less than 25 μg/m^3 (Document ID 0199, pp. 4, 6-8, 9, 12). Routine daily cleaning at this level appears to be a standard practice in this industry, not only to minimize slip hazards created by spilled product and materials, but also to maintain product quality by minimizing the unwanted spread of concentrated color pigments, which can affect product color quality.

Table IV.4.13-B Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Paint and Coatings Industry (NAICS 325510)											
	Exposure Summary			**Exposure Range**			**Exposure Profile**

4.13.3 Additional Controls

Additional Controls for Material Handlers

Based on the exposure profile in Table IV.4.13-B, OSHA concludes that all material handlers are currently below the final PEL of 50 μg/m^3, and therefore no additional controls are required for material handlers in order to meet the PEL. Additional controls, if needed, could include substitution of materials with less silica content and improved ventilation at weighing stations. The effectiveness of these options is described briefly for mixer operators.

Additional Controls for Mixer Operators

The exposure profile in Table IV.4.13-B shows that 25 percent (3 out of 12 samples) of mixer operators have exposures above the final PEL of 50 μg/m^3. On the other hand, 8 of the 9 samples below 50 μg/m^3 are also below the final action level of 25 μg/m^3. Nevertheless, OSHA finds that additional controls will be necessary to achieve the PEL for the 25 percent of these workers who are overexposed under baseline conditions. In the PEA, OSHA described the primary controls for mixer operators as bag dumping stations equipped with well-ventilated enclosures and bag compactors (also ventilated) (Document ID 1720, p. IV-237). At a site mentioned previously, ERG monitored mixer operator exposure and obtained results of less than 12 μg/m^3 and 13 μg/m^3, the sample limits of detection, while workers produced batches of paint by emptying 50-pound bags of quartz and cristobalite powder into hoppers during periods when the combined exhaust ventilation and bag disposal systems were working properly. These values are 95 percent lower than the result of 263 μg/m^3 obtained during another shift at the same plant when these controls malfunctioned (Document ID 0199, p. 9). Based on that site visit, OSHA estimates that properly functioning and adequate LEV and bag disposal systems will reduce exposures from levels exceeding 250 μg/m^3 to less than the limit of detection of 12 or 13 μg/m^3 (a 95 percent reduction) (Document ID 1720, p. IV-237).

High-efficiency particulate air (HEPA)-filtered vacuums offer an alternative to dry brushing and sweeping in plants where exhaust ventilation is insufficient to control dust during these activities. These vacuums supplement wet washing and wet sweeping that already occur in paint and coatings manufacturing facilities (Document ID 0199, pp. 4, 12).

4.13.4 Feasibility Finding

Feasibility Finding for Material Handlers

Based on the exposure profile in Table IV.4.13-B, OSHA finds the baseline exposure level for all material handlers to be less than 25 μg/m³. This finding is based on the 11 sample results - all less than 25 μg/m³ - included in the exposure profile. Thus, OSHA finds that the standard is technologically feasible for material handlers in paint and coatings manufacturing facilities.

Feasibility Finding for Mixer Operators

Based on the exposure profile in Table IV.4.13-B and other record evidence discussed above, OSHA finds that the standard is technologically feasible for most mixer operators most of the time when baseline and additional controls are used. These controls keep exposures well below the PEL when functioning properly. As previously discussed, paint and coatings facilities will need to provide ventilated bag dumping stations and bag disposal systems (also ventilated) for the 25 percent of mixer operators currently exposed to silica at levels exceeding 50 μg/m³. To eliminate dry brushing until ventilation systems are operating effectively, mixer operators can use HEPA-filtered vacuums to clean tank rims and areas that cannot be washed with water immediately after spills occur.

OSHA received no comments related to technological feasibility of the proposed rule for the operations described above. Although both the Society for Protective Coatings (SSPC) and the American Coatings Association (ACA) commented on other aspects of the proposed rule, neither of these organizations commented on the technological feasibility of reducing silica exposures below the PEL with respect to mixer operators in the paint and coatings industry (Document ID 2120; 2239, see, *e.g.*, pp. 4-5 (confining its remarks to applying paint)). Similarly, the National Automobile Dealers Association (NADA) provided extensive comments related to automotive paints (confining its remarks to the removal of paints and other products such as body fillers by automobile body shop technicians), but it did not comment on the technological feasibility of reducing the PEL for mixer operators in paint manufacturing plants (Document ID 2358; 4197; 4198). The NADA did affirm that "OEM [original equipment manufacturing] and aftermarket automotive paint manufacturers have essentially eliminated crystalline silica" from these paints (Document ID 2358, p. 3). NADA explains that "Historically, the paint systems used on automotive coatings contained small amounts of crystalline silica as a rheology agent. No crystalline silica is used currently in North America on automobile coatings and has been removed from all manufacturers' paint products since at least model year 2000." (Document ID 4198, p. 1).

Overall Feasibility Finding for Paints and Coatings Manufacturing Facilities

OSHA concludes that all material handlers and most mixer operators in paint and coatings facilities are currently exposed to silica levels below 50 μg/m^3. For mixer operators who are currently exposed above 50 μg/m^3, the engineering and work practice controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or less in most operations, most of the time. Therefore, OSHA finds that the final PEL of 50 μg/m^3 is technologically feasible for the Paint and Coatings industry.

4.14 PORCELAIN ENAMELING

4.14.1 Description

Porcelain enamel is a boro-silicate layer usually applied to metal products as a protective or decorative coating. Porcelain enameling is used in a variety of industries to produce such products as architectural panels, bathtubs, barbeques, boilers, chemical vessels, cookers, heat-exchange panels and tubes, microwave ovens, street signs, water heaters, and washing machines (Document ID 0671, pp. 3-4). Industries that can involve porcelain enameling are classified in the 2007 six-digit North American Industry Classification System (NAICS) codes 332812, Metal Coating, Engraving (except Jewelry and Silverware), and Allied Services to Manufacturers; 332998, Enameled Iron and Sanitary Ware Manufacturing; 332323, Ornamental and Architectural Metal Work Manufacturing; 339950, Sign Manufacturing; and 335211, 335221, 335222, 335224, and 335228, industries involved in household appliance manufacture (e.g., stoves, refrigerators, microwave ovens, water heaters).[83]

Porcelain enamel is produced from ground frit, a silicate glass composed of approximately 50 percent amorphous silicon dioxide, and additive ingredients. For many applications (but not all), these additives include crystalline silica or crystalline silica-containing materials such as feldspar and quartz (Document ID 0740, p. 19; 0959). The application of the enamel on the base material is performed in various ways, including manual or automatic dipping, slushing, flowcoating, manual or automatic spraying, electrostatic wet spraying, electro-deposition, and electrostatic dry powder spraying. For the purposes of this analysis, porcelain enamels can be divided into two categories: 1) clay-containing porcelain enamels that typically include 2 to 10 percent silica, are always applied as a wet slurry, and cannot be applied electrostatically, and 2) porcelain enamels classified as powder coatings, which contain no clay or silica and can be applied by electrostatic/electro-deposition processes (Document ID 0959). This discussion focuses solely on manufacturers of enamels that contain silica.

[83] The applicable 2012 NAICS codes also include 332999, 334519, and 335210

4.14) Porcelain Enameling

Establishments that perform porcelain enameling typically employ enamel preparers who mix the enamel and coatings applicators who apply the enamel to metal products. In facilities with small enameling operations, the same operator might mix the coating and apply it to products. See Table IV.4.14-A for a description of job categories, major activities, and sources of exposure. The processes used for both the porcelain enamel preparation and application are generally similar to those used to produce and apply glazes in the pottery industry, including the preparation of materials, molding, and glaze application procedures. See Table IV.4.15-A, in Section IV-4.15 – Pottery, for detailed descriptions of these processes. The major difference between the porcelain enamel used on metals and the glaze applied to pottery is that metal enamels contain more boron and less silica (2 to 10 percent silica in metal enamels compared with 23 percent in pottery glaze), which allows enamels to fuse at a lower temperature and accommodate the greater thermal expansion of metals (Document ID 1365, p. 15-4).

Table IV.4.14-A
Job Categories, Major Activities, and Sources of Exposure of Workers in the Porcelain Enameling Industry (2007 NAICS 332323, 332812, 332998, 335211, 335221, 335222, 335224, 335228, and 339950)

Job Category*	Major Activities and Sources of Exposure
Enamel Preparer	Combine frit and other raw ingredients; transfer enamel slurry to other areas of the plant. • Dust from milling and/or mixing of silica-containing materials. • Dust from manual weighing and bag dumping of silica-containing materials.
Porcelain Applicator	Apply enamel to products (manually or automated); transfer products between conveyors; perform housekeeping. • Dust from handling products coated in dried enamel. • Dust from dried overspray and dripped slurry from the application process.

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility.

4.14.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.14-B includes 35 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for workers in the Porcelain Enameling industry. The median is 44 μg/m^3, the mean is 207 μg/m^3, and the range is 3 μg/m^3 (the limit of detection (LOD)) to 2,300 μg/m^3. Table IV.4.14-B shows that, of the 35 samples, 15 (42.9 percent) exceed 50 μg/m^3.

Only 5 of the samples characterize silica exposures during porcelain enameling. In the absence of more completely documented exposure information for this industry, OSHA has primarily relied on sampling data obtained from its Integrated Management Information System (IMIS) data, and also has relied on the general exposure information provided by a contact within the industry (Document ID 0960). Drawbacks associated with IMIS data include limited documentation of worker activity, sample duration, materials being handled, exposure controls in use at the time, and other or adjacent sources of silica exposure. However, IMIS data remain the best available source of exposure data for workers involved in porcelain enameling. The OSHA contractor ERG searched IMIS data for silica sampling associated with porcelain enameling between 1979 and 2002, and identified three exposure results (as respirable dust containing silica) for enamel preparers and 23 results for porcelain applicators between 1985 and 1992 (Document ID 1365, pp. 15-6 – 15-9). In addition, the International Union of Automobile Workers (UAW) submitted nine respirable silica sample results which have been included in the final exposure profile (Document ID 4031, Attachment F, pp. 4-5). However, because of the scarcity of data for porcelain enameling, OSHA has retained the data presented in the Preliminary Economic Analysis (PEA) from before 1990.[84]

OSHA also reviewed inspection data submitted to the rulemaking record from OSHA's Information System (OIS), but determined that OIS did not include any data for silica sampling associated with porcelain enameling. The exposures summarized in Table IV.4.14-B for enamel preparers and porcelain applicators represent the best available information on the exposure levels associated with these job categories and, in the absence of more detailed information, also represent baseline conditions for enamel preparers and porcelain applicators.

Exposure Profile and Baseline Conditions for Enamel Preparers

The exposure profile in Table IV.4.14-B includes 5 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for enamel preparers in the Porcelain Enameling industry. The median is 51 μg/m^3, the mean is 71 μg/m^3, and the range is 12

[84] For more information on how OSHA handled data contained in the feasibility analysis, refer to Section IV-2–Methodology.

μg/m^3 (the limit of detection (LOD)) to 190 μg/m^3. Table IV.4.14-B shows that, of the 5 samples, 3 (60 percent) are above 50 μg/m^3. Two of respirable silica samples for enamel preparers (millers, mixers) from the IMIS database measured detectable concentrations of46 μg/m^3, and 56 μg/m^3, while a third was reported as below the LOD (Document ID 1365, p. 15-8). The value for the LOD could not be determined because the sample duration was not provided in the IMIS database, so a value of 12 ug/m3 was used in the exposure profile (see Table IV.4.14-B). Two additional silica samples of 51 μg/m^3 and 190 μg/m^3, submitted by the UAW, were added to the exposure profile (Document ID 4031, Attachment F, pp. 4-5). Limited information provided by NIOSH and from contacts within the industry indicates that most facilities performing porcelain enameling currently use automated systems to move some raw materials (such as frit) to the mixer, but that enamel preparers are most likely to introduce those additives used in smaller quantities (such as silica-containing ingredients) by dumping bags directly into a hopper at the mixer opening (Document ID 1365, p. 15-10; 1682, p. 5; 0959). Some form of exhaust ventilation is often available at the mixer opening or hopper; however, the ventilation does not necessarily offer complete dust control during mixer charging, as evidenced by reports of measurable silica exposure levels during mixer charging (Document ID 1277, 1365, p. 15-4). For example, the Porcelain Enamel Institute (PEI) noted that the industry often uses LEV with baghouses in the bag dumping area (Document ID 2281, p. 3). Although often a relatively brief task requiring approximately one hour per day, mixer charging can be the most significant source of worker silica exposure associated with porcelain enameling (Document ID 1365, pp. 15-4 – 15-5).

OSHA concludes that the exposure profile in Table IV.4.14-B for enamel preparers represents the best available information on the exposure levels associated with this job category. Accordingly, OSHA considers the profile to be representative of baseline conditions for enamel preparers.

Exposure Profile and Baseline Conditions for Porcelain Applicators

The exposure profile in Table IV.4.14-B includes 30 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for porcelain applicators in the Porcelain Enameling industry. The median is 28 μg/m^3, the mean is 229 μg/m^3, and the range is 3 μg/m^3 (the LOD) to 2,300 μg/m^3. Table IV.4.14-B shows that, of the 30 samples, 12 (40 percent) are above 50 μg/m^3, 6 (20 percent) exceeded 100 μg/m^3, and 2 (6.7 percent) exceeded 1,000 μg/m^3 (Document ID 1365, p. 15-9; 4031, Attachment F, pp. 4-5). The sampled porcelain applicators were primarily employed by appliance manufacturers with job titles such as porcelain sprayer, porcelain applicator, enameler, rework sprayer, and enamel sprayer. The IMIS data indicate that one facility was inspected by OSHA in three different years. Both porcelain applicator results exceeding 1,000 μg/m^3 were obtained in 1985 at the first inspection of this facility, along with two results of 47 μg/m^3 and 91 μg/m^3. At the two subsequent inspections, silica exposures for applicators were controlled below 50 μg/m^3. Results of 3 μg/m^3, 4 μg/m^3, 6 μg/m^3, and 22 μg/m^3 were reported in 1989, and results of 22 μg/m^3 and 23 μg/m^3 were reported in 1992 (Document ID 1698). No information on controls is available for this facility.

At Porcelain Facility A, all air sampling results for workers associated with the porcelain application line were reportedly below 100 μg/m^3 (Document ID 1365, p. 15-10; 0960). These results are associated with exhaust ventilation along the length of the spray application line. Only summary exposure data is available to OSHA from Porcelain Facility A (no individual results).

Regardless of the application method used (e.g., spray, dip, flowcoat), silica-containing porcelain enamels are typically applied as a slurry (Document ID 1365, p. 15-10; 0959). This wet application reduces exposure because silica particles cannot become airborne until dry, and when dry, porcelain enamel adheres tightly to the surface to which it is applied (Document ID 1365, pp. 15-5 – 15-6). Limited information provided by a contact within the industry indicates that ventilation is used extensively while porcelain applicators coat objects and subsequently handle the parts. All application is performed in ventilated booths (e.g., a spray booth) (Document ID 1365, p. 15-5). Written comments received by PEI also implied that the industry uses LEV systems with baghouses in the porcelain application booths (Document ID 2281, p. 3, PDF p. 7). Based on the experiences of other industries, some of the ventilation systems and booths might require maintenance or modification to operate efficiently.[85] Thus, OSHA concludes that baseline conditions for porcelain applicators include wet application methods and use of exhaust ventilation, which might or might not be functioning optimally.

OSHA concludes that the exposure profile in Table IV.4.14-B for porcelain applicators represents the best available information on the exposure levels associated with this job category. Accordingly, OSHA considers them to be representative of baseline conditions for porcelain applicators.

4.14.3 Additional Controls

Additional Controls for Enamel Preparers

The exposure profile in Table IV.4.14-B shows that 3 of 5 samples, (60%) for enamel preparers have exposures above the final PEL of 50 µg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL. Considering this profile to be representative of baseline conditions for enamel preparers, and based on other information in the rulemaking record that this work typically requires a limited amount of time to add the silica-containing materials (generally less than 10 percent of all raw materials) and can be done using ventilated mixers/mill charging equipment, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers and expects that porcelain enameling will be able to reduce exposures to the final PEL of 50 µg/m^3 or less by proper ventilation or by improved design or maintenance of existing ventilation systems at bag dumping and mixer charging stations, process automation, improved housekeeping, and substitution. These controls have proven effective in the porcelain enameling industry and in other industries with analogous job categories, such as those that manufacture pottery or structural clay (see the related Section IV-4.15 – Pottery and Section IV-4.21 – Structural Clay). Coatings preparers in these industries are exposed to silica during transfer and mixing of sand, feldspar, and other coatings or glaze ingredients. Both the pottery and structural clay industries use a substantially greater percentage of silica (also in the form of quartz or feldspar) in product coatings than are used by the porcelain enameling industry. Because of the similarity of the tasks, equipment, and materials, OSHA concludes that control methods employed by coatings preparers in the pottery and structural clay industries will function equally well in the porcelain enamel industry.

Local Exhaust Ventilation

Bag-dumping stations with properly ventilated enclosures, which capture dust release during both bag emptying and bag disposal, have been used successfully in the pottery and structural clay industries to reduce exposures. An example from the pottery industry demonstrates the value of the booth alone. A coatings preparer used a booth and a weigh scale outside the booth to mix glazes. An initial exposure of 143 µg/m^3 was reduced to 51 μg/m^3 after the baghouse ventilation system was repaired. A consultant evaluating the plant on the second (post-repair) sampling date recommended limiting use of compressed air for cleaning to further reduce silica exposure; this recommendation suggests that compressed air was used regularly in the plant (Document ID 0106, p. 55). OSHA concludes that by moving the weigh scale into the booth or adding exhaust ventilation to the scale area, and by reducing reliance on compressed air for cleaning, the exposure of this coatings preparer could be reduced to a level consistently below 50 μg/m^3.

A bag-dumping station with fully functioning local exhaust ventilation (LEV) was found to reduce silica exposure by at least 95 percent in a paint manufacturing facility where workers emptied 50-pound bags of silica-containing materials (Document ID 0199, pp. 7, 8, 11). The station consists of hoppers topped with grates enclosed by LEV hoods. After each bag is emptied, the worker releases it and suction automatically pulls the bag into the ventilation system and transfers it to an enclosed storage area. Other types of bag dumping stations also are effective at reducing respirable dust (Document ID 1369). Ventilated bag dumping stations are readily available from commercial sources (Document ID 0581; 0594; 0680; 1212; 1224). PEI commented that OSHA underestimated the amount of LEV (and the associated costs) required to effectively control exposures to 50 μg/m^3 in porcelain enameling (Document ID 2281, pp. 4-5). OSHA understands that some facilities, including those that use enamel coatings that contain higher concentrations of silica, may need to install LEV with a higher flow rate than other facilities. OSHA has not required a specific flow rate or minimum flow rate and instead is relying on employers to evaluate their exposures and install the appropriate controls based on the findings of an exposure assessment. See Chapter V of this FEA for a discussion on the associated costs.

Process Automation

Although information specific to enamel preparers is not available, the effectiveness of automated systems for transferring silica-containing materials is illustrated by exposure monitoring data obtained for material handlers at two pottery facilities. The exposure for a material handler who was monitoring automated equipment adding silica-containing raw materials to a mixer was almost 66 percent lower (29 μg/m^3 versus 85 μg/m^3) than the exposure of a material handler manually adding bags of raw materials to the mixer. At another facility, OSHA obtained a reading of 23 μg/m^3 for a material handler monitoring automated equipment that transferred dry silica sand from the storage silo and pumped a slurry of ball clay and kaolin into a mixer (Document ID 1365, p. 15-13).

An example from the structural clay industry is also instructive. At a facility inspected by OSHA, an 86 percent reduction in respirable quartz exposure readings occurred after management installed an enclosed, automated sand transfer system, despite having an incorrectly sized conveyor. With tightly sealed components, it is likely that exposures would be reduced further (Document ID 1365, p. 15-13).

Housekeeping

Dust released during mixer charging can contribute substantially to enamel preparer exposure in facilities where poor housekeeping has allowed dust to accumulate. In addition, some cleaning procedures (e.g., dry sweeping) can aggravate the situation by stirring up dust and causing it to become airborne. For those facilities where excessive dust has been allowed to accumulate, an initial thorough cleaning, followed by continuous, improved housekeeping procedures (e.g., use of a high-efficiency particulate air [HEPA]-filtered vacuum) to maintain cleanliness can reduce exposures. An example from the structural clay industry demonstrates the benefit of diligent housekeeping practices on worker silica exposure levels. A dramatic exposure reduction (in some cases a greater than 10-fold reduction) was associated with thorough (professional-level) cleaning to remove dust accumulations on the floor and structural surfaces of raw material handling areas (Document ID 0571).

Surface cleaning with HEPA vacuums instead of compressed air has proven beneficial in the pottery industry (another industry using similar silica-containing mineral powders). In a pottery industry facility, the use of compressed air to clean silica dust from the surface of molds was replaced with the use of a vacuum and abrasive pad (Document ID 0027, pp. 161-191; 1372, p. 7). Using these methods, and despite uneven functioning of the LEV at two workstations, the facility was able to reduce all of its silica exposures to 40 μg/m^3 or below (three results equal to 30 μg/m^3 and single results of 10 μg/m^3, 20 μg/m^3, and 40 μg/m^3) (Document ID 0027, pp. 32, 186, 367). As discussed in the PEA, this reflects a substantial reduction in exposure levels at this facility where 50 percent of samples previously taken by OSHA and 30 percent of results taken by NIOSH were over 50 μg/m^3 (Document ID 0027, pp. 32, 186, 367; 1720, p. IV-245).

Substitution

The use of enamels with reduced crystalline silica content represents an additional control option. By preparing coatings with low-silica ingredients, enamel preparers' exposures to silica would likely be reduced. Coatings producers typically use quartz and feldspar as ingredients in coatings to increase durability and chemical resistance; however, coatings with reduced crystalline silica content can be formulated by replacing quartz with materials such as feldspar (lower crystalline silica content) and frit (amorphous silica), which contain less crystalline silica (Document ID 1365, p. 15-14). Porcelain enamels with less than 3 percent crystalline silica are available (Document ID 0960).

PEI commented that it is not practical to use low-silica ingredients, that there are no proven replacements for mill-added crystalline silica in today's wet-applied enamel systems, and that silica offers technical advantages in finished product quality which cannot otherwise be practically and economically achieved (Document ID 2281, Attachment 1, p. 3). OSHA does not expect substitution to be a suitable control in every situation where high silica ingredients are currently used. However, OSHA continues to be convinced that substitution is a feasible control in other applications, given communication with a porcelain enameling facility that uses enamels containing less than 3 percent crystalline silica (Document ID 0960). PEI did not indicate how frequently these substitutes may be unacceptable for the referenced applications.

Additionally, OSHA considers the wet-application process itself to be a means for exposure reduction. If an establishment disfavors substitution for quality assurance reasons, additional controls, such as process automation during mixing, LEV and housekeeping to remove wet product before it dries are alternative methods for reducing exposure.

Combination of Controls

Using several of the controls discussed above (LEV, process automation, housekeeping, and substitution) simultaneously can lead to greater exposure reductions. Porcelain Facility A (described previously) uses both ventilation and good housekeeping to keep exposures low. At Porcelain Facility A, enamel preparers charge milling equipment for 1 hour per day, then monitor mills and transport the resulting enamel slurry as needed within the facility for the remainder of the shift. Exhaust ventilation holds the milling equipment under negative pressure to minimize dust release during charging and mixing (Document ID 0960; 1365, p. 15–11). In addition to ventilating the milling equipment, Porcelain Facility A uses a vacuum fitted with a HEPA filter for all cleaning. To minimize the generation of airborne dust, workers avoid dry sweeping and only shovel or scrape materials that are damp (Document ID 1365, p. 15–12).

In the PEA, OSHA discussed a report by a company representative from Porcelain Facility A stating that air monitoring conducted by OSHA at this facility found that the 8-hour TWA exposure level of porcelain preparers was controlled below the previous PEL of 100 μg/m^3 (Document ID 1365, p. 15–10; 0960). Airborne silica concentrations could, however, exceed this level during the bag dumping task. Exposures might have been still lower during this task if the bag dumping station had been designed differently and included ventilated equipment to dispose of empty bags (Document ID 1720, p. IV-245).

Additional Controls for Porcelain Applicators

The exposure profile in Table IV.4.14-B shows that 40 percent (12 of 30 samples) of porcelain applicators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL. Available controls include LEV, automation, diligent housekeeping practices, and use of low-silica enamels. Implementation of these controls might involve installing new equipment or improving current equipment.

Local Exhaust Ventilation

A common exposure control option includes the use of well-ventilated, well-enclosed booths for enamel application. In order for the booths to be effective, it is important to follow recommended exhaust rates. The American Conference of Governmental Industrial Hygienists (ACGIH) specifies ventilation designs for both large and small spray booths, including recommended air flow rates across the entire face of the booth (100 to 150 feet per minute) (Document ID 0515, pp. 13-129 – 13-132).

The effectiveness of this method in other industries that use similar, but higher, silica content coatings than the porcelain enamel industry is demonstrated by exposure monitoring data obtained at a pottery manufacturing facility visited twice by NIOSH (Document ID 0209; 0211). After the facility improved booths and LEV systems used for manual and automated spraying operations by repairing holes and openings and increasing airflow rates, median exposure readings were 44 percent, 88 percent, and 67 percent lower on the manual, semiautomatic, and automatic lines, respectively. On the semiautomatic and automatic lines, NIOSH recorded eight results. The highest result was 66 $\mu g/m^3$, the median was 30 $\mu g/m^3$, and the results included four values of 23 $\mu g/m^3$ or lower. On the manual spray line, where exposure levels decreased by only 44 percent and the maximum exposure recorded was 507 $\mu g/m^3$, reports indicate that operators used compressed air hoses to blow dust off prior to applying glaze during both site visits. OSHA concludes that it is possible that exposures on the manual spray line could be reduced further by removing dust from work pieces with vacuums and wet sponges as is done by operators on the semiautomatic spraying line.

In this facility, workers who used automated coatings application equipment had a median silica exposure level 64 percent lower than workers performing manual spraying. When the automated spray equipment is well enclosed and associated with a functioning ventilation system, operator results can be even lower (Document ID 1365, pp. 15-14 – 15-16).

Porcelain applicators should ensure that they are making optimal use of LEV. As discussed in the PEA, Porcelain Facility A encourages workers who apply enamel to avoid positioning themselves between the enamel spray and the ventilation system. During manual spraying, small items are positioned by hand within the booth so the spray is directed into the booth and toward the ventilation take-off. For large items, the facility provides a turntable support that allows porcelain applicators to rotate the item to spray all sides of the object while maintaining the spray direction pointing into the ventilated booth (Document ID 1720, p. IV-246). The workers also use great care to avoid dislodging enamel powder when handling items that are coated with dry porcelain enamel (e.g., when transferring parts to the furnace conveyor line).

Housekeeping

Dust released from dried coatings and coatings residues (e.g., drips, spills, and overspray) can contribute substantially to the silica exposure of porcelain applicators in facilities where poor housekeeping has allowed dust to accumulate. Improper cleaning procedures such as dry sweeping can aggravate the situation by stirring up dust and causing it to become airborne. An initial thorough cleaning in association with improved housekeeping procedures (e.g., use of a HEPA-filtered vacuum) to maintain cleanliness can reduce exposures in facilities where dust has accumulated (Document ID 0571). An example from the structural clay industry demonstrates the benefit of diligent housekeeping practices on worker silica exposure levels. A dramatic exposure reduction (in some cases a greater than 10-fold reduction) was associated with thorough (professional-level) cleaning to remove dust accumulations on the floor and structural surfaces of raw material handling areas (Document ID 0571).

Substitution

As discussed previously, the use of enamels with reduced crystalline silica content represents an additional control option. For further information see the previous section on Substitution under Additional Controls for Enamel Preparers.

Combination of Controls

Using several of the controls discussed above (LEV, housekeeping, and substitution) simultaneously can lead to greater exposure reductions. The aforementioned Porcelain Facility A uses ventilation, good work practices, and diligent housekeeping to keep exposures low (Document ID 1720, p. IV-247; 0960). Porcelain Facility A makes extensive use of ventilation along the entire coatings application line. Both automated and manual spray enamel application are performed inside spray booths fitted with exhaust ventilation designed for the spray booths. At this site, most operations occur in large, ventilated, walk-in spray booths, although porcelain applicators sometimes apply the coating standing outside a smaller ventilated booth (Document ID 1720, p. IV-247). In addition to using ventilated booths, Porcelain Facility A takes several steps to minimize the amount of dust that becomes airborne. Workers remove enamel residue from spray booths while it is still damp, using shovels and scrapers to recover the material for reuse (Document ID 1720, p. IV-247; 1365, p. 15–17; 0960). A company representative notes that no visible dust is generated during this process (Document ID 1365, p. 15–17). Additionally, this facility uses a large HEPA-filtered vacuum to capture any dried porcelain enamel that workers encounter outside the ventilated booths. Sweeping and shoveling dry materials is not permitted and the HEPA-filtered vacuum is used for general housekeeping throughout the facility (Document ID 1720, p. IV—247; 1365, p. 15–17; 0960). A representative exposure levels of porcelain applicators were well below the previous PEL, as calculated based on the OSHA general industry standard for silica in respirable dust (Document ID 1720, p. IV-247; 0960).

4.14.4 Feasibility Finding

Feasibility Finding for Enamel Preparers

Based on the exposure profile in Table IV.4.14-B and other record evidence discussed above, OSHA has determined that 40% of enamel preparers currently have silica exposures at or below the final PEL of 50 μg/m^3, and the remaining 60% are only slightly higher than 50 μg/m^3. For enamel preparers exposed above 50 μg/m^3, their exposure can be reduced using HEPA-filtered vacuums instead of compressed air for cleaning. OSHA has determined that when facilities implement this control, exposure levels of 50 μg/m^3 or less can be achieved for most enamel preparers most of the time.

Where additional controls are required, options for enamel preparers include adding or improving maintenance on bag dumping stations and ventilated bag disposal equipment, process automation, improved housekeeping, and substitution. These methods have reduced exposure levels in other industries that prepare vitreous coatings or use similar materials to form products. OSHA concludes and expects that these methods will be equally effective in the porcelain enameling industry and can reduce the exposure for enamel preparers to levels at or below 50 µg/m^3 for most operations, most of the time. Therefore, OSHA concludes that the PEL of 50 µg/m^3 is feasible for enamel preparers.

Feasibility Finding for Porcelain Applicators

Based on the exposure profile in Table IV.4.14-B and other record evidence discussed above, OSHA has determined that 60 percent of porcelain applicators already experience exposures at or below 50 µg/m^3. Low exposures are attributed to use of low-silica enamels; enclosed, well-ventilated automatic spray equipment; appropriately enclosed and ventilated booths for manual operations; and diligent housekeeping. OSHA concludes that exposure levels for the remaining porcelain applicators (40 percent) can be reduced to 50 µg/m^3 or less using similar, properly implemented and maintained controls.

The two highest exposures for this job category (2,300 µg/m^3 and 2,006 µg/m^3) were both obtained in 1985 at the same facility where OSHA later recorded six silica concentrations between 3 µg/m^3 and 23 µg/m^3 for porcelain applicators, demonstrating that even the highest exposures for this job category have been successfully controlled to levels below 50 µg/m^3. Therefore, OSHA concludes that the PEL of 50 µg/m^3 is technologically feasible for porcelain applicators.

Overall Feasibility Finding for the Porcelain Enameling Industry

Based on the exposure profile in Table IV.4.14-B and other record evidence discussed above, OSHA concludes that the porcelain enameling industry can control the silica exposure to levels of 50 µg/m^3 or less for most operations most of the time. Therefore, OSHA finds that the final PEL of 50 µg/m^3 is technologically feasible for the Porcelain Enameling industry.

4.15 POTTERY

4.15.1 Description

Silica-containing materials are the primary ingredients in the manufacture of pottery products, and they are also sometimes used to prepare glazes that are applied to pottery products. Facilities manufacturing pottery products are classified in the 2007 six-digit North American Industry Classification System (NAICS) codes 327111, Vitreous China Plumbing Fixtures and Bathroom Accessories; 327112, Vitreous China, Fine Earthenware, and Other Pottery Products; and 327113, Porcelain Electrical Supply Manufacturing[86] (Document ID 1365, p. 4-1).

Pottery product manufacture typically begins with the mixing of clay raw material with water in a mill, to create a slurry that is then transferred into molds. After setting, the pottery pieces are removed from the molds and finished, and glazes are mixed and applied to the pottery. The pieces are then fired in kilns and packaged (Document ID 1365, p. 4-2).

Workers in all phases of pottery product manufacture have potential for silica exposure (Document ID 1365, p. 4-2). The primary job categories with potential exposures are material handler, forming line operator, finishing operator, coatings preparer, and coatings operator (see Table IV.4.14-A). Certain workers regularly perform tasks associated with multiple job categories (Document ID 1365, p. 4-2). Details regarding activities performed by workers and the sources of exposure in each job category can be found in a review of General Industry prepared by OSHA's contractor Eastern Research Group (ERG, 2008) (Document ID 1365, pp. 4-1 - 4-33).

[86] The applicable 2012 NAICS code is 327110.

Table IV.4.14-A Job Categories, Major Activities, and Sources of Exposure of Workers in the Pottery Industry (2007 NAICS 327111, 327112, and 327113)	
Job Category	**Major Activities and Sources of Exposure**
Material Handler	Transferring silica-containing raw materials (e.g., clay, silica sand, feldspar) from storage silos to weigh hoppers via front-end loader or forklift; mixing clay slip. • Dust generated from transfer of materials. • Dust from manually opening and dumping bags of silica-containing raw materials.
Forming Line Operator	Transferring slip into molds; removing formed pottery pieces; cleaning molds for reuse; applying mold parting compound. • Dust from cleaning molds. • Dust from applying the mold parting compound.
Finishing Operator	Shaping, smoothing, trimming of dried or fired pottery pieces, and typically using handheld equipment. • Dust from finishing dried pottery pieces.
Coatings Preparer	Transferring silica-containing materials (e.g., clay, silica sand, feldspar) to weigh hoppers or mixers; mixing glazes. • Dust generated from transfer of materials. • Dust from manually opening and dumping bags of silica-containing raw materials.
Coatings Operator	Applying glazes to pieces, typically by hand-dipping or spraying. • Silica-containing aerosol during glaze spraying.
Note: Job categories are intended to represent job functions; actual job titles might differ and responsibilities might be allocated differently, depending on the facility. Source: Document ID 1365.	

4.15.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.15-B includes 87 full-shift, personal breathing zone (PBZ) samples of respirable crystalline silica for workers in the pottery industry. The median is 40 μg/m^3, the mean is 98 μg/m^3, and the range is 6 μg/m^3 (limit of detection (LOD[87])) to 1,101 μg/m^3. Table IV.4.15-B shows that, of the 87 samples, 38 (43.6 percent) are above 50 μg/m^3 and 13 (14.9 percent) exceed 100 μg/m^3.

To evaluate silica exposures of pottery production workers, OSHA reviewed full-shift personal breathing zone (PBZ) respirable quartz exposure monitoring data from six OSHA Special Emphasis Program (SEP) inspection reports, and one NIOSH site visit report. OSHA also reviewed 12 additional facility reports from the states of Michigan,

[87] LODs are as reported by the original study author. LODs are discussed in further detail in Section IV-2–Methodology.

New Jersey, and Ohio for historical reference. For the final exposure profile, OSHA eliminated all data points that were collected prior to 1990 because those data points likely overestimated current exposures in pottery facilities. The ceramics industry as a whole, including pottery production, has seen marked decreases in respirable dust and silica exposure levels and greater attention to exposure controls since the 1980s (Document ID 1720, p. IV-253).

The U.S. Environmental Protection Agency (EPA) issued a 2007 National Emissions Standard for Hazardous Air Pollutants for Clay Ceramics Manufacturing Area Sources, which includes specific provisions for managing emissions at these facilities, including inspecting and testing ventilation systems associated with pottery kilns and glaze spray booths (40 CFR 63.11435-63.11445, 2007). This rule went into effect in 2007, and OSHA believes that the inspection requirements for ducts, bag houses, and other dust control systems likely has helped to reduce exposures due to problems with ventilation system integrity.

OSHA also identified a more recent NIOSH report describing a small storefront pottery operation with four full-time workers and several part-time assistants (Document ID 0878). Because workers' activities could not be classified by job category (they all encompassed most job categories), exposure information has not been included in the exposure profile. However, the available results indicate that exposures are relatively low at this type of facility despite a lack of local exhaust ventilation (LEV). Only one of the workers evaluated had a measurable full-shift exposure; no results exceeded the final PEL of 50 $\mu g/m^3$ (one result was at 50 $\mu g/m^3$ and the other sample results were below the limit of detection [LOD], (in this case 12 $\mu g/m^3$) (Document ID 0878, p. 5). Although task-based sample results (one to two hours duration) did indicate the potential for exposure to occur during brief periods when workers handle bags of clay and mix clay, workers that perform dusty jobs also perform many other tasks during their shifts (Document ID 0878, p. 6). Thus, their cumulative silica exposure is rarely detectable and did not exceed the PEL of 50 $\mu g/m^3$. NIOSH recommended that the facility improve the building's central ventilation and air circulation and also install exhaust ventilation hoods in the areas where the most dust was generated (Document ID 0878, pp. 14-15).

These samples suggest that the limited amount of materials and equipment used in small shops pose a lower risk than similar activities in a large manufacturing operation. For example, at the storefront facility visited by NIOSH, workers reprocessed clay and mixed glazes from 10-gallon buckets (Document ID 0878, p. 2). In contrast, at a large industrial pottery facility one worker produced four 9,000-pound batches of clay on one shift (Document ID 0143, p. 153).

For each of the job categories listed in Table IV.4.14-A and included in the exposure profile, and for the pottery industry as a whole, OSHA concludes that Table IV.4.15-B represents baseline conditions.

Exposure Profile and Baseline Conditions for Material Handlers

The exposure profile in Table IV.4.15-B includes 11 samples for material handlers in the pottery industry. The median is 41µg/m^3, the mean is 149 µg/m^3, and the range is 20 µg/m^3 to 1,101 µg/m^3. Table IV.4.15-B shows that, of the 11 samples, 5 (45.5 percent) are above 50 µg/m^3 and 2 (18.2 percent) exceed 100 µg/m^3.

Of the six material handler samples with information on engineering control status (local exhaust ventilation (LEV)), three (41 µg/m^3 to 89 µg/m^3) are associated with LEV reported as relatively functional in areas where materials are dumped, both manually and using front-end loaders, and three results (67 µg/m^3 to 1,101 µg/m^3) were associated with no LEV or LEV described as inadequate. An additional two samples (23 µg/m^3 and 29 µg/m^3) made full or partial use of automated processes. Overall, these sample results suggest that exposures in facilities with LEV systems are lower than in facilities without LEV or facilities where the ventilation performs poorly. As shown in Table IV.4.14-A, the silica exposures of material handlers result primarily from airborne dust generated as materials are transferred into hoppers or bins, bags are brushed, empty bags are handled for disposal, and vehicles re-suspend settled dust in the air.

The highest sample for this job category (and also this industry), a value of 1,101 µg/m^3, was obtained when OSHA monitored a material handler shoveling dry clay into a mill that formed clay slip. No ventilation was installed in the mill area, and the material handler also shared the work space with a coatings preparer (another job category with potential to generate substantial silica dust) (Document ID 0174, pp. 69-72). A lower result of 67 µg/m^3 was obtained for a second worker at the same plant. This worker shoveled a different clay (ball clay) in the mill area and controlled the addition of water and other ingredients from silos (Document ID 0174, pp. 27, 241). The available information is insufficient to determine with certainty whether factors other than the clay type caused the results to vary so much.

Most of the facilities for which information is available have some form of ventilation system, though it was not necessarily operating effectively at the time of investigations. Inadequate ventilation systems were characterized by insufficient air flow, leaking ducts, inappropriate hood shape or position, or other factors that make dust collection less efficient.

Exposure Profile and Baseline Conditions for Forming Line Operators

The exposure profile in Table IV.4.15-B includes 36 samples for forming line operators. The median is 31 µg/m^3, the mean is 42 µg/m^3, and the range is 6 µg/m^3 (LOD) to 238 µg/m^3. Table IV.4.15-B shows that, of the 36 samples, 11 (30.6 percent) are above 50 µg/m^3 and 2 (5.6 percent) exceed 100 µg/m^3. All of the samples for forming operators are associated with operations involving wet or liquid (slip) clay mixtures, although many operators also handle dry materials, such as mold coating compounds and dried clay slip residue in molds. Four samples for which engineering control status could be established were associated with the use of LEV (median 25 µg/m^3; mean 25 µg/m^3; range 10 to 40 µg/m^3).

Exposure Profile and Baseline Conditions for Finishing Operators

The exposure profile in Table IV.4.15-B includes 10 samples for finishing operators. The median is 21 µg/m^3, the mean is 26 µg/m^3, and the range is 10 µg/m^3 (LOD) to 55 µg/m^3. Table IV.4.15-B shows that, of the 10 samples, 2 (20 percent) are above 50 µg/m^3 and none exceed 100 µg/m^3. The lowest value for this job category (reported as 10 µg/m^3) was associated with a worker using manual and machine-controlled grinding wheels to square off the bottoms and backs of sanitary ware (e.g., ceramic bathroom fixtures). At least part of this work was conducted in a ventilated booth (Document ID

0106, p. 67). On the same day, two other samples were also obtained for finishing operators at this facility. One of these workers used hand tools and steel wool pads to smooth unfired ceramic pieces, which reportedly generated a lot of visible dust (no booth mentioned), resulting in an exposure level of 53 μg/m^3. Although the other worker used a ventilated booth to perform similar work, that individual also used compressed air to remove the dust, and the consultant taking the samples again noted visible dust in the air, which likely explains the result of 55 μg/m^3 (Document ID 0106, pp. 54, 67, 74-75).

No additional information regarding baseline conditions for finishing operations was submitted to the rulemaking record; therefore, OSHA concludes that baseline conditions for finishing operators are best represented by the data contained in the exposure profile and the range of working conditions under which those samples were collected.

Exposure Profile and Baseline Conditions for Coatings Preparers

The exposure profile in Table IV.4.15-B includes 12 samples for coatings preparers. The median is 82 μg/m^3, the mean is 305 μg/m^3, and the range is 24 μg/m^3 to 983 μg/m^3. Table IV.4.15-B shows that, of the 12 samples, 10 (83.3 percent) are above 50 μg/m^3 and 5 (41.6 percent) exceed 100 μg/m^3. As discussed below, all of the samples for this job category are associated with the manual transfer of dry, silica-containing materials into mixing equipment.

The highest reading, 983 μg/m^3, was obtained for a coatings preparer who manually emptied bags of glaze components into a large, unventilated mixer located in one area of the slip house (Document ID 0174, pp. 27, 84-86, 241). Also in the same space was a material handler whose exposure level of 1,101 μg/m^3 was the highest of the values in the material handler exposure profile (Document ID 0174, pp. 69-72, 81-83). The actions of both workers would have contributed to extremely high silica dust levels in the space.

Exposures are substantially lower when workers prepare coatings at ventilated workstations. OSHA obtained an exposure reading of 86 μg/m^3 for a coatings preparer who mixed three 3,000-pound batches of glaze (Document ID 0143, p. 28). The coatings preparer manually weighed the glaze components in bags or buckets under an LEV hood. The coatings preparer then manually emptied the bags or buckets into an opening in a ball mill (Document ID 0143, pp. 122, 124-125). At another facility, OSHA obtained sample results of 51 μg/m^3 and 41 μg/m^3 for coatings preparers using a LEV system that was only partially functional. These coatings preparers batched glazes by manually weighing materials and then manually loading them into a mixer hopper inside a booth equipped with LEV. However, the scale used for weighing materials was located outside the booth. Additionally, the LEV system did not generate a sufficient exhaust rate (Document ID 0106, pp. 35, 49-54, 57, 74).

Exposure Profile and Baseline Conditions for Coatings Operators

The exposure profile in Table IV.4.15-B includes 18 samples for coatings operators. The median is 53 μg/m^3, the mean is 81 μg/m^3, and the range is 12 μg/m^3 (LOD) to 507 μg/m^3. Table IV.4.15-B shows that, of the 18 samples, 10 (55.6 percent) are above 50 μg/m^3 and 4 (22.3 percent) exceed 100 μg/m^3. All of the samples were obtained while workers used spray methods to apply silica-containing glazes onto pottery pieces. At all facilities from which sample results are available to OSHA, the spray operations took place in LEV-equipped booths; however, some of the booths were documented as performing poorly (Document ID 0106; 0143; 0211; 1365, p. 4-14).

Silica exposure levels are generally higher when workers use manual spray equipment, rather than automated equipment (Document ID 1365, p. 4-15). Automated processes tend to allow the worker to stand at a greater distance from the exposure source. Exposures occur primarily when particles of silica-containing coatings are released by pressurized spray nozzles, but fail to adhere to the pottery pieces and drift into coatings operators' breathing zones.

Table IV.4.15-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Pottery Industry (NAICS 327111, 327112, 327113)

	Exposure Summary			**Exposure Range**			**Exposure Profile**				
Pottery Industry	**N**	**Mean (µg/m³)**	**Median (µg/m³)**	**Min (µg/m³)**	**Max (µg/m³)**		**< 25 (µg/m³)**	**≥ 25 and ≤ 50 (µg/m³)**	**> 50 and ≤ 100 (µg/m³)**	**> 100 and ≤ 250 (µg/m³)**	**> 250 (µg/m³)**
Material Handler	*11*	*149*	*41*	*20*	*1,101*		*3 (27.3%)*	*3 (27.3%)*	*3 (27.3%)*	*1 (9.1%)*	*1 (9.1%)*
Forming Line Operator	*36*	*42*	*31*	*6*	*238*		*15 (41.7%)*	*10 (27.8%)*	*9 (25%)*	*2 (5.6%)*	*0 (0%)*
Finishing Operator	*10*	*26*	*21*	*10*	*55*		*6 (60%)*	*2 (20%)*	*2 (20%)*	*0 (0%)*	*0 (0%)*

4.15.3 Additional Controls

Material Handlers

The exposure profile in Table IV.4.15-B shows that 45.5 percent (5 out of 11 samples) of material handlers have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. These controls include LEV (including well-ventilated process equipment (e.g., mixers) and bag or loader dumping stations equipped with well-ventilated enclosures and, as needed, attached bag compactor); enclosed and ventilated cabs for front-end loaders; improved housekeeping; and automated transfer of silica-containing materials. Implementation of these controls might involve installing new equipment or improving existing equipment.

Local Exhaust Ventilation

Data presented in the exposure profile (Table IV.4.15-B) suggest that ventilated material transfer stations are associated with lower worker exposures. Although some results remain above the PEL of 50 μg/m^3 when workers have access to LEV described as functional, the results are markedly lower (median exposure level 85 μg/m^3) than when workers use material transfer stations where LEV is clearly inadequate or missing (median exposure level 133 μg/m^3). Adjustments that improve the ventilation system, changes in work practices (e.g., crushing empty bags or dumping materials from a loader scoop), and improved housekeeping (as discussed later in this section) will all further reduce material handler exposure levels.

During the first of two visits to a pottery facility, NIOSH noted that coatings preparers compressed bags, generating visible dust (Document ID 0209, p. 34). OSHA considers it likely that it is likely that the same practice was used by other workers, including material handlers, who also handled bags of raw materials in the same facility. Although no data exist for the pottery industry, in a paint manufacturing facility where workers emptied 50-pound bags of silica-containing materials, a bag-dumping station with fully functioning LEV and automated bag disposal was found to reduce silica exposure by at least 95 percent. After each bag is emptied, the worker releases it and suction automatically pulls the bag into the ventilation system and transfers it to an enclosed storage area (eliminating manual bag crushing) (Document ID 0199, pp. 7, 11, 12-13). As an alternative, ventilated bag compactors also eliminate manual bag crushing. Both bag dumping stations and bag crushing equipment are readily available from commercial sources (Document ID 0581; 0594; 0680; 1212; 1213; 1224). Ventilated hoppers for receiving materials transferred by front-end loaders can also be installed. OSHA expects that both types of ventilation systems will control silica exposures when designed according to ACGIH recommendations (Document ID 3883, p. 13-80 (VS-50-10 Bin & Hopper Ventilation).

Additionally, ventilation can be augmented along conveyor systems. Such control methods include covering conveyors and increasing ventilation at existing enclosed transfer points to meet the ACGIH recommended air velocity of 250 fpm/ft^2 across all openings in the enclosures (Document ID 3883, p. 13-81). OSHA has not identified specific examples from the pottery industry; however, in other industries that convey quantities of dusty silica sand, enclosed or pneumatic conveying systems are an effective part of comprehensive respirable dust management, which results in reduced exposure levels (see Sections IV-4.13 – Paint and Coatings and IV-4.21 – Structural Clay).

Enclosed Cabs

The use of well-ventilated cab enclosures for lift trucks or front-end loaders also can reduce exposure for material handlers. Although data documenting the effectiveness of such enclosures at pottery manufacturing facilities are not available, data from other sources suggest a 90 to 99.5 percent reduction in respirable dust (inside compared with outside the cab) with well-sealed, air-conditioned, and filtered cabs (Document ID 1365, p. 4-19). Operators working in heavy equipment cabs designed to meet the American Society of Agricultural Engineers' (ASAE) standard should experience exposure reductions in this general range (Document ID 0719, p. 51). Although these cabs require regular maintenance to function properly and concerns exist regarding the construction standards of new heavy equipment, OSHA expects that appropriately fitted and maintained cabs would offer an exposure reduction of at least 90 percent (the low end reported for larger equipment) for material handlers, including those using front-end loaders (Document ID 1365, p. 4-19).

Housekeeping

Poor housekeeping contributes substantially to worker exposure levels in material handling areas, and a thorough (professional-level) cleaning in association with improved housekeeping procedures (to maintain cleanliness) can reduce exposures where dust has been allowed to accumulate. For one material handler, poor housekeeping was reported as the primary source of silica exposure (Document ID 1436, p. 1). In the structural clay industry, another industry with similar material handling requirements, a thorough cleaning of a brick manufacturing facility dramatically reduced exposure levels (by 90 percent or more in some cases) for workers in areas where raw materials were transported or handled (raw material storage, near grinding equipment and conveyors, during bag dumping, and at raw material hoppers). In these areas, most worker exposures were reduced to less than 50 μg/m^3 without other abatement efforts (Document ID 1365, pp. 3-19—3-20, 4-2; 0571). In addition to regular housekeeping procedures, spillage of raw materials can sometimes be prevented by modifying conveyor belts (e.g., using troughed belts or V-rollers).

Automated Equipment

Samples at pottery manufacturing facilities with both manual and automated material transfer systems illustrate the effectiveness of the automated equipment. In one facility, exposure was almost 66 percent lower (29 μg/m^3 versus 85 μg/m^3) for a material handler tending automated equipment adding silica-containing raw materials to a mixer compared with a material handler manually adding bags of raw materials to the mixer (Document ID 1436, pp. 4, 27-35). Both workers were working in areas with functioning LEV (although the investigator's notation does not mean that the LEV was functioning optimally). At another facility, OSHA obtained a reading of 23 μg/m^3 for a material handler monitoring automated equipment to transfer dry silica sand from the storage silo and pump a slurry of ball clay and kaolin into a mixer (Document ID 0143, pp. 28, 44, 128-131).

Forming Line Operators

The exposure profile in Table IV.4.15-B shows that 30.6 percent (11 out of 36 samples) of forming line operators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Generally low exposures experienced by many forming line operators can be attributed to the fact that most materials are handled in a wet state and to the wide-spread use of LEV during the production phase. However, additional controls like those described above will reduce exposures for the nearly 31 percent of forming line operators whose exposure levels exceed 50 μg/m^3. Additional controls include improved or added LEV, eliminating the use of compressed air, using vacuums to remove residual clay from molds, and employing equipment that reduces the release of airborne dust when workers apply mold parting compound. A combination of these controls should be more effective in reducing exposures below the PEL than any one control alone.

Eliminating Use of Compressed Air for Cleaning

Changes in controls and work practices were implemented at one work site in order to reduce the exposure of forming line operators. The use of compressed air to clean molds was replaced with the use of a vacuum and abrasive pad. Additionally, the bags previously used to dust molds with talc (a parting compound containing trace amounts of silica) were redesigned to release talc from only one end in the direction of the molds. Primarily through the elimination of compressed air for cleaning, and despite uneven functioning of the LEV at two workstations, the facility reduced silica exposures substantially so that results for workers at these stations were below 40 μg/m^3. The ERG report suggested that exposures would have been lower still if the LEV were more effective (Document ID 0027, pp. 32, 186-189, 367; 1365, p. 4-23).

Finishing Operators

The exposure profile in Table IV.4.15-B shows that 20 percent (2 out of 10 samples) of finishing operators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Additional controls include improving maintenance of or modifying existing LEV and using wet methods to perform finishing operations, as discussed below.

Local Exhaust Ventilation

OSHA has obtained two sample results of 10 μg/m^3 and 55 μg/m^3 for finishing operators using LEV at a facility manufacturing sanitary ware. These samples represent the highest and the lowest exposures in the profile for this job category. The worker who experienced the exposure of 55 μg/m^3 spent the majority of an eight hour shift finishing greenware (unfired pottery) with steel wool in a ventilated booth. In addition, compressed air was used for dust removal which likely contributed to the elevated exposure (Document ID 0106, p. 74). The other worker used a grinder to square off the bottoms and backs of sanitary ware in a ventilated booth (Document ID 0106, p. 75). A study by NIOSH documented the use of a down-draft hood used in the dry finish of pottery (Document ID 1372). However, elevated results were seen due to the inadequate capture rate and the intensity of the sanding (Document 1372, pp. 6-8). OSHA anticipates that a properly designed and maintained system would have resulted in exposures at or below the PEL.

OSHA did not receive any additional data describing the use of ventilated booths to control exposures for this group of workers; however, exposure monitoring data from the foundry industry for cleaning/finishing operators provide good evidence that properly designed LEV systems can reduce exposure for pottery finishing operators. Like pottery finishing operators, foundry workers that perform similar work also use grinding equipment to remove residual silica material, typically a mixture of sand and clay, from castings. An OSHA SEP inspection report documents respirable quartz readings for foundry industry grinders of 56 μg/m^3, 80 μg/m^3, and 81 μg/m^3 (mean of 72 μg/m^3) (Document ID 0130, pp. 34). After installation of a downdraft dust collection bench, OSHA collected readings of 20 μg/m^3 and 24 μg/m^3 (mean of 22 μg/m^3) for two grinders (Document ID 1365, p. 4-24).[88] The downdraft benches were associated with a 69 percent

[88] OSHA described the system as a two-station Torit Model DDHV-45 Downdraft Bench dust collecting system designed to operate at 4,800 cfm. The system was 99 percent efficient for particles 1 micron or larger, used 51 cotton sateen filter bags, and provided 255 square feet of filter media (Document ID 1365, p. 4-24).

reduction in mean silica concentration. Exposure levels also decreased when the foundry added LEV to bench grinders. ACGIH (2010) typically offers recommended designs for booths and other ventilation-based engineering controls (Document ID 0515, pp. 13-1-13-204.

OSHA did not receive any data that demonstrate the effectiveness of using LEV-equipped tools by finishing operators in the pottery industry. However, based on the successful implementation in other industries, OSHA expects that tool-mounted LEV systems for handheld grinding equipment can be helpful for reducing exposure. In the construction industry, a tool-mounted LEV system operating at 70 cubic feet per minute (cfm) (consisting of a grinder-mounted shroud, a 2-inch diameter flexible hose, and an industrial vacuum equipped with a cyclone and a high-efficiency particulate air [HEPA] filter) reduced silica exposure substantially (Document ID 0613, pp. 3-5). OSHA notes that in this study of handheld grinding in construction both the uncontrolled and controlled silica exposure levels were extremely high during 15-minute periods of intensive grinding. OSHA expects that tool-mounted LEV in the pottery industry, where peak exposures for finishing operators are not as extreme (among the data available to OSHA, 55 $\mu g/m^3$ is the maximum value for this job category), could reduce exposures to the PEL of 50 $\mu g/m^3$ or less even if the same percentage reduction is not attained. Indeed, recent information regarding tuckpointing grinders (angle grinders used to remove mortar between bricks, historically among the construction tasks for which silica dust is most difficult to control) suggests that lower exposure levels (less than 50 $\mu g/m^3$ under certain conditions) can be achieved with these and other tools with LEV when workers are equipped with more powerful vacuums that provide greater LEV airflow and suction over an extended work period than traditional shop vacuums (Document ID 0600; 0731).

Based on this information, OSHA has determined that tool-mounted LEV can provide exposure reductions to levels of 50 $\mu g/m^3$ and less for finishing operators in the pottery products industry when LEV shrouds and vacuum systems are correctly matched to the grinding tools. For additional dust control, tool-mounted LEV can also be used in conjunction with ventilated downdraft tables or booths.

Wet Methods

Exposures also can be reduced by performing finishing operations on pottery pieces that are still slightly damp instead of dry, because silica particles are less likely to become airborne when pieces are wet (Document ID 0209, pp. 23-27, 47; 0106, p. 72). Wet finishing operations can be conducted using sponges and abrasive pads, or by moistening the outer layer of the pottery prior to abrading it. Operators also might perform finishing tasks on a piece that has not completely dried. Exposure levels were more than two times higher when operators finished fully dried pottery pieces compared with partially dried pieces with slight moisture content (Document ID 0106, p. 74 (53 and 55 μg/m^3); 0174, pp. 90-95 (22 μg/m^3)).

The other wet finishing process option, wet sanding of dried pottery, is similar to a process used in the construction industry. Drywall finishers using a damp abrasive sponge experience a 60 percent reduction in respirable dust levels compared with dry sanding (Document ID 1239). OSHA expects that pottery grinders would receive similar benefits in reducing respirable dust and that silica would be reduced proportionally. Although moistened pieces would likely require additional drying time, drying time would still be less than for the original wet casting because only the surface layer of clay would be dampened (Document ID 1365, p. 4-26).

Coatings Preparers

The exposure profile in Table IV.4.15-B shows that 83.3 percent (10 out of 12 samples) of coatings preparers have exposures above the final PEL of 50 μg/m^3; these overexposures came from each of the six facilities evaluated sampled. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. The available information suggests that some LEV is often present at pottery facilities, but in most plants the LEV is applied to only a portion of the potentially dusty operations. As further explained below, control options include consistent use of bag dumping stations equipped with well-ventilated enclosures and ventilated bag disposal equipment, ventilated mixing equipment, and improved housekeeping. Reducing reliance on compressed air for cleaning also will help limit exposures. Implementation of these controls might involve installing new equipment or improving current equipment with ventilation systems.

Local Exhaust Ventilation

To reduce coatings preparer exposure levels to at or below the PEL or, in some cases, to the lowest levels feasible above the PEL, workers must make all raw material transfers within ventilated enclosures or use equipment fitted with effective LEV. The effectiveness of such ventilation controls was demonstrated at a pottery manufacturing plant where a coatings preparer used a ventilated booth (with low airflow) to empty bags of powdered raw materials into a hopper, but also used a weigh scale outside the booth to measure some ingredients. An initial exposure value of 143 $\mu g/m^3$ was reduced to 40 $\mu g/m^3$ and 51 $\mu g/m^3$ after the baghouse ventilation system was repaired (Document ID 106, pp. 41-44). A consultant evaluating the plant during the second (post-repair) sampling date recommended that silica at this facility be reduced to its lowest possible level by taking additional steps such as limiting use of compressed air for cleaning (suggesting that compressed air was still used regularly in the plant after the ventilation system was repaired) (Document ID 0106, pp. 8, 28, 34-40, 71-72). In this example, the workers' exposure levels were reduced to approximately one-third of the original value (i.e., from 143 $\mu g/m^3$ to 40 $\mu g/m^3$ and 51 $\mu g/m^3$) simply by repairing the existing ventilation system (Document ID 0106, p. 54).

OSHA concludes that exposures could have been reduced further if the facility had taken two additional steps: 1) moving the weigh scale into the booth (or adding exhaust ventilation to the scale area), and 2) reducing reliance on compressed air for cleaning. As discussed below, exposure levels can be greatly reduced by both these modifications.

A dramatic reduction in exposure was recorded at a facility where previously OSHA had obtained the highest result for a coatings preparer. At the time of the original sample, this worker manually lifted bags of raw materials and, from a position on a platform, dumped them into an unventilated mixer in an area where another dusty operation also took place (Document ID 0174, pp. 72, 84). As part of a four-part abatement plan, the facility made substantial changes to the way materials were handled during coating production. After hiring engineering consultants to evaluate the areas where OSHA found elevated exposure, the facility installed two new dust collector systems in the glaze-making area. These included one hood under which the worker now filled a portable hopper with measured raw materials and another hood at the hatch of the ball mill into which the materials were poured. To minimize ergonomic stress, the filled hopper was lifted by a mechanical hoist to the overhead platform (level with the mill hatch) and emptied into the mill. Equipment leaking dust in other parts of the plant were also repaired. After these changes had been made (but prior to a planned comprehensive cleaning of the area) a consultant obtained a silica result of 47 $\mu g/m^3$ for a coatings preparer. A general area sample also collected in the glaze-making area resulted in a respirable quartz concentration of 34 $\mu g/m^3$ (Document ID 0174, pp. 234-235, 241, 249, 254).

The value of ventilated bag dumping systems was discussed previously with respect to material handlers where it was noted that workers using a bag-dumping station (with ventilated bag disposal equipment) in a paint manufacturing facility experienced silica exposure reductions of at least 95 percent (from 263 $\mu g/m^3$ to 12 $\mu g/m^3$). A second type of bag-dumping station equipped with an enclosure, empty bag compactor, bag disposal chute, and LEV system also was found by NIOSH to effectively control dust released during bag opening, emptying, and disposal (Document ID 1369, p. 1). As noted previously, ventilated bag-dumping stations and ventilated compactors are readily available from commercial sources (Document ID 0581; 0594; 0680; 1212; 1213; 1224).

Eliminating Use of Compressed Air for Cleaning

As noted in the discussion of additional controls for pottery industry forming line operators, a pottery facility visited by OSHA eliminated use of compressed air for removing dust from pottery pieces, substituting a vacuum instead. Despite uneven functioning of the LEV at two workstations, this modification reduced silica exposures to below 50 $\mu g/m^3$.

Housekeeping

Although there are no data describing the efficacy of housekeeping measures in the pottery industry, exposure monitoring data from the structural clay manufacturing industry provide strong evidence that housekeeping measures can reduce exposures for coatings preparers in the pottery industry. In the structural clay manufacturing and pottery industries, the same exposure reduction challenges arise for workers who transfer and mix sand and other coatings or glaze ingredients. OSHA concludes that coatings preparers in the pottery industry would benefit equally from housekeeping measures, based on the similarity in raw materials used in the structural clay and pottery industries (quartz sand and powdered silica-containing materials).

For example, in the china manufacturing facility at which the highest coatings preparer result was recorded (983 μg/m^3), the four-phase exposure abatement program included a thorough cleaning of all surfaces in the area where workers blend coatings (Document ID 0174, pp. 84-86, 249). This phase had not been completed at the time of the last results available to OSHA from this facility (47 μg/m^3, as presented in the discussion of LEV for coatings preparers) (Document ID 0174, pp. 234-235, 241, 249, 254). Based on the experience in the structural clay manufacturing industry (Document ID 1365, pp. 3-19 - 3-20, 4-2; 0571) OSHA expects that the silica exposure of this pottery industry coatings operator would have been even lower after the planned cleaning.

Coatings Operators

The exposure profile in Table IV.4.15-B shows that 55.6 percent (10 out of 18 samples) of coatings operators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. As explained below, additional controls include the use of low-silica coatings; well-enclosed, well-ventilated booths; and well-enclosed, well-ventilated automated coatings application machinery. Implementation of these controls might involve installing new equipment or improving current equipment to improve enclosure and ventilation.

Local Exhaust Ventilation and Automation

Well-ventilated, well-enclosed booths for coatings application can reduce worker exposure. The effectiveness of this method is demonstrated by exposure monitoring data obtained at a facility visited twice by NIOSH (Document ID 0211; 0209). During the initial site visit, silica sample results of 113 μg/m^3, 125 μg/m^3, 152 μg/m^3, 192 μg/m^3, 195 μg/m^3, 253 μg/m^3, 259 μg/m^3, 319 μg/m^3, and 434 μg/m^3 were obtained for operators on the semiautomatic spraying line (manual spraying of pieces mechanically transported through the booth[s] on this line) (Document ID 0209, pp. 55-56). The facility then improved the booths by repairing holes or openings that could allow particles to escape or decrease the efficiency of the LEV systems by disrupting airflow. After repairs to the booths and ventilation system, silica exposure levels were one reading of 22 μg/m^3 (the LOD in this case), three readings of 23 μg/m^3 (the LOD for these samples), and one reading of 66 μg/m^3 (Document ID 0211, p. 33). The facility also made improvements to the LEV system to increase airflow rates in the booths, which significantly reduced respirable silica exposures. NIOSH returned to evaluate operator exposure and collected five samples. On the same semiautomic spraying line, four of the five results (80 percent) were less than the LOD (less than 25 μg/m^3 in each case), and one result was 66 μg/m^3 (Document ID 0211, pp. 32-33).

The facility made similar repairs to two other spraying lines (one fully manual and the other fully automatic), which also reduced worker exposure levels, generally 70 to 90 percent (Document ID 0211, pp. 9, 21-22, 32-33). However, NIOSH noted that even after ventilation system upgrades on the fully manual line, workers used compressed air to blow dust off pottery pieces prior to applying glaze and likely contributed to worker silica exposure levels (this practice had been eliminated from the semiautomatic line by providing workers with damp sponges to remove dust from the pottery pieces) (Document ID 0211, pp. 9, 21-22). OSHA finds that additional exposure reduction will be possible by eliminating use of compressed air for removing dust from pieces (switching to vacuum system or damp sponges), making additional adjustments to further enclose the spray lines (particularly the fully automated line), reducing overspray through careful work practices and using modern high-volume-low-pressure (HVLP) spray nozzles, and limiting worker exposure while adjusting spray machines.

OSHA found in the technological feasibility analysis for the standard on hexavalent chromium that paint spray booths intended for small and medium-sized parts (including the sizes of pottery pieces, but excluding large objects the size of aircraft) are capable of controlling worker exposure to hexavalent chromium (a component of paint present in some pigment particles) to levels well below that PEL of 5 μg/m^3 (one-tenth the silica PEL of 50 μg/m^3). Spray booths were found to be an effective control even for paint containing greater than 10 percent chromate (Document ID 0934, p. III-142). OSHA finds that well-designed and effectively maintained spray booths are equally effective for silica particles in glazes as they are for chromate-containing paints. In demonstrating the effectiveness of spray booths for silica-containing coatings, OSHA notes that glazes can be 30 or more percent quartz. However, this higher percent silica is offset by the less restrictive PEL for silica compared with hexavalent chromium. Although the level of chromate (hexavalent chromium) in the paints discussed above is three times lower than the amount of silica in the pottery industry coatings, the hexavalent chromium PEL is also 10 times lower than the PEL of 50 μg/m^3 for silica. Thus, OSHA concludes that spray booths will protect pottery industry coating operators from excessive silica exposure at least as well as the booths protect painters from chromates.

Automation offers another exposure control option for coatings operators. As shown in Table IV.4.15-B, among all data available to OSHA for this job category, coatings operator silica exposure levels are dramatically lower for workers tending automated equipment than for those using manual processes. Workers in this job category will also benefit from improved housekeeping.

4.15.4 Feasibility Finding

Based on the exposure profile in Table IV.4.15-B and other record evidence discussed above, OSHA finds that the standard is technologically feasible for the different categories of pottery workers in pottery facilities and additional controls previously discussed are used. OSHA received no comments during the hearings on its preliminary findings presented in the PEA that feasible controls can be implemented in the pottery industry to achieve the final PEL of 50 μg/m^3. Evidence in the rulemaking record, as reflected in Table IV.4.15-B, however, reflects that maximum exposures under baseline conditions for material handlers, forming line operators, finishing line operators, coating preparers, and coating operators in the pottery industry have exceeded the final PEL of 50 μg/m^3, and mean and median exposures for these job categories are also generally above the PEL. Therefore, OSHA has determined that additional controls will be required. As discussed above for each job category, control options include local exhaust ventilation, use of bag dumping stations equipped with well-ventilated enclosures and ventilated bag disposal equipment, ventilated mixing equipment, and improved housekeeping. Reducing reliance on compressed air for cleaning also will help limit exposures. Implementation of these controls might involve installing new equipment or improving current equipment. OSHA concludes that the controls described above can effectively reduce silica exposure levels to 50 μg/m^3 or less for most operations, most of the time, in the pottery production industry.

Furthermore, OSHA concludes that silica exposure levels of 50 μg/m^3 or less are already achieved for most workers at smaller pottery operations that use a relatively small amount of raw materials and clay. The results obtained by NIOSH at such a shop did not exceed the final PEL of 50 μg/m^3 despite the lack of LEV (Document ID 0878). If elevated exposures do occur, the same control methods available to larger facilities, including (LEV, wet methods, and improved housekeeping, can be instituted on a smaller scale to achieve compliance with the final PEL.

Thus, OSHA concludes that, with the exception of coatings preparers and operators, most workers at pottery facilities are currently exposed to silica levels at or below 50 μg/m^3. For workers who are currently exposed above 50 μg/m^3, the engineering and work practice controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or less in most operations, most of the time. Therefore, OSHA finds that the final PEL of 50 μg/m^3 is technologically feasible for the Pottery industry.

4.16 RAILROADS

4.16.1 Description

Railroad track maintenance-of-way workers are responsible for maintaining the overall surface of the roadbed including the rails, ties, and ballast (crushed rock), and other components associated with the railroad track right-of-way. Potential exposure to silica-containing dust may occur during maintenance activities involving both the manual and automated manipulation of ballast (Document 2318, p. 8). This application group is classified in the six-digit North American Industry Classification System (NAICS) codes as 482111, Line-Haul Railroads, and 482112, Short Line Railroads (Document ID 1365, p. 12-1).

Railroad track is most often supported by a bed of material called ballast. Ballast transmits and distributes the load of the track and rolling equipment evenly across the roadbed; controls movement of the track; helps maintain proper track cross-level, surface, and alignment; and provides drainage for the track. Today, most railroads use crushed stone, especially granite, traprock, and limestone or slag for ballast on main-line tracks. In 2001, granite containing 25 to 40 percent silica accounted for approximately 46 percent of the total crushed stone sold for railroad ballast within the United States (Document ID 1365, p. 12-1). Potential exposure to silica-containing dust occurs when silica-containing ballast is dumped or otherwise manipulated during track maintenance activities (Document ID 2318, p. 8).

The two major functional job categories associated with potential silica exposure during track maintenance are 1) workers known as “ballast dumpers” who work outside cabs of on-track roadway maintenance machines and 2) operators of these machines (Document ID 1365, pp. 12-2 - 12-7). Table IV.4.16-A presents job activities and the major sources of exposure for affected job categories.

As explained in this FEA section on Federal Rules Which May Duplicate, Overlap or Conflict with the Final Rule in Chapter IX, Final Regulatory Flexibility Analysis, OSHA has general regulatory and enforcement authority to address silica exposures of railway workers. The OSH Act, however, precludes the Agency from promulgating standards in areas over which another federal agency exercises statutory authority. Section (4)(b)(1), 29 USC 653. Effective September 26, 2003, the Federal Railroad Administration (“FRA”) amended the Railroad Workplace Safety regulations, 49 CFR Part 214, to require that new and employer-designated existing on-track roadway maintenance machines (“FRA-covered RMM”) be equipped with, among other things, positive pressurized ventilation systems, and be capable of protecting employees in the cabs of the machines from exposure to air contaminants (including silica) in accordance with the OSHA Air Contaminants standard, 29 CFR 1910.1000. 49 CFR 214.505. The FRA did not require retrofitting FRA-covered RMM manufactured before 1991 based on a decision that such retrofitting would be too costly and impose an undue burden on small employers, which are the primary users of such older machines. 68 FR 44405. In contrast to this negative exercise of jurisdiction over "grandfathered" RMMs, the FRA made it clear

> that it is not adopting those OSHA standards that include protection from silica dust for employees not working inside the cabs of on-track roadway maintenance machines covered by this section. The extent of FRA's adoption of OSHA standards in this section reaches only as far as the cab of the covered on-track roadway maintenance machine. As a result, when working inside the cab, workers receive protection from FRA; when working outside the cab, workers receive protection from OSHA.

68 FR 44393-44394. Section 214.501 of 49 CFR states that any working condition involving the protection of railroad employees engaged in roadway maintenance duties but which is not specifically addressed in the subpart continues to be governed by the OSHA regulations (49 CFR 214.501; 68 FR 44391 (2003)).[89] Thus, this feasibility analysis primarily examines protections for worker exposure outside the cab, including ballast handling (e.g., dumping) or other track maintenance or construction activities along right-of-ways.

[89] FRA also clarified that “when OSHA revises the standards, FRA will enforce the revised standards on those machines over which FRA has jurisdiction.” 68 FR 44393.

Table IV.4.16-A Job Categories, Major Activities, and Sources of Exposure in the Railroads Industry (NAICS 482111 and 482112)	
Job Category*	**Major Activities and Sources of Exposure**
Ballast Dumper	Walks alongside moving ballast cars and manually or automatically (via radio remote control) opens hopper doors on moving ballast cars and dumps ballast alongside the track. • Dust generated when dry ballast falls from hopper cars.
Machine Operator	Operates heavy equipment used for track bed surfacing activities. Includes the ballast regulator to level, shape, and dress ballast, the mechanical broom to sweep tracks, tamper machines to pack down ballast under the ties, undercutter machines to lift ties and scoop out existing ballast from underneath, and rotary scarifiers to break up or loosen the track bed surface. • Dust generated during direct manipulation of the ballast.
*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility. Source: Document ID 1365, pp. 12-2—12-7; 2318, p. 8; 2366, p. 4; 3583, Tr. 2388	

4.16.2 Exposure Profile and Baseline Conditions

OSHA evaluated the silica exposures of workers in the railroad transportation industry by reviewing full-shift personal breathing zone (PBZ) respirable quartz exposure monitoring data from two NIOSH reports (Document ID 0882; 0884). These monitoring results are presented in the exposure profile Table IV.4.16-B. Full-shift area samples reported in these studies are also discussed. In preparing the FEA, OSHA searched the inspection data recorded in OSHA Information System (OIS) and other information submitted to the rulemaking record, but no additional monitoring data on railroad worker exposures were identified (Document ID 3958). The results presented in Table IV.4.16-B differ from the PEA in that ten sample results for machine operators were adjusted. One ballast dumper experienced cristobalite exposure of 50 μg/m^3 in addition to 90 μg/m^3 quartz exposure, for a total silica exposure level of 140 μg/m^3. Nine other sample results for machine operators were adjusted due to an inconsistency in the method used in the PEA to report the limit of detection (LOD) or limit of quantification (LOQ). These values have been corrected to the appropriate LOD or LOQ value as reported in the original NIOSH reports.

Exposure Profile and Baseline Conditions for Ballast Dumpers

The exposure profile in Table IV.4.16-B includes 26 samples for ballast dumpers. The median exposure is 25 µg/m^3, the mean is 68 µg/m^3, and the range is 11 µg/m^3 (LOD) to 370 µg/m^3. Of the 26 samples, 6 (23.1 percent) are above 50 µg/m^3, and 4 (15.4 percent) exceed 100 µg/m^3. These results come from a single NIOSH report issued in 2001 (Document ID 0884, pp. 13-20).

NIOSH investigators reported that some ballast was wet because the railroad company required that ballast be washed at the quarry before being loaded into hopper cars. Although some ballast was observed to be wet as it was dumped, pockets of dry ballast were still a source of dust. In general, most cars loaded with ballast were observed to be dry, and dust was created when the ballast was dumped (Document ID 0884, p. 4). A contact familiar with the industry (Mine Safety and Health Administration, 2003) reported that ballast material is not typically washed by quarries on a regular basis and washing likely depends on the size of the quarry operation as well as the tonnage of the ballast order (Document ID 0820).

The samples included in Table IV.4.16-B were gathered under a range of conditions and reflects the best available evidence of the exposures of ballast dumpers. The exposure profile reflects all data identified for this sector through literature searches performed in the development of the PEA, and no other data was submitted to the rulemaking record. OSHA considers the exposure profile in Table IV.4.16-B to represent the baseline conditions for ballast dumpers (Document ID 1365, p. 12-8)

Exposure Profile and Baseline Conditions for Machine Operators

The exposure profile in Table IV.4.16-B includes 100 samples for machine operators in railroad yards. The median exposure is 40 µg/m^3, the mean is 73 µg/m^3, and the range is 9 µg/m^3 (LOD to 440 µg/m^3). Of the 100 samples, 38 (38 percent) are at 50 µg/m^3 or above, and 19 (19 percent) exceed 100 µg/m^3. The samples in the exposure profile come from full-shift respirable quartz readings in two NIOSH reports. The exposure data described in the first of these reports were collected in 1991 (Document ID 0882, p. 1). Data described in the second NIOSH report were collected between 1993 and 1997, while the employer was in the midst of implementing a cab retrofit program to control operator exposures to silica (Document ID 0884, pp. ii and 3).

Neither report differentiated between workers who engaged in activities outsides of the cab and operators who worked exclusively inside the cab. The first report (Document ID 0882) describes two sets of workers: Track Maintenance (TM) crews (described as "pick and shovel") and Timber and Surfacing (T&S), which use mechanized equipment. Specific job titles are listed in Table 1, page 25, and correspond to the "machine operator" job description. The report states on page 6 that TM crews often assist T&S crews, and may often perform similar functions as machine operators. In the second report (Document ID 0884), NIOSH states "Although some operators walk with their machines, most are seated upon the machine–many within enclosed cabs." All are classified as "machine operators."

The data in the record do not include sufficient information on which OSHA could distinguish between the levels of exposure for workers inside a cab that is not enclosed as opposed to workers elsewhere on the machine or on the ground, nor does it suggest that the exposures of workers on the ground would be higher or lower than those on the machines without enclosed cabs (other than the possibility that it may be easier for employees on the ground to distance themselves from the source of the exposure). In fact, the maximum and minimum exposures recorded for a ballast dumper, which is defined as a person walking on the ground, are nearly identical to those of the operators of ballast dumper regulator machines who are typically on the machines. The majority of the significant potential exposures to TM or T&S crews on the ground results from the same silica exposure-generating activities to which employees on the machines are exposed. Therefore, OSHA refers generally to the entire group of maintenance of way workers (excluding the ballast dumpers, who are addressed separately) as "machine operators" and divides them into two categories for the purpose of making technological feasibility determinations: exposure while working inside a cab, and exposure while working outside the cab (including in the absence of any cab). Because of FRA jurisdiction over workers inside cabs (as well as workers on "grandfathered" machines without cabs), exposure while working outside cabs is of primary interest for the purposes of this OSHA standard.[90]

In addition to the 100 PBZ samples included in the exposure profile for machine operators, NIOSH also reported results of area samples taken on several types of heavy equipment. Twenty-seven full-shift (i.e., greater than 360 minutes duration) area respirable silica readings were collected during the use of ballast regulators, brooms, tampers, and a scrap buggy. Samples were taken either inside the cab or within approximately three feet of the operator’s PBZ. Results range from below the limit of detection (11 µg/m^3 to 32 µg/m^3, depending on the sample) to 140 µg/m^3, with a median of 50 µg/m^3 and a mean of 54 µg/m^3 (Document ID 0882, pp. 25-30; 0884, pp. 12, 14). Thirteen results (48 percent) exceed 50 µg/m^3 (although four of these were below the limit of quantification) and three results (11 percent) exceed 100 µg/m^3. An additional very high reading of 2,040 µg/m^3 quartz was associated with a less-than-full-shift (225 minute) area sample on a back broom (Document ID 0882, pp. 13, 30). Although these area samples are not direct measures of worker exposure, and are not included in the exposure profile, they illustrate the potential for significant reductions in exposure. The personal samples are much lower than the area samples, indicating that increased distance from the point of exposure reduces the level of the exposure. The NIOSH authors note that the personal sample for the broom operator on this machine was much lower (110 µg/m^3) because the worker attempted to stay upwind of the broom and dust cloud, and that this very high fixed area reading for this machine demonstrates the potential worker exposures that could occur for an operator working on a machine, suggesting that this machine may have been remotely operated (Document ID 0882, p. 13).

A report by Tucker et al. (1995) confirms the potential for overexposure among maintenance-of-way operators of older machines, most of which are likely without enclosed cabs and may therefore provide a more accurate reflection of exposures for operators outside the cabs (even though operators of the older, "grandfathered" machines

[90] While OSHA does not have authority to require retrofit of track maintenance machines with protective cabs, the 50 µg/m^3 PEL will apply, both to workers under OSHA jurisdiction, and those under FRA jurisdiction.

fall within the FRA's jurisdiction). Twenty percent of 81 full-shift PBZ samples collected on ballast regulator and broom operators were greater than 100 μg/m^3 (the American Council for Government Industrial Hygienists Threshold Limit Value (TLV) for respirable silica at that time). The machine type showing the highest percentage of operator exposures exceeding the TLV were track broom operators. While the study authors do not describe the factors that may lead to the high proportion of track broom operators experiencing elevated exposures, they do recommend that these machines be retrofitted for remotely controlled operation to reduce exposures (Document ID 1188, pp. 1083 - 1085).

Upon consideration of the evidence available in the rulemaking record, including the two NIOSH reports, the study by Tucker et al., and comments submitted to the record, OSHA has determined that the NIOSH sampling results are the best available evidence of ballast dumper and machine operator exposures. These results are reflected in the Final Exposure Profile, Table IV.4.16-B below.

Table IV.4.16-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Railroads (NAICS 482110, 482111, 482112)

	Exposure Summary			Exposure Range		Exposure Profile				
Railroads	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**	**< 25 (μg/m³)**	**≥ 25 and ≤ 50 (μg/m³)**	**> 50 and ≤ 100 (μg/m³)**	**> 100 and ≤ 250 (μg/m³)**	**> 250 (μg/m³)**
Ballast Dumper	*26*	*68*	*25*	*11*	*370*	*13 (50%)*	*7 (26.9%)*	*2 (7.7%)*	*2 (7.7%)*	*2 (7.7%)*
Machine Operator (Ballast Regulator)	38	91	45	9	370	8 (21.1%)	13 (34.2%)	8 (21.1%)	4 (10.5%)	5 (13.2%)

4.16.3 Additional Controls

Additional Controls for Ballast Dumpers

The exposure profile in Table IV.4.16-B shows that 23.1 percent (6 of 26 samples) of ballast dumpers have silica exposures above 50 μg/m^3. Although 50 percent (13 of 26 samples) are exposed at less than 25 μg/m^3, OSHA concludes that additional controls will be needed for the overexposed ballast dumpers. These controls include substitution with low-silica or silica-free ballast material, use of dust suppression, and improved work practices in conjunction with remotely controlled dumping. In testimony during public hearings, Mr. Lamont Byrd speaking on behalf of the Brotherhood of Maintenance of Way Employees Division (BMWED) of the Teamsters Rail Conference (International Brotherhood of Teamsters, IBT) supported the conclusion that implementing these controls was technologically feasible. He stated as follows:

> The BMWED Teamsters believes that engineering controls required for certain roadway maintenance machines, in addition to controls such as wetting down ballast cars prior to unloading and using remote operation dump doors on ballast cars, are feasible controls to reduce silica exposure for all workers in the railroad industry (Document ID 3581, Tr. 1610).

In written comments, he further described "quarrying methods or processes that reduce the overall content of respirable silica in ballast" as an additional feasible control strategy (Document ID 2318, p. 4).

Substitution

The silica released during ballast dumping depends in part on the silica content of the ballast material. Ballast material with high silica content (e.g., granite, sandstone, quartzite) will generate dust with high silica content, whereas ballast material with low silica content (e.g., slag products, low-silica limestone[91]) will generate dust with reduced silica content. Slag products are reported to contain less than 1 percent silica, and the

[91] The silica content in limestone can vary greatly. Low-silica limestone silica content generally ranges from < 1 to 9 percent silica, while high-silica limestone silica general ranges from 9 to up-to 67 percent (Document ID 1365, p. 12-2).

FRA specifically permits crushed slag as a suitable material for ballast (Document ID 0388; 0693, pp. 5.56, 6.47).[92]

Objecting to the use of limestone as a substitute ballast material, the Association of American Railroads (AAR) and the American Short Line and Regional Railroad Association (ASLRRA) jointly commented that the use of limestone as a substitute would create safety hazards:

> Limestone is not nearly as strong as granite and limestone ballast does not drain as well as granite ballast. Prior use of limestone ballast by one AAR member, dating back to the late 1970's, produced unsatisfactory results, due to poor drainage (i.e., mud and cementing) which necessitated yearly resurfacing of the track bed. Additionally, a more frequent resurfacing program creates additional potential exposure of employees to silica * * * Poor drainage also affects walking conditions, creating potential hazards for rail employees to sustain injuries from slipping, tripping, and falling. Finally, a weakened track structure could jeopardize the safe operation of trains, which * * * can cause derailments * * * (Document ID 2366, p. 6).

AAR and ASLRRA comments imply that OSHA proposed the removal and replacement of granite ballast that is currently in place on railway road beds, and go on to describe the costs of replacing the granite ballast that is currently installed (Document ID 2366, pp. 6-7). In fact, OSHA proposed only that lower silica alternatives to granite be considered for ballast installed after the standard's effective date. Limestone and other materials already account for a significant percentage of ballast. In 2001, limestone accounted for 16 percent of crushed stone sold for railroad ballast, while granite accounted for less than half (Document ID 1365, p. 12-2). An additional 26 percent of ballast used in 2001 was composed of other low silica crushed stone, namely, traprock and dolomite (Document

[92] A NIOSH-sponsored study evaluated the dust generated when various materials (including several types of slag) were used as grit for abrasive blasting. This study concluded that, while low in silica, the dust from slags "have substantially higher levels of some other health-related agents (metals), as compared to silica sand" (Document ID 0773, pp. iii and, 90). Because ballast-handling can also generate airborne dust, OSHA notes that when low-silica aggregates such as slag are used as ballast, employers must evaluate the need to protect workers from other contaminants.

ID 1365, p. 12-2).[93] OSHA is not suggesting that limestone can safely be used for all installations. However, these data clearly demonstrate that the use of certain low-silica limestone and other low silica ballast is currently in use and therefore feasible in a great many instances, without compromising track safety.

Engineering Controls in Conjunction with Work Practices

Remote operation of hydraulic dump doors on ballast cars has the potential to limit worker exposure to silica during ballast dumping, as well as reducing the risk of personnel injury. Radio remote controls for ballast cars are commercially available (Document ID 0583; 0584; 0884, pp. 3-4). However, this control does not eliminate the dust at its source, and is only effective when workers are able to maintain distance from the dumping operation, and stay upwind in order to avoid dust clouds generated during dumping. NIOSH noted that this may be challenging in narrow right-of-ways (Document ID 0884, p. 4). However, no comments were received in the record indicating that worker distancing and remotely controlled ballast dumping operations are not technologically feasible. OSHA concludes that workers should almost always be able to move up or down the length of the track to avoid the dust source, and can, with proper controls, become proficient at remote monitoring of ballast dumping operations from an increased distance.

In hearing testimony, BMWED described remote operation of ballast dump doors, as well as wetting down of ballast cars prior to unloading, as "feasible * * * to reduce silica exposure for all workers in the railroad industry" (Document ID 3581, Tr. 1610). Industry representatives did not so much contest the feasibility of the dust control method as the cost. Ms. Yurasko, representing AAR and ASLRRA, noted in written comments that "some of the Class I railroads utilize GPS technology to conduct ballast dumping operations remotely, virtually eliminating employee exposure to silica dust for these

[93] 1,400,000 metric tons of limestone, and 4,090,000 metric tons of granite were used that year. This figure includes both high silica and low silica limestone. However, since the ASLRRA / AAR comments do not draw any distinction between the suitability of high versus low silica limestone, OSHA concludes that use of low silica limestone is suitable. Several other types of crushed stone were also reported to be used in 2001, including two with lower silica content than granite - traprock (1,940,000 tons, 1-12 percent silica), and dolomite (355,000 tons, 0-3 percent silica) (Document ID 1365, p. 12-2).

operations" (Document ID 2366, Attachment 1, pp. 2-3). But, Ms. Yurasko noted, the GPS technology for remotely controlled dumping is not widely used by smaller railroads due to its cost; one railroad representative estimated a cost of $6,000 per day to contract the use of a GPS ballast train (Document ID 2366, p. 3, 5).

No quantitative exposure reduction data regarding worker positioning in relation to ballast dust are available in the record. Nonetheless, OSHA concludes that upwind positioning from dust caused by dumping ballast is often feasible and that exposures will be reduced when workers do not position themselves within or downwind of silica-containing dust clouds (see also Document ID 1720, p. IV-281; 1365, p. 12-17).

Dust Suppressants

Washing ballast before it is loaded into hopper cars reduces the amount of fine particulate matter generated during dumping. In other industries like asphalt paving products (see Section IV-4.1 – Asphalt Paving Products) the use of washed sand results in silica exposures that are generally lower than when sand is not pre-washed, and increased moisture content decreases the amount of dust generated. Water sprays should be applied to material before it reaches a transfer point so that the dust has time to absorb the water. Washing ballast would help achieve both of these goals, i.e., reducing the amount of fine (respirable) particulate present in the ballast, and suppressing airborne dust generated during dumping (Document ID 1365, p. 12-16).

Since ballast wetted at the supplier's site might dry prior to reaching the dumping site, one option to reduce evaporation is to apply an additional layer of blanketing foam or other sealing chemical suppressant to the top of the rail car at the load-out station. This chemical sealant system has been used effectively by a quarry to eliminate dust emissions during transit, and is commercially available for sealing open rail cars in the United States (Document ID 0635; 0809, p. 2). A number of other types of long-acting chemical suppressants have been used effectively for dust suppression in other industry sectors, such as mining, abrasive blasting, and on unpaved roadways (Document ID 1360, pp. 1-2; 0773, p. 45; 0516, pp. 109 - 110; 1540, pp. 64-65, 253-256). Water with surfactant could be used effectively at the point of ballast dumping (Document ID 1360, pp. 1-2).

Although OSHA is unaware of commercially available original equipment options including spray systems that are specifically designed for dumping ballast from rail cars, mobile rock-crushing and mining equipment, are equipped with spray nozzles and connectors are commercially available (Document ID 0770, p. 2). OSHA estimates that a directional mist applied during dumping activities could reduce exposures by over 70 percent (Document ID 1365, pp. 12-16 – 12-17). The NIOSH Dust Control Handbook for Industrial Minerals Mining and Processing provides schematics for water spray application for "typical loader dump dust control application" and also describes electronically controlled self-contained water delivery systems that can automatically adjust the liquid flow rate in response to changes in dust loading, to optimize dust control (Document ID 1540, pp. 69, 71).

Similarly, in brick manufacture, NIOSH described use of a citrus-based foam surfactant suppressant system installed on a conveyor supplying shale to a loading hopper (Document ID 0239, p. 8). Anthony Bodway of the National Asphalt Pavement Association noted that, for asphalt milling machines, water spray treated with surfactant are effective, and described a study showing that water treated with a foaming agent that reduced exposures four to five times more than water aerosol alone. Mr. Bodway concluded that when water spray is used with a surfactant, "silica exposures can be consistently maintained below the PEL without the use of respirators" (Document ID 2181, pp. 10-11, 16). While these situations are not identical to ballast dumping, they all involve the transfer of large quantities of silica-containing materials. OSHA concludes that the processes are similar enough to suggest that the technology could be readily adapted to allow for wetting or application of other suppressants to ballast prior to dumping.

Industry representatives expressed various environmental and safety concerns over chemical or water dust suppressants:

> [S]praying the ballast with chemicals could * * * trigger the need for a National Pollutant Discharge Elimination System (NPDES) permit * * *. [S]praying water spray * * * could affect walking conditions around the roadbed, creating additional opportunities for employee injury.

> Additionally, spraying liquid on ballast will have limited, if any, effectiveness given that, depending upon the ambient temperature, the water or chemical spray could evaporate before or after coming in contact with the ballast or freeze upon application. OSHA should not require the rail industry to spray water or chemicals on ballast, as it unnecessarily creates environmental and safety hazards to railroad employees and the public (Document ID 2366, pp. 7-8).

The NIOSH Dust Control Handbook for Industrial Minerals Mining and Processing (2012) discusses suppressant options for mining haul roads. This handbook addresses environmental concerns when it describes options such as polymers and petroleum emulsions that are nontoxic or of low toxicity, and maintain their effectiveness over extended time periods because they do not evaporate or wash away after a rainstorm (Document ID 1540, pp. 255- 256). Addo and Sanders note that many dust suppressants, particularly chloride salts, are used in much greater quantity for road de-icing than as suppressants, and that when used as suppressants, they "stay mostly at one place in the road surface" instead of being immediately washed off as snow and ice melt, so that the environmental effects of suppressants are overshadowed by their use as deicers (Document ID 0516, p. 32). In regard to freezing conditions, Addo and Sanders (1995) describe a number of chloride salts used as chemical suppressants that can be used in freezing conditions and, in fact, are effective in lowering the freezing point of water, to as low as -60F (Document ID 0516, pp. 119 – 122). Regarding the concern that use of wet suppressants may contribute to slippery walking and working surfaces, OSHA notes that misting was found to be effective in controlling silica exposures during concrete breaking (jackhammer operation), "without adding a substantial amount of water to the work site" (Document ID 1431, p. 3-48).

OSHA acknowledges that wet methods or chemical suppressants may not be practical in all circumstances. Nevertheless, OSHA concludes that these methods can be used effectively in many cases, as they have been successfully implemented in other sectors such as mining and construction.

Additional Controls for Machine Operators and Other Employees Working Outside the Cab

The exposure profile in Table IV.4.16-B shows that 38 percent (38 of 100 samples) have exposure above the final PEL of 50 μg/m^3. Although the exposure profile does not distinguish clearly between exposures to machine operators inside and outside of cabs, OSHA concludes that additional controls will be required for those operators who experience silica exposures above 50 μg/m^3. In addition to the substitution described above for ballast dumpers, OSHA has identified several controls and methods appropriate to protect maintenance of way employees working outside the cab. As noted earlier, because FRA exerts jurisdiction over employees exposed to silica while working inside machine cabs (as those on older, pre-2004 machines that were not required to be retrofitted with cabs), OSHA uses the term “operator” in this context generally to represent the group of employees (excluding ballast dumpers) who could be exposed to silica as the result of activities on the ground.

Dust suppression kits

An engineering control option to protect workers outside the cabs is the use of dust control kits. These kits use local exhaust ventilation and air filtration to reduce the amount of ballast dust released during track maintenance and they are currently available from equipment manufacturers. For example, dust control kits are available for new brooming equipment, although information regarding their effectiveness is not available (Document ID 1365, pp. 12-19 - 12-20). However, AAR and ASLRRA noted that “one of AAR's member railroads has utilized equipment with a dust collection system, but discontinued the practice after the results were determined to be unsatisfactory” (Document ID 2366, p. 5). It is not clear from this statement the nature of the dissatisfaction, how long ago this experience occurred, and whether more recent technology that would produce a more satisfactory result is now available.

AAR and ASLRRA also stated that OSHA’s suggestion to use dust suppression kits as an alternative to protective cabs “exceeds the scope of OSHA's jurisdiction over the railroad employees working inside the cabs of this equipment” (Document ID 2366, p. 4). The commenter misconstrues the purpose of these controls. They are intended to reduce exposures for employees working *outside* the cabs in the area that, as explained earlier, the FRA has clearly reserved for OSHA jurisdiction; OSHA is not requiring them for employers or machines covered by the FRA regulations. While the dust suppression kits may have the secondary effect of also reducing operator exposure when working inside a cab that is not enclosed, OSHA is evaluating this control method as a means of protecting workers working outside the cab in the vicinity of the equipment, like the ballast dumpers or track maintenance crews. This standard does not mandate the use of any specific controls. Employers are free to use any combination of these and other control strategies to meet the PEL.

Another option for broom operators, who have the greatest potential for elevated exposure, would be remotely controlled operation. Existing equipment can be retrofitted for remote control, automating brooming operations (Document ID 1365, p. 12-19).

Wet dust suppression methods are also an option. Water or chemical suppressants applied during dumping will provide dust suppression for activities performed days or weeks afterwards. But, if necessary, the track area can be re-wetted or re-coated with dust suppressant, for example, if maintenance operations are being performed months or years after the last aggregate dump (or substantial rainfall). Although no data are available for the railroad industry, the available data for construction (see IV-5.3 Heavy Equipment Operators) and materials handlers (IV-4.3 Concrete Products) suggest that the use of water and/or chemical dust suppressants applied to the yard or aggregate piles can reduce exposure to respirable silica-containing dust for machine operators and other maintenance of way employees working outside of cabs (Document ID 1365, pp. 5-10, 5-15 – 5-19; 1431, p. 3-36).

Worker positioning

In most cases, the controls and practices capable of reducing silica exposures for ballast dumpers will also reduce exposures to other maintenance of way workers on the ground. One of those practices is ensuring that there is a greater distance between the source of the silica exposure and the worker. As with ballast dumpers, no quantitative exposure reduction data regarding worker positioning in relation to dust are available in the record.

Nonetheless, for the reasons discussed with respect to ballast dumpers, OSHA concludes that exposures will be reduced when workers do not position themselves within or downstream of silica-containing dust clouds.

4.16.4 Feasibility Findings

Feasibility Finding for Ballast Dumpers

The exposure profile in Table IV.4.16-B shows that 77 percent of ballast dumper exposures are already at or below 50 µg/m^3, and the median for this job category is 25 µg/m^3 (13 of 26 ballast dumpers sampled were below the 25 µg/m^3 action level). Based on the exposure profile and other information in the rulemaking record described above, OSHA concludes that the silica exposures of ballast dumpers in the railroad industry can be reduced to 50 µg/m^3 or less most of the time. Additional controls will be needed for the 23 percent of ballast dumpers who currently have exposures above 50 µg/m^3. Employers who provide low silica content ballast and dust suppressants (e.g., wet methods), and who require that employees use safe work practices will reduce ballast dumpers' silica exposure to at or below 50 µg/m^3. Safe work practices include administrative controls that require ballast dumpers to stand at a distance from the dump point (also a good practice to avoid physical injury) and modifying ballast car doors for remote operation, a feature already commercially available to this industry (Document ID 0584). OSHA thus finds that the standard is technologically feasible for ballast dumpers when baseline and additional controls are used.

Feasibility Finding for Machine Operators and Other Employees Working Outside the Cab

Based on the exposure profile in Table IV.4.16-B and information in the rulemaking record discussed above, OSHA concludes that the silica exposures of machine operators and other maintenance of way workers working outside the cab (excluding ballast dumpers), can be reduced to levels of 50 µg/m^3 or less most of the time. This conclusion is based in part on the finding that 62 percent of machine operator exposures were already at or below this level (see Table IV.4.16-B) prior to the 2004 FRA requirement that operative positive pressurized ventilation systems be provided to new on-track-roadway maintenance machines (RRMs). Additional controls will be necessary for machine operators who currently experience exposure levels above 50 µg/m^3 while working outside cabs. When additional controls are needed, employers can reduce these employees' silica exposure to 50 µg/m^3 or less through use of one or more of the following controls: low silica content ballast, dust suppressants, and/or automated broom machines. Therefore, OSHA finds that the standard is technologically feasible for maintenance operators and other employees working outside cabs (and hence coming within OSHA, not FRA jurisdiction), when baseline and additional controls are used.

Overall Feasibility Finding

OSHA concludes that most exposures to silica dust in the railroad track maintenance industry covered by this standard are currently at or below the PEL of 50 µg/m^3. Where such exposures are currently above the PEL, OSHA finds that feasible control methods described above exist to reduce exposures to respirable crystalline silica to levels at or below the PEL for most operations most of the time in this industry. Therefore, OSHA finds that the final PEL of 50 µg/m^3 is technologically feasible for the Railroad industry.[94]

[94] OSHA is not making any feasibility finding with respect to operators working exclusively inside a cab on a machine that the FRA chose to exempt from its requirements in 49 CFR 214.505 for environmentally controlled cabs. The FRA has reserved jurisdiction over the protection of these workers but has not mandated any exposure limits tied to OSHA's PEL with respect to these employees, so there is no need for OSHA to evaluate the feasibility of protecting these employees.

4.17 READY MIX CONCRETE

4.17.1 Description

Ready-mixed concrete refers to concrete that is delivered to the customer in a freshly mixed and unhardened state (Document ID 1365, p. 13-1; 2318, p. 5). Ready-mixed concrete is typically comprised of Portland cement containing aggregates and water. Silica-containing materials are used as fine and coarse aggregate ingredients in the manufacture of ready-mixed concrete. The most commonly used silica-containing aggregates include sand, gravel, and crushed stone (Document ID 1203, p. 1). Ready-mixed concrete can be created inside of a delivery truck barrel (dry batch) or come from a central facility that mixes concrete (wet batch). At dry batch facilities, the raw materials (cement and aggregate) and water are added directly to the truck barrel with contents mixed in the truck mixer in the plant yard, while driving to the job site, or at the job site. At wet batch plants, the concrete is prepared in a plant mixer and then discharged after blending into a truck for delivery to the job site (Document ID 1365, pp. 13-1 – 13-2; 0923, pp. 4-5).

Concrete batch plants are dispersed nationally and are usually located in areas convenient for the delivery of raw materials (cement and aggregates). A typical facility includes storage areas for the raw materials; tanks and conveyors for holding, mixing, and dispensing raw materials; a computerized control room to weigh, mix, and load materials into trucks; a dispatch room to schedule pickups and deliveries; a yard area to wash and park trucks; a maintenance garage; and offices (Document ID 1365, p. 13-2; 1405, p. 2). Ready-mixed concrete facilities are classified in the six-digit North American Industry Classification System (NAICS) 327320, Ready-Mixed Concrete Manufacturing.

Workers are potentially exposed to silica at both dry and wet batch concrete plants. The job categories with potential for exposure to silica include:

- material handler, responsible for overseeing the transfer of aggregates and cement to bins, hoppers, or storage silos;

- batch operator, operates controls to weigh the aggregates and cement, which are then sent either to an agitator truck or an on-site mixer for blending with a premeasured quantity of water;
- quality control technician, responsible for collecting and testing samples of raw materials and prepared concrete;
- maintenance worker, performs intermittent, non-routine tasks, primarily involving equipment maintenance and repair; and
- truck driver, responsible for (1) checking and filling the water and additive (admixture) tanks that are attached to the truck; (2) checking and adjusting the concrete slump when the truck is fully loaded and prior to discharge; (3) operating the drum rotation speed according to the concrete specifications and mixing instructions; and (4) hosing down the truck (inside and/or outside) when fully loaded, after the mixer is completely discharged (Document ID 1365, p. 13-3; 0214, pp. 2-4; 0966).

Table IV.4.17-A summarizes the major activities and primary sources of silica exposure in this industry.

4.17) Ready Mix Concrete

Table IV.4.17-A
Job Categories, Major Activities, and Sources of Exposure for Workers in the Ready-Mixed Concrete Industry (NAICS 327320)

Job Category*	Major Activities and Sources of Exposure
Material Handler	Transferring dry aggregate and cement to bins, hoppers, and storage piles. • Dust from transferring silica-containing raw materials by open material handling equipment, conveyor, or bucket elevator. • Dust from outside piles of aggregates (yard dust).
Batch Operator	Controlling release, weighing, and transfer of aggregates, cement, and water to mixers (plant and/or truck) and discharging of central mixed concrete into haul trucks. • Dust from manual batch operations (approximately 10 percent of ready-mixed concrete facilities have manual batch operations).
Quality Control Technician	Collecting and testing samples of dry raw materials (such as sand and gravel) and concrete. • Dust from collecting and testing samples of raw materials and prepared concrete. • Dust from outside piles of aggregates (yard dust). • Dust from recirculation of settled dust at the plant and construction sites.
Truck Driver/Specialty Contractor	Occasionally (e.g., twice per year) entering and cleaning interior of mixer drum to remove hardened concrete.** • Dust from removing hardened concrete from mixer drums using pneumatic chippers.
Maintenance Operator	Performing maintenance and repair on equipment throughout plant; in some cases using hand tools (such as sledgehammers) to remove residual concrete from inside plant mixing drum. • Dust from changing parts or maintaining equipment in aggregate conveyors and batch plant. • Dust from cleaning cement chute and removing residual concrete from plant mixer.

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility.
**Truck mixer drum cleaning is completed by only a small number of truck drivers. This task is increasingly performed by contractors who specialize in removing hardened concrete from ready-mixed truck drums (Document ID 0922, p. 11; 2024, p. 2; 2305, p. 7). Instead of infrequent exposure, contractors receive regular silica exposure from this activity, perhaps on a daily basis.

Sources: Document ID 1365, pp. 13-3 – 13-5, 13-6; 0924; 0923; 0922, p. 11.

4.17.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.17-B includes 33 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for workers in the Ready-Mixed Concrete industry. The median is 13 μg/m^3, the mean is 338μg/m^3, and the range is 10 μg/m^3 (the limit of detection (LOD)) to 9,804 μg/m^3. Table IV.4.17-B shows that, of the 33 samples, 8 (24.2 percent) exceed 50 μg/m^3.

The following sections describe the baseline conditions and respirable crystalline silica (RCS) exposure levels for each affected job category based on two NIOSH research reports, two OSHA Special Emphasis Program (SEP) inspection reports, and unpublished consultant data obtained from the Georgia and Illinois state consultation programs (Document ID 0214; 0245; 0198; 0095; 1226; 3732, Attachment 3). In addition, OSHA reviewed the OSHA Information System (OIS) compliance sampling data submitted to the docket and identified an additional 12 samples from Ready-Mixed concrete facilities that were added to increase the number of measurements in the exposure profile from 21 in the PEA, to 33 samples presented in Table IV.4.17-B in this section (Document ID 3958).

For each of the job categories listed in Table IV.4.17-A and included in the exposure profile, and for the Ready-Mixed Concrete industry as a whole, OSHA concludes that Table IV.4.17-B represents baseline conditions.

Exposure Profile and Baseline conditions for Material Handlers

The exposure profile in Table IV.4.17-B includes 13 full shift personal breathing zone (PBZ) samples of respirable crystalline silica for material handlers in the Ready-Mixed Concrete industry. The median is 14 μg/m^3, the mean is 31 μg/m^3 and the range is 10 μg/m^3 (the limit of detection (LOD)) to 131 μg/m^3. Table IV.4.17-B shows that, of the 13 samples, 3 (23 percent) exceed 50 μg/m^3.

The 13 full-shift samples obtained were from workers whose job functions include material handling equipment operators, such as front-end loaders operators, of which three were greater than 50 μg/m^3. Of the remaining 10 respirable silica exposure samples, one was between 25 and 50 µg/m^3, and the rest were below 25 µg/m^3 (Document ID 0095, p. 193; 1226, p. 31; 3958).

Of the 13 samples collected for this job category, there are two samples associated with enclosed cabs, two samples that OSHA has assumed are associated with open cabs, and the rest are associated with various or unspecified conditions (Document ID 1720, p. IV-289; 3958). OSHA considers the results summarized in Table IV.4.17-B to represent exposure levels for this job category.

As discussed in other FEA technological feasibility sections, higher exposures to silica can occur if material handling equipment is operated without completely enclosed, sealed, and properly maintained cabs (e.g., one or more cab windows is left open, or ineffective filters are used in a cab air conditioning system). Some material handlers perform other yard-related tasks in addition to the transfer of dry aggregate. Such tasks can include operating a hopper or material conveyor. Depending on the task and the level of dust control, somewhat higher silica exposures can occur. However, OSHA has concluded that these exposures are represented in the overall profile and as discussed below, these exposures can be controlled with water and other dust suppressants within and around the plant.

Post hearing comments submitted by the National Ready-Mixed Concrete Association (NRMCA) are consistent with and support OSHA’s findings that most material handlers currently have a TWA exposure level at or below the new PEL (Document ID 3732, Attachment 4). The NRMCA’s written comments stated that the majority of exposures were currently below the proposed PEL as follows:

> Industry monitoring data from a large ready mixed concrete company with ready mixed concrete plants throughout the Southern and Midwest regions from 2003 through 2012 show . . . [e]xposure for batch plant operators was only 20% of the proposed PEL, maintenance operators was 26%, and material handlers was 32 (Document ID 2305, pp. 9-10).

However, OSHA did not include the industry monitoring data in the Final Exposure Profile since the sample results did not provide sufficient detail on the activities of the workers sampled.

OSHA concludes that the exposure profile in Table IV.4.17-B for material handlers represents the best available information on the exposure levels associated with this job category. Accordingly, OSHA considers the profile to be representative of baseline conditions for material handlers.

Exposure Profile and Baseline conditions for Batch Operators

The exposure profile in Table IV.4.17-B includes 8 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for batch operators in the Ready-Mixed Concrete industry. The median is 14 μg/m^3, the mean is 22 μg/m^3, and the range is 11 μg/m^3 (the limit of detection (LOD)) to 76 μg/m^3. Table IV.4.17-B shows that, of the 8 samples, 1 (12.5 percent) exceeds 50 μg/m^3.

According to industry contacts, about 90 percent of batch operations are automated, and the associated operator exposure is believed to be minimal (Document ID 1365, p. 13-3; 0966). Although manual batch operations may still occur at some ready-mixed facilities, OSHA was not able to obtain information regarding potential operator exposure to silica during manual batch mixing. An area sample collected beneath a dry-loading hopper considered by the researcher to represent the "worst case" for batch mixers (as well as truck drivers) for a 296-minute sample was 19 μg/m^3 (Document ID 1227), suggesting that silica exposure during manual batch mixing is low.

Using information obtained in NIOSH studies, OSHA SEP inspection reports, and unpublished consultant reports, OSHA finds that baseline conditions for ready-mixed batch operators include working within an enclosed booth or office and that their exposure to silica is typically not detectable or very low (Document ID 0214; 0198; 1226).

NRMCA agreed with OSHA's assessment. NRMCA provided exposure sample results for a large Southeast NRMCA member company, which reflected that all exposures including exposures for batch operators were below 50 µg/m^3 (Document ID 3732, Attachment 4)[95].

OSHA concludes that the exposure profile in Table IV.4.17-B for batch operators represents the best available information on the exposure levels associated with this job category. Accordingly, OSHA considers the profile to be representative of baseline conditions for batch operators.

Exposure Profile and Baseline conditions for Quality Control Technicians

The exposure profile in Table IV.4.17-B includes 4 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for quality control technicians in the Ready-Mixed Concrete industry. The median is 12 µg/m^3, the mean is 12 µg/m^3, and the range is 11 µg/m^3 (the limit of detection (LOD)) to 12 µg/m^3. Table IV.4.17-B shows that, of the 4 samples, no samples exceeded 50 µg/m^3.

The exposure characterization for quality control technicians is based on two samples reported in one NIOSH-case study (Document ID 0214) and two sample results from OSHA's OIS database. The quality control technician's work tasks included performing office work (100 percent of the work shift on the first day of sampling), dry sweeping the office area, collecting aggregate samples (70 percent of the work shift on the second day of sampling), and conducting offsite visits to construction sites (Document ID 0214, pp. 6, 8). At the construction sites, technicians work primarily with samples of wet or already-cured concrete. Similarly, the two sample results from OIS were below 25 µg/m^3, although the conditions and controls were not reported.

Task-related exposure for quality control technicians is expected to be limited because silica- dust producing activities are often conducted inside a laboratory fume hood (aggregate and concrete testing) or minimized through the use of wet methods, that is, the use of water and other dust suppressants to minimize dust created from yard traffic and other dust generated adjacent to or by the quality control technician. In a NIOSH survey

[95] OSHA assumes that batch operator activities would be represented by either the job category plant operator or loader operator in the data submitted.

of six ready-mixed plants, no silica was detected in a 234-minute area sample obtained in the laboratory of one plant. Road dust from the plant lots was the only apparent source of silica (Document ID 0905, pp. 3, 8). Based on these findings, and considering that baseline conditions include local exhaust ventilation (LEV) in the laboratory and controlling adjacent sources of dust, OSHA has determined that quality control technicians are not likely to be exposed to respirable silica at concentrations that exceed 50 μg/m^3.

OSHA concludes that the exposure profile in Table IV.4.17-B for quality control technicians represents the best available information on the exposure levels associated with this job category. Accordingly, OSHA considers the profile to be representative of baseline conditions for quality control technicians.

Exposure Profile and Baseline conditions for Truck Drivers (when cleaning hardened concrete from mixer)

The exposure profile in Table IV.4.17-B includes 3 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for truck drivers in the Ready-Mixed Concrete industry. The median is 370 μg/m^3, the mean is 3,467 μg/m^3 and the range is 170 μg/m^3 (the limit of detection (LOD)) to 9,804 μg/m^3. Of the 3 samples, all (100 percent) exceeded 50 μg/m^3.

Truck drivers spend most of the shift on the road delivering concrete, and thus their exposure from sources at the concrete plant or construction sites is normally minimal.[96] However, truck drivers occasionally perform maintenance to remove hardened concrete from the inside of the concrete truck mixing drums. This activity is typically performed

[96] Based on the assumption that truck drivers spend more than 75 percent of the shift (6 of every 8 hours) making deliveries away from the plant, OSHA estimates that typical exposure levels for normal work shifts that do not involve truck drum cleaning would be less than 25 percent of the levels experienced by material handlers in this industry. As indicated in Table IV.4.17-B, the maximum exposure level for material handlers is 57 μg/m^3; 25 percent of that value results in an estimated maximum daily exposure level of about 14 μg/m^3 for truck drivers. While it is possible that some truck drivers occasionally experience some silica exposure at customer sites delivering concrete, OSHA expects that these exposure levels are also minimal because concrete delivery trucks spend only a few minutes at the site (although they might need to wait on an adjacent road until they can be unloaded), and they are typically on the perimeter of the site where construction dust levels are lowest.

twice per year (Document ID 0922, p. 11),[97] but on those occasions, the activity subjects truck drivers to extremely high silica exposure levels. The exposure profile for truck drivers includes only results associated with truck drum cleaning.

Industry representatives agreed with OSHA's conclusion that truck drivers usually would only experience silica-dust exposures during drum chipping. During hearing testimony, Robert Garbini of the NRMCA testified that "the drum chipping is the major area where any worker would be exposed" (Document ID 3589, Tr. 4337). In addition, industry contacts indicate that there is a growing trend for ready-mixed companies to subcontract drum cleaning to outside contractors that specialize in the removal of hardened concrete. Therefore, subcontract employees might be exposed to substantial levels of respirable crystalline silica on nearly a daily basis (Document ID 0922, p. 11; 2024, p. 2; 2305, p. 7).

The exposure profile for truck drivers/specialty contractors is based on three full-shift PBZ samples obtained from a NIOSH research report and unpublished consultant data from the Georgia onsite consultation program (Document ID 0245, pp. 9-10; 1226, p. 31). All three of the sample results exceeded 100 μg/m^3. The highest result (9,804 μg/m^3) was associated with a driver who used a pneumatic chisel to chip (break up) hardened concrete inside a truck mixer for 362 minutes (Document ID 1226, p. 31). Two additional full-shift sample results (170 μg/m^3 and 340 μg/m^3)[98] were based on approximately 90 minutes of chipping time inside truck mixers with a jackhammer (pneumatic hammer) (Document ID 0245, pp. 9-10).

OSHA also reviewed a large number of partial-shift exposure samples, that is, samples conducted for less than 360 minutes, for workers cleaning truck mixers (Document ID 1365, p. 13-3; 1157, pp. D122-D123). The 33 partial-shift sample results range from 69 μg/m^3 to 7,740 μg/m^3, with a median of 770 μg/m^3. Assuming no additional exposure

[97] Results of a 2008-NRMCA benchmarking survey (Document ID 0922, p. 11) showed that mixing truck drums were typically cleaned every 6.7 months (average for more than 6 dozen establishments in the ready-mixed concrete industry that responded to the survey).

[98] The full shift exposure calculations – employee #1 (1,820 x 90 minutes)/480 minutes = 340 and employee #2 full shift calculation (910 x 90 minutes)/480 = 170.

throughout the remainder of the work shift, the 8-hour TWA exposures for the partial-shift samples range from 11 µg/m^3 to 4,894 µg/m^3, with a median of 148 µg/m^3. Seventy-six percent (25 samples) of the 8-hour TWAs exceed 50 µg/m^3, and 67 percent (22 samples) exceed 100 µg/m^3 (Document ID 1365; 1157). These partial-shift results generally support the exposure profile in indicating that most results are well above 50 µg/m^3.

Contactors who perform drum cleaning are included in this exposure profile. Similar to the partial-shift exposure samples discussed above, the workers whose full-shift exposure results of 170 µg/m^3 and 340 µg/m^3 represent only about 90 minutes chipping time inside truck mixers with a jackhammer (Document ID 1226, p. 31). If these workers were to perform this activity throughout the day, at the same exposure level measured during the 90 minute sample, the employee exposures could have been as high as 910 µg/m^3 and 1,820 µg/m^3 (Document ID 1365, p. 13-3).

Truck drivers who remove hardened concrete from inside truck mixer drums rarely use any dust controls (Document ID 1365, p. 13-17; 1157, pp. D122-D123). If mechanical ventilation is used, it usually consists of a fan placed over the charge hopper or within the concrete discharge chute to exhaust air out of the mixer drum (Document ID 1365, p. 13-17). However, daily truck rinsing (after the mixer is completely discharged and again at the end of the day) is an indirect baseline control that affects the amount of concrete buildup and the resulting airborne silica concentrations when truck drivers do eventually chip concrete from mixer drums. All three results in the exposure profile are associated with baseline conditions, including the practice of rinsing the drum to some extent every day (Document ID 1365, p. 13-24). Therefore, OSHA concludes that the median exposure for truck drivers engaged in such hardened-concrete removal and cleaning presented in Table IV.4.17-B (370 µg/m^3) represents the baseline condition for this job category.

OSHA concludes that the exposure profile in Table IV.4.17-B for truck drivers who remove hardened concrete from inside tuck mixer drums represents the best available information on the exposure levels associated with this job category. Accordingly, OSHA considers the profile to be representative of baseline conditions for these truck drivers.

Exposure Profile and Baseline conditions for Maintenance Operators

The exposure profile in Table IV.4.17-B includes 5 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for maintenance operators in the Ready-Mixed Concrete industry. The median is 11 μg/m^3, the mean is 27 μg/m^3, and the range is 11 μg/m^3 (the limit of detection (LOD)) to 58 μg/m^3. Table IV.4.17-B shows that, of the 5 samples, 1 (20 percent) exceeded 50 μg/m^3.

No silica was detected in three of the five full-shift sample results for maintenance workers. The other two full-shift sample results are somewhat higher (43 μg/m^3 and 58 μg/m^3), but less than 100 μg/m^3 (Document ID 1365, pp. 13-16 – 13-17; 0214, p. 8). These two values reflect work conducted inside the in-plant mixer to remove hardened concrete (with a sledgehammer) during a portion of the work shift.[99] From the information presented in Table IV.4.17-B, OSHA concludes that approximately 20 percent of maintenance workers are exposed to silica at levels exceeding 50 μg/m^3 during such activities. This percentage could be higher if pneumatic tools are used, especially pneumatic chippers and chisels; however, the relative convenience of both rinsing and chipping in-plant mixing equipment (compared with truck drums) means less dusty manual methods often suffice for the in-plant equipment.

Based on information obtained from NIOSH-EPHB 247-19 (2001) and Wickman (2004), OSHA finds that maintenance workers also have the potential for silica exposure while working in the plant yard; while working on or near the aggregate conveyors and batch plant; and during the routine removal of hardened concrete inside the plant mixer (Document ID 1365, pp. 13-16—13-17; 0245; 1227, pp. 2-3). Baseline exposure controls include using water and other dust suppression methods to control adjacent sources of

[99] Facilities use in-plant mixers to mix concrete that is then delivered by many trucks, so an in-plant mixer regularly mixes many more batches than does an individual mixing truck. Furthermore, the in-plant mixers have a more open, accessible design than mixing truck drums (although both can meet the criteria for confined spaces). Maintenance operators tend to chip hardened concrete from the in-plant mixers and while they have potential for short term moderate exposure 90 percent of the time is normally spent in plant areas with far less potential for exposure (Document ID 0214, p. 3).

dust; using LEV at the loading point of the concrete batch mixing drum; and scheduling preventive maintenance activities for nonproduction intervals. No engineering controls are used while removing concrete residues from inside the mixing drum (Document ID 1365, pp. 13-16, 13-20—13-21). All three samples in the exposure profile are associated with these baseline conditions. Therefore, OSHA concludes that the median exposure level for maintenance operators presented in Table IV.4.17-B represents the baseline condition for this job category. OSHA did not receive comments on the potential exposures of maintenance workers at ready mixed facilities.

OSHA concludes that the exposure profile in Table IV.4.17-B for maintenance workers represents the best available information on the exposure levels associated with this job category. Accordingly, OSHA considers the profile to be representative of baseline conditions for maintenance workers.

The following Final Exposure Profile reflects the best data on exposures available to OSHA for workers in the Ready-Mixed Concrete industry.

Table IV.4.17-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Ready-Mixed Concrete Industry (NAICS 327320)

	Exposure Summary			Exposure Range		Exposure Profile				
Ready-Mixed Concrete Industry	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**	**<25 (μg/m³)**	**≥25 and ≤50 (μg/m³)**	**>50 and ≤100 (μg/m³)**	**>100 and ≤250 (μg/m³)**	**>250 (μg/m³)**
Material Handler	13	31	14	10	131	9 (69.2%)	1 (7.7%)	2 (15.4%)	1 (7.7%)	0 (0%)
Batch Operator	8	22	14	11	76	7 (87.5%)	0 (0%)	1 (12.5%)	0 (0%)	0 (0%)
Quality Control Technician	4	12	12	11	12	4 (100%)	0 (0%)	0 (0%)	0 (0%)	0 (0%)
Truck Driver (when cleaning hardened concrete from mixer)	3	3,467	370	170	9,804	0 (0%)	0 (0%)	0 (0%)	1 (33.3%)	2 (66.7%)
Maintenance Operator	5	27	11	11	58	3 (60%)	1 (20%)	1 (20%)	0 (0%)	0 (0%)

4.17.3 Additional Controls

Additional Controls for Material Handlers

The baseline conditions for this job category are associated with a median exposure level of 14 μg/m^3; however, Table IV.4.17-B indicates that 23 percent of material handlers at ready mixed concrete plants experience exposures greater than the new PEL of 50 μg/m^3 and will require additional controls to meet this level. Additional controls for material handlers include the use of properly enclosed, ventilated cabs with air conditioning in conjunction with the use of dust suppression methods. Research conducted by NIOSH of exposures of employees working in these types of cabs in the ready-mixed concrete industry as well as other industries where there were similar material handling tasks found that the use of these cabs reduced respirable dust or silica exposures to levels at or below 50 μg/m^3, that is, by 90 to 97 percent (Document ID 0589, p. 1; 0590; 0214, p. 5; 0898, p. 10; 0884, p. 14).

Some commenters indicated that the use of enclosed cabs was difficult due to communication issues (e.g., Document ID 4217, p. 29). However, during hearing testimony, Robert Garbini further explained how his company effectively uses enclosed cabs and avoids issues with the use of enclosed cabs inhibiting workplace communication by using alternate means of communication. He stated, “What they’re using is the Nextel phones, also hand signals up to the operator and back from the operator down to the closed cab. And a lot of them use walkie-talkies” (Document ID 3589, Tr. 4348). David Bosarge of MMC Materials, Inc., in a post-hearing statement wrote, “MMC Materials strongly encourages all employees to operate their equipment with all windows in a closed position so to minimize their exposure to silica and respirable particulate via this potential route of exposure” (Document ID 2024, p. 3).

Where material handlers perform other yard-related tasks, the use of effective dust suppression methods can reduce silica exposures to at below the PEL. Exposure observations of material handlers at concrete manufacturing facilities that implemented yard-dust management controls, e.g., dust suppressants, wetted yard dust, and/or power sweeping, show that levels substantially below 50 μg/m^3 can be achieved in almost all cases (Document ID 1365, p. 13-19; 0220, pp. 5-10; 0234, pp. 5-6). As shown in Table IV.4.17-B, the highest result for material handlers is 131 μg/m^3. Therefore, OSHA concludes that improvement in cabs, that is, ensuring proper sealing and ventilation, and dust management will achieve material handler exposure levels at or below the PEL of 50 μg/m^3.

Additional Controls for Batch Operators

The baseline conditions for batch operators are associated with median exposure of 14 μg/m^3 and 7 of the 8 full-shift PBZ exposure sample results available for batch operators are below the individual sample LODs and well below 50 μg/m^3. OSHA does not expect that the routine activities of batch operators will result in exposure to silica concentrations in excess of 50 μg/m^3 because the batch operator's workstation, which is usually a booth or office that is typically isolated from plant operations. Therefore, no additional exposure controls are required for most batch operators. (Document ID 1365, p. 13-16).

For batch operators who use manual batching processes (not automated) experience elevated exposures (at approximately 10 percent of facilities)[100], silica levels can be reduced by automating the batching process (including adding an operator's booth) and installing engineering controls such as LEV at the mouth of the concrete batching drum and spray bars on conveyors.[101] As noted previously, automation is the norm for this industry and is already incorporated into the vast majority of plants, approximately 90 percent. Automation and LEV used together, as at a concrete ready-mixed wet/dry batch plant described in NIOSH ECTB 233-101c (1999), reduced batch operator silica exposures to levels less than the LOD (reported as 11 μg/m^3) on two sampling dates, each covering the entire 8- to 9-hour shift. Automation permitted the operator to spend most of

[100] As discussed in the Preliminary Economic Analysis (Document ID 1720, p. IV-291), OSHA estimated the percentage of facilities with automated processes. This was based on industry contacts and supported by the industry profile. OSHA did not receive any comments disputing this assertion.

[101] The LEV system is described as an unflanged, tapered hood (32 inches by 32 inches) with an average face velocity of 480 feet per minute [3400 cubic feet per minute]. The system is powered by a 40-horse power squirrel cage fan and connected to a bag house containing 48 4-inch bags with a reverse pulse jet cleaning system. The bags are changed annually, but inspected for leaks daily (Document ID 0214, p. 5).

the shift in the booth. However, silica results obtained for other workers at this plant suggest that the engineering controls also adequately controlled dust: most silica results for all job categories were below the respective LODs (all 13 μg/m^3 or less) and just one result exceeded the PEL of 50 μg/m^3 (58 μg/m^3 for the maintenance operator who chipped hardened concrete from the in-plant mixer barrel) (Document ID 0214, pp. 5, 7-8).

Additional Controls for Quality Control Technicians

All 4 samples in the exposure profile for quality control technicians are 12 μg/m^3 or less. The data and information available to OSHA suggest that the exposure levels of quality control technicians are currently well below 25 μg/m^3. Additional controls are therefore not required for this job category.

Additional Controls for Truck Drivers/Specialty Contractors

The exposure profile for truck drive/specialty contractor contains 3 samples, all of which exceed 100 μg/m^3, with a median of 370 μg/m^3. The exposure data available to OSHA suggest that most truck drivers who remove hardened concrete inside ready-mixed truck mixers have silica exposure levels greater than 100 μg/m^3 on the rare occasions when they perform this task (e.g., twice per year).[102] Many of these exposures are of short duration and high intensity with some exposures approaching 10,000 μg/m^3. Additional controls are required to reduce the exposures or truck drivers or contractors, who specialize in the removal of hardened concrete while they remove hardened concrete from inside truck mixers with pneumatic tools. As further discussed below, these controls currently include: 1) wet methods, 2) mechanical ventilation, 3) a combination of wet methods and mechanical ventilation, and 4) administrative controls.

OSHA has determined that the truck drivers' activities other than drum chipping do not generate appreciable exposures to silica. For example, over the past 10 years, MMC Materials, which subcontracts out 100 percent of drum chipping to specialty contracts, found that their employees who were monitored for their exposure to respirable silica (as

[102] Contractors that perform this work would experience the same exposures more frequently.

quartz) and respirable particulate had TWA exposures below the laboratory's level of quantification and thus the corresponding OSHA PEL (Document ID 2024, p. 2). OSHA has therefore determined that additional controls are only necessary for the removal of hardened concrete inside ready-mixed truck mixers. The control options for this activity are discussed in the paragraphs below.

Wet Methods

Wet methods for dust control during mixer cleaning include spraying the drum interior with water before and during cleaning and/or using a pneumatic tool equipped with a water spray nozzle. Exposure reductions associated with this method of control range from 70 to 98 percent and are discussed in detail in the report by OSHA's contractor ERG (2008), which reviewed the literature. ERG also discussed the possible constraints associated with the use of wet methods such as freezing weather, slip hazards, and electrical hazards (Document ID 1365, pp. 13-20 – 13-23). In response to a question inquiring about the availability and prevalence of the use of water nozzled chipping hammers to remove harden concrete from mixer trucks by NRMCA members, Robert Garabini of the NRMCA agreed their use was prevalent (Document ID 3589, Tr. 4331).

The Illinois Ready Mixed Concrete Association (IRMCA) Industrial Hygiene Study reported that a handheld pneumatic chipper equipped with a water supply hose and spray nozzle reduced worker exposure to silica by 70 percent during concrete truck drum cleaning (Document ID 3732, Attachment 3, p. 14). Workers periodically sprayed the interior surface of the drum and had a continuous water spray directed at the chisel point during chipping. The operator adjusted the water flow rate, which was described as a controlled mist that did not generate excess water. Williams and Sam further reported that workers were very comfortable using the water-equipped chipper and that all workers noticed a substantial reduction in dust during chipping (Document ID 1136, p. 2). When using this technique, all electrical cords connected to lights or fans near the drum must be plugged into a ground-fault circuit interrupter (Document ID 3723, Attachment 3).

The use of high pressure and ultra-high pressure water-blasting (or water-jetting) is an optional cleaning procedure that could be an effective alternative for some ready-mixed concrete companies. High-pressure pump manufacturers market water-jetting cleaning applications for the interior and exterior of concrete mix trucks (Document ID 1247; 0695). Additionally, a single-operator, ultra-high pressure-water-wash system for removing hardened concrete inside mixer drums was recently commercialized (Document ID 0556). The boom-mounted washer is operated wirelessly from a work platform. No human entry into the mixer drum is required, eliminating the dangerous and labor-intensive job of chipping away dried concrete by hand (Document ID 0556). Limited PBZ sampling conducted by the company in 2009 demonstrated that use of this system substantially reduced silica exposures from cleaning the interior of mixer drums. Six partial-shift PBZ dust samples (three total dust and three respirable dust samples with sampling durations of 60, 80, and 95 minutes) obtained during demonstration tasks, which represent moderate-to-worst case potential daily exposure, yielded no detectable amounts of silica on any of the samples (Document ID 0557).[103] OSHA observes that the maximum concentration of respirable dust of 150 µg/m^3 measured during these test periods suggests that even if silica had been present on the sample filter as a relatively high percentage (e.g., 25 percent)[104] of the respirable dust, the maximum concentration of silica would have been 38 µg/m^3 during periods of intensive drum cleaning.

In their comments, the NRMCA described a process of truck cleaning which eliminates the need for entering the mixer to chip dried concrete. Instead, a specially designed water spray nozzle can be inserted into the mixer to remove dried cement with high pressure water (Document ID 3589, Tr. 4338).

Mechanical Ventilation

Investigators have evaluated various types of mechanical ventilation (LEV, general exhaust ventilation, forced dilution ventilation, and LEV in combination with general

[103] OSHA notes that although silica was not detected, depending on the method used to obtain the samples, the LOD could be as high as 100 µg/m^3 for the samples with the shortest duration.

[104] The hypothetical “worst case” value of 25 percent silica in the sample is approximately twice the level reported in respirable dust during truck drum cleaning. NIOSH found 7 to 13 percent silica in respirable dust air samples obtained over 6 days for truck drivers chipping concrete from mixing truck barrels on two dates (Document ID 0245). Strelec (2008) reported 7.6 and 16 percent silica in respirable dust samples obtained during truck drum cleaning (Document ID 1157, p. D123).

exhaust ventilation) alone or in combination with wet methods. For example, in an evaluation of ventilation techniques for cleaning residual concrete from ready-mixed truck drums, NIOSH investigators found that workers who used general exhaust ventilation alone reduced silica concentrations by 25 percent (from 970 $\mu g/m^3$ to 730 $\mu g/m^3$) (Document ID 0245, p. 11).

The most substantial silica reductions obtained using exhaust ventilation are associated with test scenarios that provided workers with: 1) a combination of LEV-equipped chipping tools and general exhaust ventilation, which achieved a 78 percent reduction in geometric mean, from 970 $\mu g/m^3$ to 220 $\mu g/m^3$ (Document ID 0245, p. 12); or 2) forced dilution ventilation alone, which resulted in an 81 percent reduction in the median respirable quartz level (reduced from 5,378 $\mu g/m^3$ to 1,029 $\mu g/m^3$ as calculated from results obtained by Wickman et al. [2003]) (Document ID 1226, p. 31; 1365, p. 13-22).[105] The median respirable silica reading obtained for three samples (3,401 $\mu g/m^3$, 5,378 $\mu g/m^3$, and 7,677 $\mu g/m^3$) where no controls were used was 5,378 $\mu g/m^3$. Sample durations were 315, 210, and 306 minutes, respectively. When forced dilution ventilation was evaluated, the median respirable quartz reading obtained for four samples was 1,029 $\mu g/m^3$ (493 $\mu g/m^3$, 997 $\mu g/m^3$, 1,061 $\mu g/m^3$ and 1,301 $\mu g/m^3$). Sample durations for the forced dilution ventilation samples were 277, 71, 289, and 62 minutes, respectively (Document ID 1365, p. 13-22). However, the placement of fans was critical and is not effective if air flow direction moves contaminated air across workers' breathing zones (Document ID 3732, Attachment 3). As discussed below, while there was a substantial reduction in exposures with the use of mechanical ventilation, OSHA concludes that it is highly unlikely that the use of this control exclusively will reduce exposures to at or below the PEL.

Combined Control Methods

Strelec (2008) described a ready-mixed concrete facility where a combination of engineering controls, including a water misting device and a push/pull ventilation system, reduced breathing zone silica results (Document ID 1157, p. D123). Although the silica

[105] The respirable silica exposure was calculated by multiplying the total respirable dust TWA by the percent silica in the sample.

level decreased from 1,264 μg/m^3 to 128 μg/m^3, the result still exceeded OSHA's previous general industry PEL. At the time of OSHA's initial inspection (exposure levels 1,264 μg/m^3), the facility, which employed 33 truck drivers, had hired two workers from a local temporary employment agency to remove concrete from multiple truck drums (Document ID 1157). These exposures were those of the temporary workers. Based on information presented by the author, OSHA estimates that the engineering controls, the reduced level of silica in the dust, and other worksite factors contributed in equal measure to the change in silica exposure level.[106] OSHA estimates that the use of controls discussed above reduced the total dust exposures by approximately 78 percent.

The report further recommends the use of the following methods to minimize employee exposure when chipping the drum:

1) Hatch of drum open
2) Place box fan horizontally in hopper
3) Set on high speed and exhaust the air flow out of the drum
4) Use chipping hammer equipped with water spray nozzle
5) Initially spray the entire inner surface of the drum with water
6) Adjust the water spray so that it is aimed at the point of the chisel
7) Ensure water sprays at all times when the chipper is in operation
8) If during the cleaning procedure, concrete surfaces dry to the point that dust is being generated while chipping, the surface should be re-sprayed with water (Document ID 3732, Attachment 3, p. 9)

Illinois Ready Mixed Concrete Association (IRMCA) presented data that indicated that the use of the combination of controls listed above (including water spray nozzle attached to the chipper) can reduce workers' exposures to at or below the PEL of 50 μg/m^3.

---

[106] OSHA calculated the 8-hour TWA concentration of the workers' silica exposure based on the 8-hour TWA respirable dust concentration and the percent quartz in the respirable dust, both provided by Strelec (2008). Before controls, respirable dust was 7,900 μg/m^3 (7.9 mg/m^3) containing 16 percent quartz (1,264 μg/m^3 silica). After controls were initiated, respirable dust was 1,690 μg/m^3 (1.69 mg/m^3) containing 7.6 percent quartz (128 μg/m^3 silica). The percent reduction of exposure to total dust is 78 percent ((7,900-1,690)/7,900) (Document ID 1157, p. D123).

However, this is dependent on the percent silica in the concrete and the duration of the task being less than 2 hours (Document ID 3732, Attachment 3, p. 16).

The IRMCA Industrial Hygiene Study indicates that the truck mixer drums meet OSHA's definition of a confined space as defined by 29 CFR 1910.146 (Document ID 3732, Attachment 3). The OSHA *Pocket Guide Worker Safety Series Concrete Manufacturing (No. 3221)* states that ready-mix trucks have confined spaces that pose safety risks for workers. Employers will need to assess how the standard applies to their specific situation including the appropriate procedures, PPE, respirators, and ventilation. However, the controls discussed in this section to reduce exposures to silica are compatible with §1910.146.

Administrative Controls

Administrative controls primarily include implementing good mixer drum rinsing procedures and increasing the frequency of rinsing to prevent or reduce the amount of concrete buildup. Good drum rinsing procedures include a rinse after each load is poured and a triple rinse at the end of each work shift (Document ID 3732, Attachment 3, p. 9). Additionally, Williams and Sam (1999) reported that construction site conditions can cause a driver to pour concrete from the truck slowly, which can result in excess concrete beginning to harden on the drum wall. In that case, three-quarters-inch aggregate loaded into the drum and rotated for 30 minutes will scour the hardening concrete from the inner surface of the drum and reduce the amount of buildup (the aggregate can then be used in the next batch of concrete) (Document ID 1365, p. 13-24).

OSHA concludes work practices that reduce the amount of concrete buildup in drums will reduce the amount of time required later to remove the hardened concrete from the drum. All other factors being equal, a shorter period of drum cleaning during the shift will result in a correspondingly lower full-shift silica exposure level.

Additional Controls for Maintenance Operators

Although the exposure data available to OSHA suggest that 80 percent of maintenance operators in this industry have silica exposures less than 50 $\mu g/m^3$, as discussed above, one situation in particular can result in higher levels. Additional controls are required where maintenance operators experience elevated exposures while removing hardened concrete from inside plant mixer drums. The controls available for in-plant concrete mixers are similar to those for concrete mixer trucks. Such controls include the use of polyurethane drum liners, good rinsing procedures to remove residual concrete before it dries and builds up, increasing the frequency of mixer cleaning, wet methods, and various types or combinations of mechanical ventilation when hardened concrete must be chipped from drums. Wet methods and mechanical ventilation controls applicable to maintenance operators are described in the earlier discussion on truck drivers (see discussion under the heading Additional Controls for Truck Drivers/Specialty Contractors) (Document ID 1365, p. 13-23).

Polyurethane drum liners are available for plant mixers and reportedly reduce the buildup of hardened concrete. Industry sources indicate that polyurethane-lined drums generally require weekly rather than daily clean out. Reducing the amount of concrete buildup should reduce worker exposure to silica during cleaning because less time will be required to remove the buildup (Document ID 1365, p. 13-26). OSHA was unable to obtain exposure data demonstrating the potential reduction in silica exposure that might be achieved from use of polyurethane-lined drums in plant mixers.

As noted with truck mixer drums, increasing rinse frequency and using good drum rinsing procedures (e.g., rinsing mixers with high pressure water after each batch of concrete) minimizes concrete buildup and the amount of cleaning required to remove hardened concrete (Document ID 1365, p. 13-24). In turn, the reduced cleaning time should reduce exposure to silica.

Depending on the method utilized, the additional controls described for truck drivers reduced silica exposures by 25 to 98 percent during drum cleaning. For example, in an evaluation of ventilation techniques for cleaning residual concrete from ready-mixed truck drums, NIOSH investigators found that workers who used general exhaust ventilation alone reduced silica concentrations by 25 percent, from 970 μg/m^3 to 730 μg/m^3 (Document ID 0245, p. 11). Assuming that this control would reduce exposure to maintenance operators cleaning plant mixers by a similar amount, OSHA expects that the highest levels reported in the exposure profile for maintenance operators removing hardened concrete with a sledge hammer (43 μg/m^3 and 58 μg/m^3) would be reduced by 25 percent to values at or below 50 μg/m^3 (32 μg/m^3 and 44 μg/m^3, respectively).

4.17.4 Feasibility Finding

In written comments, Robert Garbini, the President of NMRCA, described the management practices currently used to minimize exposure to silica dust in their industry as follows:

> To further ensure a safe and healthy work environment, common and best management practices at ready mixed concrete plants consist of wetting aggregates and driveways, keeping truck and loader cabs in good condition, closed building and vehicle windows with air conditioners and heaters, minimal sweeping, dust ventilation systems, strict adherence to confined space regulations, PPE and frequent worker training (Document ID 2305, p. 10).

Sampling data submitted to the record by the NRMCA to characterize worker exposure to crystalline silica at a large southeast ready-mix concrete producer indicated exposure to at or below the PEL. Out of approximately 90 samples comprising the defined position descriptions of Loader, Mechanic, Operator and Driver, no sample was above the final PEL (Document ID 3732, Attachment 4).

Feasibility Finding for Material Handlers

Based on the available information, OSHA finds that most material handlers (69 percent) in this industry are currently exposed to silica at levels less than 25 μg/m^3. Only 23 percent of the 13 samples in the exposure profile exceed the revised PEL of 50 μg/m^3. For these workers, OSHA concludes that the primary option for reducing exposure to levels at or below the PEL is the use of enclosed operator cabs that are well sealed and ventilated with positive pressure and filtered air. An additional option that will reduce exposures to levels at or below 50 μg/m^3 is the application of effective dust suppression methods in yards and during raw material handling, exclusively or in conjunction with enclosed operator cabs.

As discussed above, NIOSH research indicates that the use of enclosed operator cabs reduced respirable dust or silica exposures to levels at or below 50 µg/m^3, (Document ID 0589; 0590; 0214; 0898; 0884). Exposure observations for material handlers at concrete manufacturing facilities that implemented yard dust management controls show that levels substantially below 50 µg/m^3 were achieved in almost all cases (Document ID 1365, p. 13-19; 0220; 0234).

Upon OSHA's final review of exposure data and baseline conditions for material handlers including associated engineering and administrative controls, OSHA concludes that material handlers can achieve exposures at or below 50 µg/m^3 most of the time with the control methods described in this section.

Feasibility Finding for Batch Operators

The available exposure data indicate that most batch operators are not exposed to silica levels in excess of 25 µg/m^3. Seven of the 8 samples in the exposure profile were less than 25 µg/m^3. Additional exposure controls do not appear to be necessary for this job category. However, in the event that a batch operator is exposed to elevated levels of silica, for example, because of dust levels at the central mix area or dust tracked into the batch operator's work station, the facility can achieve exposures of 25 µg/m^3 or less for that worker by improving housekeeping and seals on the operator's booth or by improving maintenance on dust controls in the central mix area.

Upon OSHA's final review of exposure data and baseline conditions for batch operators including associated engineering and administrative controls, OSHA concludes that batch operators can achieve exposures of less than 50 µg/m^3 most of the time with the control methods described in this section.

Feasibility Finding for Quality Control Technicians

Based on the available information, OSHA does not expect that the routine activities of quality control technicians will generate exposures that exceed 25 µg/m^3. Additional exposure controls do not appear to be necessary for this job category. However, if technicians are exposed to silica while obtaining samples in the raw materials storage areas, their exposure will be reduced when exposures in other job categories are controlled. Other control options for these workers include: implementing administrative policies that allow quality control technicians to avoid dusty plant process areas until dust subsides and adding LEV (e.g., a laboratory fume hood) in the laboratory.

Upon OSHA's final review of exposure data and baseline conditions for quality control technicians including associated engineering and administrative controls, OSHA concludes that quality control technicians can achieve exposures of less than 50 μg/m^3 most of the time with the control methods described in this section.

Feasibility Finding for Truck Driver/Specialty Contractors

As indicated in Table IV.4.17-B, the silica levels of all truck drivers are greater than 100 μg/m^3 only on the rare occasions (e.g., twice per year) when the truck drivers chip hardened concrete from their truck mixing drums. However, it is much more common for this work to be conducted by contractors who move from plant to plant chipping concrete from truck drums as reflected in the comment described above (Document ID 2024, p. 2).

OSHA concludes that the exposure levels of most truck drivers engaged in chipping cement off the inside walls of mixing drums can be reduced to silica levels that fall between approximately 100 μg/m^3 and 500 μg/m^3 when this activity is performed over an entire shift This range of exposure levels has been achieved by several investigators using various combinations of controls for workers who spent at least half of the sampling period (and usually the entire period) chipping concrete from inside truck mixing drums. The combination of controls described here will reduce most workers' exposures during truck drum cleaning but will not eliminate the need to provide supplemental respiratory protection to reduce exposures to at or below the PEL.

Examples of controls used to controls dust while chipping out hardened concrete from truck drums and the associated exposure levels are as follows:

- LEV-equipped chipping tool plus general exhaust ventilation: Silica levels reduced to 220 μg/m^3 (Document ID 0245, p. 12).

- Water misting device and push/pull ventilation system: Silica levels reduced to 128 µg/m^3 (Document ID 1157, p. D123).
- Periodic spraying of the interior surface of the drum and directing continuous water spray at the chisel point during chipping kept silica levels reduced to less than 100 µg/m^3 or somewhat less (Document ID 1365, pp. 13-21, 13-25).

IRMCA showed that with the use of a combination of administrative controls to minimize the build up of hardened concrete from the truck-mixing drum and the use of a combination controls as discussed above, including forced air dilution ventilation, for short duration jobs (under 2 hours), can reduce truck driver exposures to at or below 50 µg/m^3 (Document ID 3732, Attachment 3, p. 16). Alternative cleaning techniques, such as high- or ultra-high-pressure water blasting, which is available from a single-source supplier, might also be effective under some circumstances.

OSHA concludes that the same controls that will reduce the exposures for truck drivers will reduce exposures for specialty contractors while chipping hardened concrete from the truck mixing drums. However, due to the increase duration of performing this activity, specialty contractors may experience higher exposures then the truck drivers who may perform this activity for short durations and may need respirators in addition to engineering controls to reduce exposures to at or below the PEL.

OSHA concludes that most truck drivers that only occasionally (e.g., twice per year) enter and clean the interiors of mixer drums to remove hardened concrete can achieve exposure at or below the 50 µg/m^3 PEL if the job is less than two hours. However, for specialty contractors or truck drivers that spend a larger portion of their shift chipping hardened concrete from the truck mixing drum, the use of supplemental respiratory protection may be necessary.

Upon OSHA's final review of exposure data and baseline conditions for truck drivers and specialty contractors including associated engineering and administrative controls, OSHA concludes that truck drivers and specialty contractors can achieve exposures of less than 50 µg/m^3 most of the time with the control methods described in this section.

Feasibility Finding for Maintenance Operators

OSHA finds that the exposure levels of 80 percent of maintenance operators are currently well below 50 µg/m^3. By using one or more of the additional controls described in this section, the remaining operators will achieve results at or below 50 µg/m^3. Appropriate controls include using polyurethane drum liners, employing good rinsing procedures to remove residual concrete before it dries and builds up, increasing the frequency of mixer cleaning (to reduce the amount of hardened concrete that needs to be removed), using forced dilution or general exhaust ventilation, and using pneumatic tools equipped with LEV or a water spray. Alternative cleaning techniques, such as high- or ultra-high-pressure water blasting, also might effectively control worker exposures to silica during in-plant mixer cleaning and eliminate the need to send workers inside the mixer to manually remove hardened concrete buildup. Substantially higher exposure levels that might be associated with the use of pneumatic tools to clean in-plant mixers would require the same controls or combinations of controls as outlined for truck drivers.

Upon OSHA's final review of exposure data and baseline conditions for maintenance operators including associated engineering and administrative controls, OSHA concludes that maintenance operators can achieve exposures of less than 50 µg/m^3 most of the time with the control methods described in this section.

Overall Feasibility Finding

Based on OSHA's analysis of the available monitoring data and industry comments, OSHA concludes that material handlers, batch operators, quality control technicians, and maintenance operators can achieve exposures of less than 50 µg/m^3 most of the time with the controls described in this section. OSHA also concludes that most truck drivers that only occasionally (e.g., twice per year) enter and clean the interior of a mixer drum to remove hardened concrete can achieve exposure to at or below the PEL if the job is less than two hours through the use of a combination of administrative controls (minimizing the amount of harden concrete) and engineering controls such as LEV and water spray as described above. However, for specialty contractors or truck drivers that spend a larger portion of their shift chipping hardened concrete from the truck mixing drum, the use of supplemental respiratory protection may be necessary.

The available monitoring data presented in Table IV.4.17-B indicate that overall 76 percent of the samples are already at or below the PEL of 50 $\mu g/m^3$. For the workers currently exposed above 50 $\mu g/m^3$, the engineering and administrative control measures described in this section can, in most cases, reduce exposures to 50 $\mu g/m^3$ or less. Accordingly, OSHA finds the final PEL of 50 $\mu g/m^3$ is technologically feasible in the Ready-Mixed Concrete industry.

4.18 REFRACTORIES

4.18.1 Description

Facilities manufacturing refractory products are classified in the 2007 six-digit North American Industry Classification System (NAICS) codes 327124, Clay Refractory Manufacturing, and 327125, Nonclay Refractory Manufacturing.[107] Silica-containing materials are used in these industries to produce a wide range of heat-resistant products. Refractory products include oven and furnace linings, materials used for casting molten substances (metals and glass), and insulation for high-temperature processes and equipment.

The manufacturing facilities in this industry typically produce one or more of the following three distinct product forms: 1) pre-formed refractory items such as fire bricks and custom shapes; 2) glass-like refractory ceramic fibers (RCF);[108] and 3) unshaped powder products, called monolithic refractories. The monoliths are typically sold in sacks and intended to be either cast in place or applied as mortars or coatings at customer facilities (Document ID 1365, p. 14-1; 0965, p. 1; 1392, pp. 25, 31-32).

Within each of these general forms, a variety of product types exist, including refractories based on compounds of silica, aluminum, chromium, magnesium, or other minerals. Some examples of common raw ingredients for refractory materials include aluminum silicate clays, aluminum oxide ore, chromium compounds, ceramic frit, ground quartz, and calcined materials (the calcining process can convert any amorphous silica to cristobalite).[109] Refractory materials contain silica either as a key component or as a minor contaminant depending on the temperature the refractory material needs to withstand. For example, high silica-based refractory products, often referred to as high-

[107] The applicable 2012 NAICS code is 327120, Clay Building Material and Refractories Manufacturing.

[108] Refractory ceramic fiber production accounts for approximately 1 percent (80 million pounds per year) of the total U.S. man-made vitreous fiber manufacture. In total, about 800 workers are involved in RCF manufacturing (Document ID 0965, p. 2).

[109] Cristobalite is a type of crystalline silica with an existing PEL equivalent to 50 μg/m^3 (29 CFR 1910.1000 Table Z-3).

duty brick, can contain upwards of 50 percent silica and are able to withstand higher temperatures. High aluminum clay refractory products, often referred to as low-duty brick, might only contain a fraction of a percent of silica (Document ID 1365, p. 14-1; 0266, pp. 4-5).

One commenter noted that her company produced a low duty, or low temperature, refractory brick using clay that contained 29 percent quartz (i.e., silica). She commented that this brick was made of clay only and was no different from clays used in clay brick manufacturing. OSHA notes that during the public hearings representatives from the structural clay brick industry confirmed that structural brick typically contains "10 through to 30-odd percent" free silica (Document ID 3577, Tr.704). She further noted that their low duty refractory brick does "not contain additional additives such as pitch, chromium, resins, or other organic additives that higher temperature-performance refractory brick typically include[s]" (Document ID 3731, p. 1).

Additionally, this industry recycles a substantial amount of fired refractory material for use in new product. The fired refractory material may add additional amounts of silica in the form of cristobalite. As a result of this wide variability in composition, silica exposure can be variable from day to day and product to product within an individual production facility (Document ID 1365, pp. 14-1 – 14-2).

Workers are potentially exposed to silica throughout all phases of production: when they manually manipulate and mix silica-containing raw ingredients; use dry casting methods to form bricks and shapes; finish cast shapes with grinders and saws; charge or tend melting furnaces used to form ceramic fibers; and package dry powdered refractory materials. See Table IV.4.18-A for a description of the major activities and sources of exposures for affected job categories (material handler, forming operator, finishing operator, ceramic fiber furnace operator, and packaging operator). OSHA notes that the raw materials, job activities, and production methods used in this industry are similar to those employed by the Structural Clay Products, Concrete Products, Glass Products, and Pottery Products industries (also described in the respective sections of this report: IV-4.21, IV-4.3, IV-4.9, and IV-4.15).

4.18) Refractories

Table IV.4.18-A **Job Categories, Major Activities, and Sources of Exposure of Workers in the Refractories Industry** **(2007 NAICS 327124 and 327125)**	
Job Category*	**Major Activities and Sources of Exposure**
Material Handler	Operating forklifts and loaders to transport materials; transferring, weighing, and dumping raw materials by hand or using automated equipment; charging and operating mixing and milling machines. • Dust from manual emptying of bags of silica-containing materials into batch bins, hoppers, mixers, and milling machines. • Dust disturbed during transfer of silica-containing materials using open conveying equipment. • Dust released while operating unventilated, open mixing, or blending equipment.
Forming Operator	Transferring dry or wet mixed ingredients into molds and compacting using automated or manually operated equipment; removing formed product from molds; cleaning molds. • Dust that becomes airborne during compacting of dry silica-containing ingredients using vibrating machinery or mechanical presses. • Dust disturbed during cleaning of molds, surfaces, and floors using brooms or compressed air. Using automated processes to extrude and cut refractory clay brick. • Dust from spilled clay and handling dried bricks (unfired).
Finishing Operator	Cutting, shaping, and grinding products by hand or with semi-automated equipment. • Dust from grinding and sawing fired products by hand or with automated equipment. • Dust disturbed during cleaning of floors and surfaces using brooms or compressed air.
Ceramic Fiber Furnace Operator	Charging melting furnaces with silica-containing ingredients and raking raw materials; operating fiber production equipment; performing housekeeping in the furnace area. • Dust released while charging furnaces with raw materials.[110] • Dust disturbed during cleaning of floors and surfaces using brooms or compressed air.
Packaging Operator	Filling bags with loose, dry powder or aggregate products using automated or semi-automated equipment; handling filled bags manually or using automated equipment. • Dust escaping from bag packing equipment. • Dust emitted from newly filled bags during stacking and palletizing activities. • Dust disturbed during cleaning of floors and surfaces using brooms or compressed air.
*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility. Source: Document ID 1365, pp. 14-3 – 14-6.	

[110] Newly manufactured RCF contain little or no silica. Thus, handling raw ingredients presents the greatest opportunity for exposure to silica. Once the raw ingredients are melted (to the amorphous form), silica exposure is unlikely to occur.

In a follow-up response to questions asked during the public hearings, one small business noted that approximately 70 percent of its work force performed tasks that would be subject to the proposed rule. These employees were categorized as grinders, kiln firemen, unloaders, maintenance workers, shippers, blenders, press operators, and plant supervisors. This commenter also noted that they tumble fired brick (a process that involves "running the bricks through a rotating cylinder so they bump against the sides and each other," to give them an "old world appearance") and crush out-of-spec brick (Document ID 3731, pp. 1-2). OSHA believes that each of these duties would fall within the job categories described in Table IV.4.18-A. OSHA received no other comments regarding job categories or activities that present the potential for silica exposures in this industry.

For each of the job categories listed in Table IV.4.18-B and included in the exposure profile, and for the refractories industry as a whole, OSHA concludes that Table IV.4.18-B represents baseline conditions.

4.18.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.18-B includes 63 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for workers in the refractories industry. The median is 23 $\mu g/m^3$, the mean is 47 $\mu g/m^3$, and the range is 10 $\mu g/m^3$ to 526 $\mu g/m^3$. Table IV.4.18-B shows that, of the 63 samples, 14 (22.2 percent) are above 50 $\mu g/m^3$ and 7 (11.1 percent) exceed 100 $\mu g/m^3$.

OSHA's exposure profile in the PEA for the refractories application group included monitoring data from OSHA Special Emphasis Program (SEP) inspection reports and NIOSH reports on silica exposure in refractory product manufacturing facilities and analogous operations. Each of the facilities covered in these reports produces multiple product forms (e.g., shapes or bricks, ceramic fibers, packaged monolithic refractory materials) (Document ID 1365, pp. 14-6 – 14-7; 0193, pp. 5-6; 0089, p. 29; 0266, p. 3; 1720, pp. IV-305-310). In the final exposure profile presented in Table IV.4.18-B, OSHA supplemented this data with 12 sample results at three facilities from the OSHA Information System (OIS) for material handlers (3 samples), forming operators (8 samples), and packaging operators (1 sample) (Document ID 3958, Rows 525-531,822, 824, 960-962).[111] Exposure monitoring data for each job category are discussed in detail below.

Exposure Profile and Baseline Conditions for Material Handlers

The exposure profile in Table IV.4.18-B includes 30 samples for material handlers in the refractories industry. The median is 32 μg/m^3, the mean is 71 μg/m^3, and the range is 12 μg/m^3 to 526 μg/m^3. Table IV.4.18-B shows that, of the 30 samples, 12 (40 percent) are above 50 μg/m^3 and 6 (20 percent) exceed 100 μg/m^3.

The 30 samples were obtained at five facilities (the three facilities included in the Preliminary Economic Analysis (PEA) exposure profile, as well as two of the three facilities covered in the OIS data) during manufacture of a variety of products (shapes, bricks, fibers, aggregate) (Document ID 1365, p. 14-8; 0193, pp. 25-27, 36, 58; 0089, pp. 43-46, 53-57, 63-67, 72; 0266, pp. 14-15; 3958).

The 6 samples above 100 μg/m^3 were obtained from three separate facilities and are associated with manual bag dumping (Document ID 0089; 0193; 0266). These 6 samples range from 120 μg/m^3 to 526 μg/m^3, with a median of 164 μg/m^3 and mean of 220 μg/m^3. Quartz values were reported for all of these samples, but 1 sample contained cristobalite as well. The result for this sample was 170 μg/m^3 of total silica;[112] however, the report offered no information on the percentages of these types of silica in the materials that this worker handled. Total respirable dust concentrations associated with these 6 elevated samples range from 3.0 mg/m^3 to 11.0 mg/m^3, suggesting incomplete dust control during the bag dumping task at all three facilities (Document ID 1365, pp. 14-8 – 14-9; 0193, p. 58; 0089, p. 72; 0266, p. 14). At one of the facilities, NIOSH indicated that the “area was equipped with a dust control ventilation system,” but that its use was “not a regular occurrence,” and that “dust was dispersed from holes in the duct elbows” that had been

[111] One sample was excluded from the exposure profile because the worker was performing unrelated tasks (Document ID 3958, Row 823).

[112] Sample was composed of respirable cristobalite at 100 μg/m^3 and respirable quartz at 70 μg/m^3. Where cristobalite and quartz are identified in a sample, values are added together to create a total silica result.

worn through by abrasion. The report did not, however, indicate which samples (if any or all) were associated with local exhaust ventilation (LEV) at the workstation (Document ID 0266, p. 6).

Although several silica samples below 25 μg/m^3 were obtained for workers dumping bags at some of the same workstations where elevated samples were obtained, these values were generally associated with handling of materials with very low silica levels (i.e., silica levels below the limit of detection (LOD), which was less than 1 percent in the sample) and lower total respirable dust concentrations (between 1.0 mg/m^3 and 3.0 mg/m^3) (Document ID 1365, pp. 14-8 – 14-9; 0193, p. 35; 0089, pp. 63-67, 72; 0266, pp. 14-15). These findings likely represent variations in work practices or respirable-size silica content of materials dumped.

Two respirable silica samples from a separate facility (included from the OIS data) were also for material handlers dumping bags into the hopper or adding materials into the blend. Both samples were below the LOD of 12 μg/m^3. While information was not available regarding the silica content of the material, both were associated with lower total respirable dust concentrations (0.230 mg/m^3 and 2.3 mg/m^3 compared to 3.0 mg/m^3 to 11.0 mg/m^3 mentioned above) indicating that the operations were generally not dusty or were well controlled (Document ID 3958). Other silica samples below 25 μg/m^3 in the exposure profile for material handlers include operating transportation equipment (e.g., forklift, mullite dump truck), overseeing automated material conveyance, and working at a brick crusher (Document ID 1365, p. 14-9; 0266, p. 14; 3958).

Three of the five facilities had LEV installed for some of their mixing and charging operations (the other two facilities provided general dilution ventilation for all but one of the observed operations). The 4 samples for material handlers definitively associated with LEV are less than or equal to 14 μg/m^3 (the LOD), 36 μg/m^3, 53 μg/m^3, and 87 μg/m^3 (Document ID 0089, pp. 53-57, 63-67, 72; 0193, pp. 25-32).[113] However, the LEV air

[113] Results reported as “none detected” are assigned a value equal to the LOD. The LOD is determined individually for each sample based on the volume of air sampled and the method used to analyze the sample, therefore, the limit of detection varies between samples. See Section IV-2–Methodology for additional information on LODs.

velocity provided at one of the facilities was below that recommended by ACGIH (2010) (Document ID 1365, p. 14-14; 3997; 0089, pp. 53, 63). The 2 OIS samples associated with general dilution ventilation were both below the LOD of 12 μg/m^3.

The only information OSHA received regarding baseline conditions for material handlers during the public comment period was a follow-up response to questions asked during the public hearings. One small refractory brick manufacturer noted that its material handler also crushes "out of spec" brick. Although the commenter did not provide exposure data or a detailed description for this task, they did note that the task was done under a water spray, which was monitored due to EPA requirements (Document ID 3731, p. 2).

Based on the available data, OSHA has determined that baseline conditions for material handlers include routine manual bag dumping, and operating forklifts and loaders to transport materials. Ventilation systems for mixing and dumping equipment, if available, have been observed to function sub-optimally (Document ID 1365, pp. 14-14 – 14-16; 0089, pp. 19, 27-33, 133-139; 0266, pp. 6, 8, 10-13). Although OSHA requested additional exposure data for material handlers in refractories industries during the public comment period, it did not receive any. OSHA has determined that the exposure profile for material handlers summarized in Table IV.4.18-B, which was obtained from the best available evidence, and shows a range of exposures from 12 to 526 μg/m^3, with a median of 32 μg/m^3, represents baseline conditions for this job category.

Exposure Profile and Baseline Conditions for Forming Operators

The exposure profile in Table IV.4.18-B includes 8 samples for forming operators in the refractories industry. The median is 35 μg/m^3, the mean is 37 μg/m^3, and the range is 12 μg/m^3 to 71 μg/m^3. Table IV.4.18-B shows that, of the 8 samples, 1 (12.5 percent) is above 50 μg/m^3 and none exceed 100 μg/m^3.

Due to limited exposure data, OSHA used surrogate exposure data derived from analogous operations for forming operators in the structural clay, pottery products, and concrete products manufacturing industries to characterize the exposure profile for forming operators in the refractories manufacturing industries in the PEA (Document ID 1720, pp. IV-307 – IV-308). Data contained in OIS, however, provide 8 full-shift, time weighted average (TWA) samples for forming operators at two refractory manufacturing plants (Document ID 3958, Rows 525-531, 824). Although OSHA believes the surrogate data used in the PEA provided a credible exposure profile for refractory manufacturing forming operators in the absence of industry specific data, OSHA has concluded that 8 samples from OIS provide the basis for a more appropriate, industry-specific exposure profile. These 8 samples, summarized in Table IV.4.18-B, have a median silica exposure of 35 μg/m^3, a mean of 37 μg/m^3, and range from 12 μg/m^3 to 71 μg/m^3. One sample (12.5 percent) exceeded 50 μg/m^3, all others (87.5 percent) were below 50 μg/m^3 (Document ID 3958).

This exposure profile is consistent with, but slightly lower than, the profile based on the surrogate data presented in the PEA: the median and mean exposure levels were similar, with a median of 30 μg/m^3 and a mean of 47 μg/m^3. While the percentage of samples that exceeded 50 μg/m^3 was about half (12.5 percent compared to 27 percent), 7 of the 8 samples from OIS were for workers performing tasks with LEV which may explain this decrease in exposure levels. The surrogate data used in the PEA contained sample results from a manufacturing facility where the exhaust ventilation system did not fully capture visible dust at any of the product lines, and the ventilation system was disconnected entirely at one press where the most visible dust was released, resulting in higher exposure values (Document ID 1720, p. IV-308; 0202, pp. 15-20, 22).

OSHA concludes that LEV and general dilution ventilation are baseline conditions for forming operators at most refractory product manufacturing facilities. Although OSHA requested additional exposure data for forming operators in refractories during the public comment period, it did not receive any. In the absence of additional data, OSHA concludes the exposure levels summarized in Table IV.4.18-B for forming operators accurately reflect as a baseline condition a median exposure level of 35 μg/m^3.

Exposure Profile and Baseline Conditions for Finishing Operators

The exposure profile in Table IV.4.18-B includes 8 samples for material handlers in the refractories industry. The median is 13 μg/m^3, the mean is 13 μg/m^3, and the range is 13 μg/m^3 to 14 μg/m^3. Table IV.4.18-B shows that, of the 8 samples, none are above 50 μg/m^3 and none exceed 100 μg/m^3.

Eight full-shift finishing operator samples were identified for a refractory products manufacturing facility visited by NIOSH. On the days that sampling was conducted, finishing operators performed manual grinding on low-temperature fire brick (hydrous aluminum silicate clay and plaster) at ventilated grinding stations. All eight exposures were below the LOD (13 μg/m^3 to 14 μg/m^3) (Document ID 1365, p. 14-11; 0266, pp. 11-12, 14-15).

These samples for finishing operators are associated with LEV, which was present on all the manual grinding stations. The adjacent automated grinding machines, drill presses, and saws (not operated during the evaluation) were also fitted with LEV. At the time of sampling, NIOSH determined that air velocity for the LEVs at the manual grinding stations an inch from the 36-inch grinding wheels was 300 feet per minute, with half the grinder/LEV stations operating (volumetric airflow was not provided) (Document ID 0266, p. 8). However, settled dust in the area and high respirable dust sample results suggest that the LEV did not completely capture grinding dust (Document ID 0266, p. 6). Dust control is further reduced when workers manually open dampers to the remaining grinding stations when those other machines are also in use. In addition, NIOSH noted that these workers spend a portion of their shift performing clean-up activities and that dry sweeping also contributes to the workers' dust exposure (Document ID 1365, p. 14-11; 0266, pp. 4, 8). LEV or ventilated enclosures and wet methods were also associated with grinders at a second refractory brick manufacturing plant evaluated by NIOSH, but for which no PBZ silica samples were obtained (Document ID 0909, p. 22-Encl 2).

OSHA received one comment regarding baseline conditions for finishing operators in a follow-up response to questions asked during the public hearings. One small refractory brick manufacturer noted that its finishing operators tumble fired brick as part of their finishing process and that the dust from the tumbling operation is controlled by a dust collector, which is monitored as required in the manufacturer's EPA Title V operating permit (Document ID 3731, p. 2). The commenter did not provide any exposure data associated with this task so OSHA could not include the data in its exposure profile for finishing operators, but this information supports OSHA's conclusion that LEV is typically used in finishing operations.

Based on the presence of LEV for finishing operations in these manufacturing facilities discussed above, OSHA concludes that the use of LEV represents baseline conditions in the finishing areas of refractory product manufacturing facilities. Although OSHA requested additional data exposure for finishing operators in refractories, it did not receive any. In the absence of additional data, OSHA concludes that the exposure levels summarized in Table IV.4.18-B for finishing operators accurately reflect as a baseline condition a median exposure level of 13 μg/m^3.

Exposure Profile and Baseline Conditions for Ceramic Fiber Furnace Operators

The exposure profile in Table IV.4.18-B includes 4 samples for ceramic fiber furnace operators in the refractories industry. The median is 14 μg/m^3, the mean is 13 μg/m^3, and the range is 12 μg/m^3 to 14 μg/m^3. Table IV.4.18-B shows that, of the 4 samples, none is at or above 50 μg/m^3.

Four samples were identified for ceramic fiber furnace operators. Although limited, these represent the best data available to OSHA for ceramic fiber furnace operators in the refractory products industry. NIOSH collected these air samples on two consecutive days at a facility that manufactured refractory fibers (Document ID 0266, pp. 6-7, 11-12). The 4 samples for the furnace operator and production assistant all were less than or equal to the limits of detection (12 μg/m^3 to 14 μg/m^3), despite the fact that silica sand quartz accounted for 50 percent of the ingredients added to the furnace (Document ID 0266, p. 6-7, 14-15). The furnace operator spent 75 percent of the time in a control room and occasionally checked on equipment or collected samples outside the booth (Document ID 0266, pp. 6, 11). The production assistant spent both shifts working and cleaning around the furnace and fiber production equipment. The furnace was equipped with a low-volume ventilation system (suggesting that the system was designed to remove heat rather than air contaminants) (Document ID 1365, 4-12; 0266, p. 9). The production assistant, referred to at this facility as a shot-man, charged the furnace by dumping silica flour into the charge hopper from 2-ton sacks suspended from a pallet jack (Document ID 1365, p. 14-12; 0266, p. 12).

The high-quality sand required for the delicate process of vitreous fiber production is one factor that might contribute to the low silica exposure of furnace operators. Clean, uniform sand particles optimize melting and minimize impurities that can cause problems in the production process or reduce product quality (Document 1365, p. 14-12). NIOSH indicated that the silica flour used in spun ceramic fibers was of mesh number 140 or less, meaning approximately 100 µm or less maximum particle size (Document ID 1365, p. 14-12; 0266, p. 6). Sand particles are also routinely separated to limit the lower particle size, so it is possible that the flour used contained minimal particles in the respirable range (Document ID 1365, p. 14-12; 0205, pp. 4-5).

The glass manufacturing industry typically uses automated equipment to charge melting furnaces (see Section IV-4.9 – Glass Products). However, at the refractory product facility visited by NIOSH, the shot-man spent a portion of the shift emptying large bags of sand into the furnace hopper (Document ID 1365, p. 14-12; 0266, p. 12). OSHA received no comments on the type of controls used at the refractory product facilities for furnace operators, but assumes, consistent with the conditions that applied to its collected data, that baseline conditions for furnace operators include a control booth for the operator and only heat extraction ventilation on the furnace. Silica ingredients for fiber production are typically sized larger than the respirable range, which might limit respirable-size particles fed to the furnace (Document ID 1365, p. 14-12; 0205, pp. 4-5; 0266, p. 6).

Although OSHA requested during the comment period additional exposure data for ceramic fiber furnace operators in refractories industries, it did not receive any. In the absence of additional data, OSHA concludes that the exposure levels summarized in Table IV.4.18-B for ceramic fiber furnace operators accurately reflect as a baseline condition a median of 14 µg/m^3.

Exposure Profile and Baseline Conditions for Packaging Operators

The exposure profile in Table IV.4.18-B includes 13 samples for packaging operators in the refractories industry. The median is 23 µg/m^3, the mean is 30 µg/m^3, and the range is 10 µg/m^3 to 118 µg/m^3. Table IV.4.18-B shows that, of the 13 samples, 1 (7.7 percent) is above 50 µg/m^3 and 1 (7.7 percent) exceeds 100 µg/m^3. Seven of the remaining 13 samples (53.8 percent) are 25 µg/m^3 or less (Document ID 1365, pp. 14-12 – 14-13; 0193, pp. 55, 58; 0089, pp. 38-42, 47-52, 58-62, 69, 72; 0266, pp. 14-15; 3958).

The highest exposure, 118 µg/m^3, was associated with a worker who spent the 8-hour shift alternating between tending a bag-packing machine and charging blending equipment with the ingredients needed for the next product to be packaged by the bag-packing machine. This latter activity involved manually dumping bags of raw materials into the ventilated charge hopper. A significant source of exposure for this worker was an adjacent bulk bag filling station, which leaked a substantial amount of dust that was subsequently pulled through the worker's breathing area by the charge hopper ventilation (Document ID 1365, p. 14-13; 0089). Operators at other unventilated bag-packing stations who did not charge hoppers had exposures of 23 µg/m^3, less than or equal to 30 µg/m^3 (LOD), and 41 µg/m^3 (Document ID 1365, p. 14-13).[114] OSHA recommended that the employer add LEV to all packing stations.

NIOSH and OSHA sample results from two other facilities also suggest that bag dumping and mixing activities are a greater source of exposure than packaging. NIOSH reported 4 packaging operator samples (bag-packing only) (one at 19 µg/m^3, and three below the LOD), while OSHA reported 1 packaging operator sample (bag packing only) (12 µg/m^3). However, a supervisor at the facility visited by NIOSH, who also managed the mixing area, had an exposure of 38 µg/m^3, twice that of highest packaging operator sample result (Document ID 1365, p. 14-13; 0266, p. 14; 3958).

[114]At this facility, ingredients for the products the workers packaged could contain up to 50 percent quartz, but bulk sampling indicated actual concentrations were in the range of 1.0 to 5.0 percent quartz (Document ID 1365, p. 14-13; 0266, pp. 5-6).

4.18) Refractories

Although OSHA requested additional exposure data for packaging operators in the refractories industries during the public comment period, it did not receive any. In addition, OSHA received no comments on its description of baseline conditions for refractory packaging operators in the PEA. Based on this and on the information described above, OSHA concludes that baseline conditions for packaging operators in this industry typically include unventilated bag-packing equipment and potential exposure from adjacent uncontrolled or inadequately controlled processes. The majority of the sample results summarized in the exposure profile in Table IV.4.18-B were obtained under these conditions. As a result, OSHA concludes that the exposure levels summarized in Table IV.4.18-B for packaging operators accurately reflect as a baseline condition a median exposure level of 23 $\mu g/m^3$ and a mean of 30 $\mu g/m^3$.

Table IV.4.18-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Refractories Industry (2007 NAICS 327124, 327125)

	Exposure Summary			Exposure Range		Exposure Profile

4.18.3 Additional Controls

Additional Controls for Material Handlers

The exposure profile in Table IV.4.18-B shows that 40 percent (12 out of 30 samples) of material handlers have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Additional controls include improved ventilation at bag dumping stations and associated ventilated bag compactors, and increased use of automated equipment to charge hoppers and mixing equipment.

One control option that would reduce exposures to at or below 50 μg/m^3 involves bag dumping stations with properly ventilated enclosures, which capture dust released during both bag emptying and bag disposal. A bag dumping station with fully functioning LEV was found to reduce silica exposure by at least 92 percent (Document ID 0199, pp. 6-13). The stations consisted of hoppers topped with grates that were enclosed by LEV hoods. After each bag is emptied, the worker releases it, and suction automatically pulls the bag into the ventilation system and transfers it to an enclosed storage area. Although no exposure information was identified for refractory products facilities using such bag dumping stations, comparable respirable quartz exposure monitoring data exist for workers using bag dumping stations to empty 50-pound bags of silica-containing materials at a paint manufacturing facility (Document ID 0199, pp. 6-12). Other similar types of bag dumping stations (e.g., systems incorporating enclosures, empty bag compactors, bag disposal chutes, LEV) also have been proven effective (Document ID 1365, pp. 14-14 – 14-15; 1681). Ventilated bag stations are readily available from commercial sources (Document ID 0581; 1429; 0680; 1212; 1224).

Automated material transfer equipment can also help reduce dust released as hoppers are filled. A sample result below the LOD (13 μg/m^3) was obtained for a material handler monitoring the automated transfer of raw materials (Document ID 1365, p. 14-15; 0266, pp. 10, 14-15). Although the value of this sample result is limited by the low silica content of the respirable dust sample (less than 1 percent, the LOD), sample results obtained in similar industries further demonstrate the value of automated equipment for reducing exposure. For example, at a structural clay facility inspected by OSHA, an 86-percent reduction in respirable quartz exposure readings (from 501 μg/m^3 to 70 μg/m^3) occurred after management installed an enclosed, automated sand transfer system (Document ID 1365, p. 14-15; 0161, pp. 183, 424-427, 1059-1060). The inspection report noted that sand leaked from the conveyor leading to the hopper because it was not the correct size. With tightly sealed components, exposures could be reduced further.

Additional Controls for Forming Operators

The exposure profile in Table IV.4.18-B shows that 12.5 percent (1 out of 8 samples) of forming operators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

As noted above, OSHA has determined that the exposures above 50 μg/m^3 for forming operators in the refractory products industry are associated with activities without ventilation or with ventilation that is not operating properly. OSHA believes that in such cases, forming operator exposure levels would be reduced to 50 μg/m^3 or less by controlling dust released from adjacent operations (bag dumping and mixing performed by material handlers), improving maintenance on existing LEV at forming stations, installing new LEV systems, and/or using wet methods or a high-efficiency particulate air (HEPA)-filtered vacuum rather than compressed air to clean molds (Document ID 1365, p. 14-16; 0266, p. 13; 1720, p. IV-311).

In particular, combination “push-pull” ventilation—designed to exhaust contaminated air near the source while supplying a similar amount of clean air behind or above the worker’s head—has been demonstrated to be very effective. Experimental data from Heinonen et al. (1996) during the simulated manual weighing of flour additive powder showed that compared with general ventilation alone, breathing zone total dust concentrations were reduced by 98 percent (from 42 mg/m^3 to 1.0 mg/m^3 or less) when the work surface was fitted with exhaust ventilation (at the front, side, or as a downdraft) in combination with local clean air supply above the workers head (Document ID 1393, pp. 357, 360). Although there are no data on the use of this type of system in refractory product facilities, OSHA expects this type of “push-pull” ventilation system would be similarly effective for reducing levels of respirable silica for refractory products forming operators that work at specific stations (Document ID 1393, p. 360).

As noted previously, some of the highest silica exposures reported in the surrogate data discussed in the PEA were associated with poorly functioning LEV. Improved maintenance on the existing LEV (reconnecting and repositioning exhaust ducts) would improve dust control at individual presses. Further control options focus on limiting dust emitted from the mold cleaning process, which occurs every few seconds. For example, better enclosure of the area around the mold and increased exhaust ventilation rate will capture more of the dust disbursed during mold cleaning. Alternatively, use of a HEPA-filtered vacuum brush to clean residual clay from the molds (rather than compressed air) would reduce airborne concentrations of silica, a control strategy that would require changes to the automated press design (Document ID 1720, p. IV-311).

Additional Controls for Finishing Operators

The exposure profile in Table IV.4.18-B shows that none of the finishing operators has exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that no additional controls will be necessary to achieve the PEL for these workers.

The exposure profile indicates that finishing operators’ silica sample results are well below 50 μg/m^3. However, OSHA has determined that the exposure profile might underestimate the potential for exposure for finishing operators in the refractory products industry because all of the data in the exposure profile were collected at a single facility during work with alumina-based refractory products that contained only a small percentage of silica. If operators work on materials containing a modestly higher proportion of silica, the existing exhaust ventilation systems will continue to maintain exposures at or below 50 μg/m^3. However, at the limited number of facilities where finishing operators cut or grind high-quartz or high-cristobalite materials, used especially for shaped products such as fire bricks (no data available for the exposure profile), exposures are likely to be significantly higher. At these facilities, additional controls might be required. Appropriate engineering controls associated with finishing equipment include LEV and water-fed equipment (Document ID 1365, p. 14-17).

Although no data are available for cleaning/finishing operators in the refractory products industry, exposure monitoring data from the foundry industry (using grinding equipment to remove residual refractory mold material, typically a mixture of sand and clay, from metal castings) provide good evidence for the effectiveness of LEV. In analogous foundry operations, the use of downdraft benches was associated with a 69-percent reduction in mean silica concentration for grinders (Document ID 1365, pp. 4-24 – 4-25; 0130).

Similarly, limited data are available to support the use of water-fed equipment with refractory products. OSHA reported a silica concentration of 18 μg/m^3 in the breathing zone of a construction worker using a water-fed stationary masonry saw to cut refractory fire brick during a 340-minute sampling period (less than full shift) (Document ID 1365, pp. 14-17; 0102, pp. 3, 7-10, 40).[115] Based on this information from similar processes in other industries, such as the concrete products industry, OSHA has determined that LEV and wet methods can also be effectively used to control exposure when cutting refractory brick in the refractory products industries. For further discussion of both water-fed (dust suppression) and LEV (dust capture) dust control for finishing equipment, see Section IV-4.3 – Concrete Products.

To further reduce exposures, combinations of controls have been effective. LEV combined with wet methods was used with grinders at a second refractory brick manufacturing plant evaluated by NIOSH (Document ID 0909, pp. 21-Encl 2 - 22-Encl 2). There, the grinders were enclosed in a ventilated cabinet, and water or oil was used during grinding to keep dust down. Although no PBZ silica samples were obtained at this facility, OSHA SEP inspection reports from the stone and stone products industry suggest that a combination of controls can reduce silica levels. For example, the median full-shift PBZ silica exposure level was 31 μg/m^3 for eight sawyers at four facilities that

[115] Sample values were reported in Document ID 0161 as 0.20 mg/m^3 and differ slightly due to data handling. See Section IV-2–Methodology for more detailed information.

implemented housekeeping in combination with other control measures, such as enclosing the saw in a booth with a fan, pre-washing stone, managing slurry, increasing water flow for wet processes, and controlling dust from adjacent processes (Document ID 1365, pp. 11-17; 0046, p. 76; 0157, p. 340; 0176, pp. 93, 96; 0180, pp. 3, 13, 52, 56).

Additional Controls for Ceramic Fiber Furnace Operators

The exposure profile in Table IV.4.18-B shows that none of fiber furnace operators has exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that no additional controls are required.

The data in the Table IV.4.18-B suggest that the exposure levels of furnace operators handling quartz-containing batch mixes are less than 25 μg/m^3. The exposure results summarized in the exposure profile were obtained using sized ingredients that minimized the amount of respirable particles. Furthermore, a chemical glass manufacturing facility also reported sample results below the LOD during delivery and transport of size-separated bulk quartz that included a uniform range of particles considerably larger than respirable size (Document ID 1365, p. 14-18; 0949). Thus, where raw materials containing larger-than-respirable-size particles are used additional controls would not be required for this job category.

Additional Controls for Packaging Operators

The exposure profile in Table IV.4.18-B shows that 7.7 percent (1 out of 13 samples) of packaging operators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

As shown by Table IV.4.18-B, most packaging operator exposure levels are at or below 50 μg/m^3. Slightly more than ninety-two percent of packaging operators in the refractory products industry already experience exposures at or below the PEL. However, the sample results for 7.7 percent of the workers in the job category (1 of 13) exceed this level. As discussed in the baseline conditions section, exposure levels of most of these workers will be reduced when silica emissions from adjacent operations (e.g., material handling) are better controlled (Document ID 1365, pp. 14-19 – 14-21; 0089). In some cases, the bag-packing equipment might also require additional controls, which can include adding to and improving existing ventilation at bag filling equipment and hoppers, installing a dual nozzle system on bag filling equipment, and using effective bag valves (Document ID 1365, p. 14-19 – 14-21; 1326, pp. 754, 759; 1689, p. 8).

The only packaging operator sample that exceeded 50 μg/m^3 (118 μg/m^3), involved a worker who was adjacent to unventilated and leaking bulk bag filling equipment. This worker also manually dumped bags of silica-containing material to charge the bag filling equipment. OSHA recommended that the employer add ventilation to the bag filling equipment (Document ID 1365, p. 14-19; 0089). Additional sources of exposure at typical bag-packaging equipment, noted in a report on the concrete products industry, can include dust generated while bags are being filled; when filled bags are dropped and impact the conveyor; and when workers use compressed air to clean their clothing (Document ID 1365, p. 14-19; 1689, p. 8). Recommendations for reducing exposures included repairing leaks in the LEV system, installing LEV hoods on the fill nozzles, reducing the distance that filled bags must fall to the conveyor, and prohibiting the use of compressed air to clean clothing.

OSHA SEP inspection results illustrate the effectiveness of well-designed LEV for analogous packaging tasks. At a concrete products facility, installation of a more powerful fan motor and new filter bag for the bag filling machine, LEV, and moving the hoods closer to the packaging operator's position reduced respirable dust exposure by 92.5 percent (Document ID 1365, p. 14-19 – 14-20; 0126). After these improvements, a packaging operator had a full-shift silica exposure of less than or equal to 11 μg/m^3 (LOD) (Document ID 1365, p. 14-20; 0126). An inspection at another facility obtained a full-shift exposure reading of 12 μg/m^3 (LOD) for a worker who operated a dry concrete mix bagging machine equipped with a dust collection system (Document ID 1365, p. 14-20; 0073). Another type of ventilation for bag filling operations, an overhead air supply island system (OASIS), has been shown to reduce respirable dust exposure by 98 percent and 82 percent for packaging operators at two mineral processing facilities (Document ID 0161, pp. 1549-1554; 1326, p. 754). OSHA expects that OASIS would be similarly effective at reducing silica exposures of packaging operators in the refractory products industry.

A dual nozzle system for bag filling machines can also reduce exposures for packaging operators. This system consists of an inner fill nozzle (to load the bag with material) surrounded by an outer nozzle (to depressurize the filled bag and remove dust from the bag valve, thereby preventing dust release). This type of system has been shown to reduce respirable dust levels by 83 percent at a mineral processing facility (Document ID 1365, p. 14-20; 1326, p. 754). The use of bag valves that seal effectively and prevent product leakage from filled bags is another way to control exposure. Respirable dust exposures were reduced by more than 60 percent with the use of 6-inch extended polyethylene valves compared with standard paper valves, and by more than 45 percent with the use of 4-inch foam valves (Document ID 1365, pp. 14-20 – 14-21; 1326, p. 759). Based on this information, OSHA expects that a dual nozzle system and effective bag valves can be effectively used to reduce silica exposures of packaging operators in the refractory products industry.

Finally, the bag quality or use of inappropriate bags for the product could also be a significant source of exposure. Bags that break during filling can be a notable source of silica dust and can contribute to operator exposures of two to three times the preceding permissible exposure limit (PEL). On a busy production line, improperly handled or low-quality bags might break frequently, up to 10 to 20 times per two hours (Document ID 1365, p. 14-21; 0587, p. 2). In addition, leakage from bags which are inappropriate for the product type can also be a major source of exposure. In one dry concrete bagging facility, changing the type of bag used in packaging from a three-ply bag perforated throughout to a two-ply bag perforated only on the inner layer reduced respirable dust by 83 percent (Document ID 0766). Workers should be trained on proper techniques for filling and handling bags as well as provided with high-quality bags of a type recommended for the product type, filling equipment, and subsequent handling requirements to control for these types of bag failures (Document ID 1365, p. 14-21; 0587, p. 2).

4.18.4 Feasibility Findings

Based on the exposure profile in Table IV.4.18-B and other record evidence discussed above, OSHA finds that the standard is technologically feasible for the different categories of refractories workers in refractory industries and additional controls previously discussed are used.

OSHA received comments from two small refractory manufacturers arguing that a PEL of 50 μg/m^3 was not technologically feasible; both expressed a similar belief that "it may not be possible to attain lower levels than 100 μg/m^3 in a given process, even with significant process and engineering controls" (Document ID 2056, p. 1; 3731, p. 1). Neither commenter provided exposure data or any supporting detail.

OSHA's inspection database reflects facilities that are both well-controlled and facilities that have poor or no controls at all, indicating that exposures can be significantly reduced with the appropriate engineering controls and work practices. As a result, OSHA disagrees with these comments and believes that the available data summarized above demonstrate that exposure levels for 77.8 percent of the workers in this industry are already at or below the PEL and exposure levels can be controlled to at or below the PEL for the remaining workers in the industry with existing, effective control technologies.

Feasibility Finding for Material Handlers

Based on the exposure profile in Table IV.4.18-B and other record evidence discussed above, OSHA finds that more than half (60 percent) of all material handlers in this industry already achieve exposure levels of 50 μg/m^3 or less. OSHA finds that by improving or adding ventilation at bag dumping stations and adding ventilated bag compactors, as well as by enclosing and ventilating mixing equipment, the exposure levels for most material handlers can be reduced to at or below 50 μg/m^3 most of the time. This conclusion is based on sampling results from the paint manufacturing industry, previously discussed under additional controls for material handlers, which indicate that a well-functioning ventilation and bag disposal system at manual charge hoppers can reduce exposures by 92 percent or more (Document ID 0199, pp. 6-13). A similar reduction in the refractory products industry would yield a maximum exposure well below the PEL of 50 µg/m^3.

Based on the information included in this section, OSHA concludes that the enclosure and ventilation controls alone will effectively reduce the exposure level of material handlers to 50 µg/m^3. However, when material handlers work with specific refractory materials with very high silica content, further controls, such as automated material transfer equipment, may be necessary. An 86-percent exposure reduction (observed in the structural clay industry for an enclosed, automated sand transfer system) would reduce all but the highest exposure to 50 µg/m^3 or less (Document ID 1365, p. 3-26; 0161).

Feasibility Finding for Forming Operators

Based on the exposure profile in Table IV.4.18-B and other record evidence discussed above, OSHA finds that most forming operators (87.5 percent) already experience exposure levels at or below 50 µg/m^3. OSHA finds that by controlling dust released during adjacent material-handling activities, increasing maintenance on existing LEV systems in the forming area, and using wet methods to clean molds, exposure levels at or below 50 µg/m^3 can be achieved for most forming operators most of the time.

Feasibility Finding for Finishing Operators

Based on the exposure profile in Table IV.4.18-B and other record evidence discussed above, OSHA finds that finishing operator exposures are already well below the PEL of 50 µg/m^3. Even if the exposure profile underestimates the exposures for workers who may cut or grind high-quartz materials, their exposure levels can be maintained at or below 50 µg/m^3 through improved LEV on saws and grinders, wet methods, or a combination of controls, as recommended by ACGIH (Document ID 3997).

Feasibility Finding for Ceramic Fiber Furnace Operators

Based on the exposure profile in Table IV.4.18-B and other record evidence discussed above, OSHA finds that the exposure of all ceramic fiber furnace operators is already less than 50 µg/m^3. Thus, additional controls are not required. However, if higher exposure levels are encountered, the use of sized ingredients can limit the number of respirable particles.

Feasibility Finding for Packaging Operators

Based on the exposure profile in Table IV.4.18-B and other record evidence discussed above, OSHA finds that, most (92.3 percent) packaging operators are already exposed at or below 50 µg/m^3. For the remaining packaging operators, OSHA finds that improved workstation ventilation can control exposure to levels of 50 µg/m^3 or less. If further controls are required, a dual-nozzle filling system and/or the use of effective bag valves can reduce exposures. In some cases, the exposure levels of packaging operators will be reduced when facilities control adjacent sources of airborne silica associated with other job categories.

Overall Feasibility Finding

Based on the exposure profile in Table IV.4.18-B and other record evidence discussed above, most workers sampled (77.8 percent) in the refractory products manufacturing industry are exposed to 50 µg/m^3 or below. Thus, OSHA concludes that most workers at refractory facilities are currently exposed to silica levels at or below 50 µg/m^3. For workers who are currently exposed above 50 µg/m^3, most notably material handlers, forming operators, and packaging operators, the engineering and work practice controls described in this section can be implemented to reduce silica exposure levels to 50 µg/m^3 or less in most operations, most of the time. Therefore, OSHA finds that the final PEL of 50 µg/m^3 is technologically feasible for the Refractory industry.

4.19 REFRACTORY REPAIR

4.19.1 Description

Refractory materials, also known as refractories, are typically used to line furnaces or other equipment where commercial production processes exceed temperatures of 1,000 degrees Fahrenheit. Refractories are produced with raw materials that include silica-containing minerals such as quartz, cristobalite, bauxite, and fireclay. Refractory materials are used in the construction of furnaces, boilers, cupolas, hot gas stacks, ladle linings, smelting pits, and incinerators. High-temperature applications requiring refractory equipment occur in a wide range of industries, including brick and pottery manufacturing, glass manufacturing, metal casting (foundries), smelting operations, steel production, chemical plants, and waste incineration.

While some facilities utilize their own maintenance workers to repair and replace refractory materials, others subcontract this work to firms that specialize in refractory repair. In-plant foundry workers who handle refractory material are covered in Section IV-4.8 – Foundries (Metal Casting). Other industries (as well as most foundries planning to completely reline furnaces) are more likely to use the services of contractors. Workers who repair and replace refractory materials as their primary activity are typically employed by refractory repair and replacement services contractors; up to 75 percent of all companies across all industries use a contract service to reline their furnaces (Document ID 1159, p. 1). These workers travel to customers' facilities, or, less frequently, customers' equipment is brought to them for refractory relining. Workers who specialize in refractory repair are classified under the six-digit North American Industry Classification System (NAICS) code 423840, Industrial Supplies Merchant Wholesalers. Refractory workers employed by refractory product suppliers are likely to service a range of industries and work with diverse refractory materials (Document ID 1365, p. 16-3).

Refractory workers typically perform a variety of activities during a work shift, such as set up, tear out, installation, and cleanup (Document ID 1365, p. 16-5). Table IV.4.19-A summarizes, under the single job category of contract refractory worker, the major activities and primary sources of silica exposure for workers performing refractory repairs. The relining process involves two basic steps: 1) removal and demolition of the old or damaged lining (or portion thereof), and 2) installation of new or replacement refractory material. Demolition of refractory is the activity that has the most potential to produce elevated exposures as silica-containing material becomes airborne due to the mechanical energy of demolition tools.[116] Workers rarely remove, or demolish, refractory material for a full shift; up to 2 hours per day is more typical, particularly if the job is small (Document ID 1161; 0121, p. 27). However, workers may also perform demolition activities for longer than two hours, and large jobs can take up to an entire shift. One report indicated that the removal of an old refractory took 60 minutes and the entire relining operation could be completed efficiently in five hours (Document ID 0121, p. 10).

The refractory materials are chipped and torn out using hammers, jackhammers, pneumatic chisels (handheld or mounted on wheeled equipment), and rakes. Refractory workers then use shovels, brooms, buckets, and cranes to transfer the resulting waste materials to waste bins (Document ID 1365, pp. 16-3—16-5; 0793, pp. 46-47; 1161, p. 1). Although refractory workers use remote mechanical removal processes (e.g., hydraulically controlled chisels attached to a small tractor) for as much as 70 percent of their work, some refractory removal jobs require work with handheld tools (Document ID 1162). Workers use hand tools exclusively in tight spaces and around delicate portions of the equipment (Document ID 1365, p. 16-3).

New linings are applied by various methods; the method depends on the type of lining being installed. In some cases, workers pour and ram (i.e., compact using gas- or electric-powered vibrating equipment) low-moisture powdered refractory materials. These materials also can be blown into place using air guns that introduce a small amount of water into the spray as a “shotcrete”-type operation. Alternatively, refractory workers (sometimes classified as masons) position prefabricated refractory ceramic shapes, bricks, bats, or tiles and use refractory mortar (mixed from powdered product received in

[116] OSHA expects that the other activities performed by refractory repair workers do not generate as much airborne dust as demolition activities, which are responsible for the highest recorded exposures (Document ID 0050).

sacks) to seal the spaces between the shapes (Document ID 0969, p. 1). Other lining materials are mixed (in a bucket or tote) from powder and liquid ingredients by refractory workers who then trowel or pour the resulting “plastic” paste into position, in processes similar to plastering or casting concrete. Workers typically perform much of refractory installation work manually, within arm’s length of the worker’s breathing zone and often within the enclosed confines of the furnace or oven (which might be classified as a confined space) (Document ID 1365, p. 16-4; 1390).

The North American Insulation Manufacturers Association (NAIMA) agrees with OSHA’s characterization of these operations. NAIMA stated that repairs or rebuilds have two components: the removal of the refractory brick or lining, and the installation of new refractory material (Document ID 2348, Attachment 1, p. 4). NAIMA further explained:

> The demolition phase results in potential worker exposure to dust as the silica-containing refractory is removed. Although some refractory blocks can easily be removed with pry bars, others may require the use of jackhammers, air chisels, and other tools. During rebuild operations all or part of the existing furnace, channel, and forehearth is demolished and then rebuilt. The demolition process may be performed by the manufacturer’s employees or a construction contractor’s employees or a combination of both.
>
> The installation of new refractory, or the rebricking phase, results in potential worker exposure to silica as the refractory brick and preformed pieces may need to be cut and adjusted during installation. Silica exposure similarly occurs with refractory repair work performed between furnace rebuilds. During repairs, workers have to remove the refractory brick and replace it with new refractory brick that may have to be cut and formed on an urgent basis. New refractory brick is typically cut with wet sawing techniques that would greatly limit dust from the sawing process and the finished piece. Silica exposure, above the proposed [permissible exposure limit] PEL and action level would more likely occur during demolition or removal of spent refractories (Document ID 2348, Attachment 1, pp. 4-5).

The Glass Association of North America (GANA) similarly commented that employees and contractors have exposure to silica when doing furnace rebuild or repair work, such as tearing out old refractories, replacing them with new refractories, hauling away waste refractories, cleaning used refractory bricks for recycling, and cleaning furnace control equipment (Document ID 2215, p. 4).

Table IV.4.19-A Job Categories, Major Activities, and Sources of Exposure of Workers in the Refractory Repair Industry (NAICS 423840)	
Job Category*	**Major Activities and Sources of Exposure**
Contract Refractory Worker	Removing/demolishing old or damaged refractory material from furnaces and other equipment. • Dust generated by using handheld or hydraulically controlled demolition tools (e.g., chisels, jackhammers, rakes). • Preparing new refractory materials for installation. • Dust released when mixing dry ingredients. • Dust generated by dry cutting bricks with saw. Installing new dry refractory materials. • Dust released by emptying sacks of product. • Dust raised by compacting product with vibrating tools. • Dust released by applying product with air gun. Installing new refractory brick or precast shapes using refractory mortar or grout to seal surfaces and cracks. • Dust raised when handling dry, powdered mortar. • Performing cleanup and housekeeping activities. • Dust raised from dry sweeping, shoveling, and transporting silica-containing debris and materials.
*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility. Source: Document ID 1720, p. IV-318.	

Table IV.4.19-B summarizes the available exposure information for refractory workers. OSHA concludes that Table IV.4.19-B represents baseline conditions.

4.19.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.19-B includes 6 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for workers in the refractory repair industry. The median is 33 µg/m^3, the mean is 63 µg/m^3, and the range is 12 µg/m^3 (i.e., LOD) to 196 µg/m^3. Table IV.4.19-B shows that, of the 6 samples, 2 (33.4 percent) are above 50 µg/m^3 and one (16.7 percent) exceeds 100 µg/m^3. Five of these samples were obtained from two OSHA Special Emphasis Program (SEP) inspection reports, and one sample was obtained from the OSHA Information System (OIS) database (Document ID 0164; 0037; 3958). These limited results include four exposures (67 percent) less than or equal to 50 µg/m^3.

Two samples below 50 µg/m^3 were collected while workers relined a furnace at a customer's facility. During the refractory removal process, the workers used a jackhammer and shovel to chip the lining and collect debris. One worker used a crane to transport refractory waste to a trash receptacle, while the other used a "wet vacuum" (and changed the vacuum filter). The samples were also analyzed for cristobalite, but none was detected in any of the samples (Document ID 0037, pp. 4, 132-139). Two samples, 90 μg/m^3 and 196 μg/m^3 (cristobalite was not analyzed), were obtained at a refractory service provider's work site where workers were reconditioning a furnace. These elevated results are associated with two workers who used a jackhammer and crowbar to remove the refractory furnace lining during the entire shift (Document ID 0164, pp. 70-77).

Samples from the foundry industry also show that exposures occur during refractory removal. As presented in Section IV-4.8 – Foundries (Metal Casting) of this analysis, exposure data from refractory removal and relining activities by in-plant workers at foundries show that exposures may exceed 200 μg/m^3 and exceed the levels identified for refractory workers providing contract services. However, OSHA has reason to believe that the most elevated foundry results might not be typical of the highest exposures likely to be experienced by contract refractory workers. Contract refractory service providers perform the same work on a daily basis and, compared with foundry workers, are more experienced and better equipped to reduce exposure levels during removals by using engineering controls and installing refractory materials in a manner that is less likely to generate dust (Document ID 1720, p. IV-321).

Silica exposures are not expected to occur during installation of refractory ceramic fibers (RCF), but could be possible during removal activities after the material has been in service as reflected in two studies revealing that elevated silica exposures can (but do not always) occur during removal of RCF (Document ID 1414, p. 361; 1389, p. 532). Data from a 1998 study by Maxim,et al., suggest that silica exposure above 50 μg/m^3 based on task sampling is not common during RCF removal (demolition) work (mean concentration was 43 μg/m^3). These data were excluded from the exposure profile because they predate 1990 (Document ID 0793, p. 51).[117]

[117] See Section IV-2–Methodology for sampling data criteria.

NAIMA submitted a summary of exposure results to the docket. These results were not incorporated into the exposure profile because they are summary results and not individual PBZ samples, and three of the samples are area samples while the other eleven samples do not have a characterization of sample type (Document ID 3999, Attachment 1, pp. 2, 4). NAIMA provided summary results from fourteen exposure samples for refractory repair, obtained from its wool manufacturing members (Document ID 3999, Attachment 1, pp. 2, 4). NAIMA submitted two tables containing exposure results during furnace demolition and rebuild. The first table identifies the geometric mean of 11 samples taken during furnace demolition and rebuild operations as 21.92 μg/m^3. Although it is not clear from its submission, it is likely that these measurements were from personal breathing zone samples since NAIMA included area sample results on a different table (Document ID 3999, Attachment 1, p. 2). There were three area samples for furnace demolition and repair activities, which ranged from 29 to 30 μg/m^3 (Document ID 3999, Attachment 1, p. 4). In its earlier submission to the rulemaking record, NAIMA stated that its furnace demolition, cleanup, and rebuild exposure data ranged from 4.6 to 62 μg/m^3 (Document ID 2348, Attachment 1, p. 17).

GANA acknowledged the use of engineering controls, wet methods, and ventilation during furnace rebuild operations. It commented, however, that personal protective equipment (PPE) to limit exposures to silica dust was needed because it was not feasible to use engineering controls alone to control dust exposures (Document ID 2215, pp. 4, 6-7.)

OSHA reviewed several reports that describe engineering controls currently being used for refractory repair work. Based on published literature and information from industry members, OSHA has determined that up to 70 percent of refractory work is performed using hydraulically controlled tools mounted on equipment outside the furnace and a few feet away from the point where dust is generated (Document ID 1162). Another semi-remotely controlled process involving a hydraulic “pusher” system is increasingly common for removing refractory lining from cylindrical induction furnaces. Manufacturers now build this capability into all induction furnaces over 4 tons and sell approximately 50 percent of new furnaces with this option (Document ID 1269; 0687).

Facilities for which OSHA has process information rarely report that exhaust ventilation is used to reduce the spread of silica (or refractory ceramic fibers). Thus, OSHA concludes that few refractory workers operate with the benefit of local exhaust ventilation (LEV) installed on the furnaces (Document ID 1365, pp. 16-11– 16-12).

Some refractory workers use vacuums for cleanup (Document ID 0576, p. 719-720; 0037, p. 134). Other sources report at least occasional use of wet dust control methods during refractory demolition or installation. OSHA therefore concludes that water-fed masonry saws are typically used for cutting firebrick (Document ID 0576, p. 719-720; 1365, p. 16-12).

NAIMA also stated that the mineral wool industry has implemented many of the engineering and work practice controls identified in the PEA for furnace rebuilds where practicable (Document ID 2348, Attachment 1, p. 22). NAIMA described the exposure control strategy its members currently employ:

> For rebuilds, where potential exposures to crystalline silica and other deleterious materials occur, mineral wool manufacturers have specified safety and health precautions to be followed to minimize worker exposures. These include but are not limited to: 1) restricting access to the furnace demolition and rebuild area to only those workers or contractors directly engaged with the project; 2) using respirators, protective clothing (*e.g.*, Tyvek suits), and other PPE to minimize airborne exposures and protect against other safety related hazards; 3) use water mist, other wetting means or dust suppressants to control dust generation; 4) vacuum clean-up of spilled mixed batch from the area prior to demolition; 5) where possible, removal of preformed refractory block by pry-bar rather than by powered air-chisels; and 6) air monitoring to better understand the airborne exposures and thus select appropriate PPE (Document ID 2348, Attachment 1, p. 22).

Based on a review of inspection reports, published literature, industry contacts, and submissions to the rulemaking record, OSHA has determined that refractory workers most commonly perform a combination of manual processes and semi-remote mechanical processes in areas with general ventilation in many cases, or with dedicated LEV in atypical cases (Document ID 1720, p. IV-322; 2348, Attachment 1, pp. 12, 13, 21; 1365, pp. 16-11 - 16-12). Additionally, baseline conditions include the use of other engineering controls such as automation, substitution, wet methods, and work practices by some employers (Document ID 2348, Attachment 1, p. 21; 1365, pp. 16-11–16-12). The median exposure for this job category (33 μg/m^3), presented in Table IV.4.19-B, is based on six samples obtained while workers repaired and replaced refractory materials. OSHA considers these results, although limited in number, to be representative of baseline conditions for contract refractory repair workers.

Table IV.4.19-B Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Refractory Repair Industry (NAICS 423840)											
	Exposure Summary			**Exposure Range**			**Exposure Profile**				
Job Category	**N**	**Mean ($\mu g/m^3$)**	**Median ($\mu g/m^3$)**	**Min ($\mu g/m^3$)**	**Max ($\mu g/m^3$)**		**<25 ($\mu g/m^3$)**	**≥25 and ≤50 ($\mu g/m^3$)**	**>50 and ≤100 ($\mu g/m^3$)**	**>100 and ≤250 ($\mu g/m^3$)**	**>250 ($\mu g/m^3$)**

4.19.3 Additional Controls

The exposure profile in Table IV.4.19-B shows that 33.3 percent (2 out of 6 samples) of material handlers have exposures above the final PEL of 50 µg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. The exposure profile, based on results from 4 of the 6 exposure samples, suggests that 67 percent of all contract refractory workers are currently exposed to silica levels at or below 50 µg/m^3. The remaining 33 percent will require additional controls. The exposure profile, however, may overestimate exposures in light of the NAIMA data, which reflect a geometric median of 21.92 µg/m^3 (Document ID 3999, Attachment 1, p. 2).[118]

Some stakeholders commented that the engineering controls presented are not capable of reducing exposures to or below 50 µg/m^3 for all workers (see, e.g., Document ID 2215, Attachment 1, p. 7; 2348, Attachment 1, pp. 25-26). GANA requested that the Flat Glass Manufacturing Industry be permitted to continue using respirators, wet spray, and other work practices during rebuilds (Document ID 2215, Attachment 1, pp. 7-8). This standard for general industry is performance-based and adopts OSHA's standard hierarchy of controls, under which respirators are viewed as a last resort after engineering and work practice controls; as such, respirators are neither mandated nor prohibited as part of an employer’s control strategy for refractory repair workers that limits their exposure to the PEL or below. Based on the information in the record, however, OSHA has concluded that there are feasible engineering and work practice controls that can consistently reduce most workers’ exposure to – and often well below – 50 µg/m^3 most of the time.

Additional controls include use of low-silica-content refractory materials, use of pre-formed materials, local exhaust ventilation, and wet methods; increased use of semi-remote or automated removal processes; improved work practices; and additional worker training. In describing these controls, OSHA has drawn from the experiences of industries such as mineral wool manufacturing, glass manufacturing, and foundries, whose workers perform work that is similar to contract refractory repair workers. OSHA

[118] OSHA did not incorporate NAIMA's data into the final exposure profile because it included only summary information and not individual sample results.

expects that these controls will be effective for controlling silica exposure during refractory demolition and installation, which is the source of most and highest silica exposures for this application group.

Several stakeholders have stated in response to the PEA that these engineering controls are not capable of reducing exposures to or below the PEL to all workers. GANA stated:

> During rebuild operations, the Flat Glass Manufacturing Industry currently uses various engineering controls and PPE to limit exposure to various materials, including silica dust, during the demolition. However, there are no identified feasible engineering controls that alone will reduce exposure levels to at or below the proposed PEL for all workers in all manufacturing facilities (Document ID 2215, p. 7).

Additionally, NAIMA argued that its analysis shows that engineering controls are not feasible:

> There is no evidence in the record identifying specific engineering controls or work practices that would lead to these workers' slightly elevated exposures being reduced below the PEL. Given the sporadic nature of these exposures and the physical characteristics of the furnace and hot end portion of the manufacturing plants, the only feasible option will be to increase use of PPE. The Final Rule should permit such use (Document ID 2348, Attachment 1, p. 32).

Both NAIMA and GANA argued that, because of the lack of feasible controls, its members should be permitted the flexibility to use engineering controls and work practices of their choosing.

OSHA is not limiting employer flexibility to meet the standard or requiring any specific control to the exclusion of an alternative effective control, but expects as a general matter that "slightly elevated exposures" can be reduced to the PEL or below with the use of additional controls. As the evidence presented in this section shows, there are feasible engineering controls capable of significantly reducing workers' silica dust exposures. As shown by the exposure profile and summary data submitted by NAIMA, most exposures to silica are already below the PEL of 50 μg/m^3. Based on the record, OSHA therefore concludes that controls exist to reduce worker exposure below the PEL most of the time during refractory repair and replacement.

Reduced-Silica Refractory Materials

Refractory materials with low silica content (5 to 10 percent silica compared with 90 percent silica) are readily available from commercial sources, although each low-silica refractory material is not necessarily compatible with every application for which refractory materials are used (Document ID 0691, p. 1; 1365, p. 16-12).

NAIMA argued that reduced silica refractory materials are not technologically feasible, and that using low-silica refractories would greatly reduce furnace life and result in more frequent furnace rebuilds (Document ID 2348, Attachment 1, p. 25). Similarly, Verallia stated that using a standard low silica refractory would shorten the furnace life dramatically, and that transitioning to low-silica refractory would add about 10 times to the cost (Document ID 3584, Tr. 2847).

OSHA understands that refractories are designed for specific purposes, and that substitution to reduced-silica refractory materials is not possible in every situation. However, the record shows that using low-silica refractory materials is viable for many refractories. For example, an OSHA inspection demonstrated that substitution provides an effective way to reduce exposures and also increase the furnace utility cycle. The Agency performed an inspection at a foundry where silica exposures were reduced by 90 percent after implementing a comprehensive exposure control program that included switching to a low-silica refractory applied to furnace walls by means of spray guns. The replacement refractory material was stronger and lasted longer, permitting refractory workers to use less material during cupola repair operations (Document ID 0121, pp. 2, 8-9, 13).

OSHA is not imposing specific requirements in the final rule requiring the use of alternative refractory material. Nevertheless, using lower silica-containing refractory material is a feasible control in some situations.

<u>Automated and Remotely Controlled Processes</u>

Automated refractory demolition and installation methods can reduce the number of workers exposed, the duration of exposure, and the exposure levels of refractory workers. A "pusher" system installed in coreless induction furnaces allows refractory linings to be automatically removed by push plates installed in furnace bottoms. The refractory materials are pushed or extruded out of the furnace, which has been tipped to lie horizontally. Waste falls directly into a disposal bin positioned at the furnace mouth (Document ID 0684). New induction furnaces fitted with push equipment are commercially available, accounting for 50 percent of new furnace sales, and all larger induction furnaces (over 4-ton capacity) have built-in push capability (Document ID 1269, p. 1; 0687). Additionally, existing furnaces might be retrofitted (Document ID 1269).

Although the evidence shows the push process to be quite dusty, it requires fewer workers and substantially less time than traditional removals. For properly equipped induction furnaces, a "push" removal can be completed in 15 to 30 minutes, while traditional methods might take up to two full days of using chipping hammers operated by foundry workers standing or crouching inside the furnace (Document ID 0684; 1358; 0686; 0713). No data are available to quantify the exposure reduction that a pusher system provides; however, a rough estimate can be made by comparing the relative time spent on the task under each removal method. Assuming that each method generates comparable breathing zone silica concentrations, a 30-minute push process would expose the worker for just 6 percent of a 480 minute shift; thus, exposure would be 94 percent lower for workers using the push process. In reality, it is also likely that some additional cleanup would be necessary for both removal methods.

For furnaces that cannot be fitted with pusher systems, large amounts of refractory material can be removed using chipping equipment attached to a hydraulically controlled articulated arm commonly available on some types of construction equipment. The operator remains outside the furnace and manipulates the arm from inside the equipment cab. The arm can be fitted with a camera to allow the worker to see the work area. Although this method is not suitable for very small furnaces or work around delicate instrument controls, one company that uses such methods estimates that 70 percent of large-scale lining removal jobs are performed this way (Document ID 1162). Although no data are available for the refractory repair industry, researchers have shown that well-ventilated cabs fitted and maintained to minimize dust can reduce in-cab dust levels by more than 90 percent (Document ID 1563, p. 4). OSHA concludes that the increased distance between the source of the dust and the worker's breathing zone and a well-ventilated cab would each substantially reduce worker exposure.

Automation also is an option for reducing exposures during furnace relining. A study described an automated system for installing dry rammable refractory material in coreless induction furnaces (Document ID 1390, pp. 6-7, 9-11). With this system, 70 percent fewer workers are required to complete the job, and the reported exposure levels during furnace relining ranged from less than or equal to 10 $\mu g/m^3$ to 20 $\mu g/m^3$ at five foundries using the automated equipment (Document ID 1367, pp. 10-11).

Precast Refractory Materials

Relining of induction and other furnace types also might be accomplished using precast refractory materials that are set in place as units, with minimal risk of exposure. Precast refractory materials can look like typical construction bricks, or they can have more sophisticated geometries that facilitate installation.

For example, curved shapes can be cast that sit flush against the furnace wall. The custom-made precast materials are sealed with refractory grout, mixed from a powder (Document ID 0713; 0969). When appropriate for a particular application, preformed refractory shapes can reduce installation labor, improve performance, and provide a longer service life compared with some brick and poured materials. When repairs are required, standard shapes mean that replacement parts can be kept on hand and that repairs can be isolated to the worn section of the lining, eliminating the need for complete tear-out and extended the period of time workers are exposed during demolition and relining (Document ID 1179). Because of these and other advantages, companies are more frequently using precast shapes instead of powdered products (monolithics) for certain applications (Document ID 0713).

NAIMA commented that these materials will not completely eliminate exposures nor will companies have a full inventory of precast materials for every repair. NAIMA also noted that not all furnace designs are amenable to precast shapes when the best design is simple refractory brick (Document ID 2348, Attachment 1, p. 26). Although precast refractory materials will not always be appropriate, there is evidence demonstrating that precast materials are being used more frequently than monolithic refractory materials (Document ID 0713). Using precast refractory materials can reduce exposures during installation and removal applications and can also result in longer overall refractory service life, reducing the time workers are potentially exposed to silica during replacement and repair (Document ID 1179).

Local Exhaust Ventilation (LEV)

The ventilation systems installed on furnaces to remove the heat and fumes generated during normal operation of the furnace cannot be considered an effective control for refractory workers. These ventilation systems are designed to exhaust rising fumes or gas during heating and are inadequate to control silica dust generated during periodic refractory replacement activities. The overhead design that is most effective for capturing rising heat exhaust is inappropriate for capturing dust generated on the walls and floor of the furnace because it pulls contaminated air through the worker's breathing zone (Document ID 3883, pp. 6-31 – 6-32).

LEV is an effective option to control dust generated when refractory workers chip or apply refractory linings inside the furnace. A company that provides refractory overhaul services developed a method for installing temporary LEV in a gas-fired furnace. This method is used for complete lining removals, but also is applicable to smaller patching jobs. The method, associated with silica exposures between 50 $\mu g/m^3$ and 100 $\mu g/m^3$, involves company-built exhaust fans fitted with air filters (three filters of increasing efficiency in series) (Document ID 1161; 1365, p. 16-15). Plastic sheeting is used as necessary to ensure that fresh air enters the furnace only from the most advantageous point, causing clean air to flow past the worker's breathing zone. Fan/filter boxes are set into the opposite and lower end of the furnace to exhaust dusty air from near the chipping point. Placement of the boxes should be carefully considered to obtain optimum performance (Document ID 1162). LEV also is a dust control option for refractory workers who empty bags or mix refractory powders (Document ID 1720). For smaller jobs, workers who dump bags of silica-containing materials can empty the bags into a movable hopper or other receptacle and then use a flexible sleeve to guide material from the hopper to the distribution point (e.g., a furnace bottom). A portable exhaust trunk (preferably with a semicircular slot or flanged hood) positioned near the bag dumping hopper can capture a portion of the dust released during that activity. Because additional silica exposure can occur when workers compress empty bags, this task also should be located near a portable exhaust trunk. Bag dumping for large jobs can sometimes be eliminated by obtaining powdered materials in bulk bags (e.g., 1-ton sack) filled by the supplier with the predetermined amount of product required for the job. As a standard feature, bulk bags come fitted with a sleeve through which material is dispensed. Bulk bags and sleeves are used for installing high-silica rammable refractory powder in induction furnaces. Maintaining the bottom of the sleeve, which releases material, at a level just below the surface of deposited material can keep dust emissions to a minimum (Document ID 0691, p. 2; 1367, p. 4).

Workers who mix high-silica refractory materials also would benefit from the use of a portable exhaust hood which is similar to the portable exhaust trunk discussed above (both are forms of LEV). The hood is able to capture some of the dust released while workers mix materials. Information from IV-4.17 – Pottery shows that the silica exposure of a coatings preparer (mixes silica-containing material) was reduced from 983 $\mu g/m^3$ to 47 $\mu g/m^3$ after exhaust ventilation was installed at the raw material hopper and the ball mill hatch (ball mill is a type of mixing equipment), and dust leaks were sealed elsewhere in the plant (Document ID 0174, pp. 98, 241). See also IV-4.15 – Paints and Coating (citing Document ID 0199, p. 9).

NAIMA and GANA commented that LEV control for furnaces and portable LEV for the other operations mentioned above are not feasible during demolition and rebuild operations. They objected that when the furnace or smelter is shut down, some of the associated engineering controls that help reduce exposure, including bag houses, collection chambers, and exhaust stacks, are also shut down (Document ID 2215, p. 7;

2348, Attachment 1, p. 26). Considering the evidence and testimony presented in this and in Section IV-4.8 – Foundries (Metal Casting), OSHA understands that while there may be challenges to installing efficient ventilation controls, particularly for large furnaces, other types of controls exist to mitigate workers' exposures, like automatic and ventilated chipping tools, which are discussed below. Ventilation systems are commercially available, or could also be designed by facilities based on their needs with readily available materials (Document ID 1162).

Ventilated Chipping Tools

The chipping of refractory materials in demolition is similar to chipping concrete, another silica-containing material. The tool-mounted systems used for controlling silica in other industries (e.g., construction and the ready-mixed concrete industries) can also be used in furnace demolition. NIOSH tested two tool-mounted LEV shrouds for handheld pneumatic chipping equipment (impact drills): one custom built, the other a commercially available model. Comparing multiple short-term samples, NIOSH found that rock-drill shrouds reduced total respirable dust to 870 $\mu g/m^3$, a 58 percent reduction, and custom-made shrouds reduced respirable dust to 1,120 $\mu g/m^3$, a 46 percent reduction from 2,060 $\mu g/m^3$ with no controls (Document ID 0865, p. 9).

In a separate evaluation, NIOSH showed that this type of LEV system controls dust equally well for larger chipping equipment. NIOSH collected short-term samples while workers used 25- or 30-pound jackhammers to chip concrete from inside concrete mixer truck drums. During 90- to 120-minute periods of active chipping, mean silica levels decreased 69 percent (from 970 $\mu g/m^3$ to 300 $\mu g/m^3$) when the workers used a tool-mounted LEV shroud in these enclosed spaces (Document ID 0862, p. 10). Although exposures in this NIOSH study are higher than exposures during demolition of refractory material (as the exposure profile shows), the control methods used would also work in reducing exposures during refractory demolition.

NIOSH also evaluated a combination of ventilation controls as part of the same study. The tool-mounted LEV shroud plus general exhaust ventilation provided an additional exposure reduction compared with uncontrolled conditions, resulting in a 78 percent decrease in silica readings (from 970 μg/m^3 to 220 μg/m^3) and a 69 percent decrease in respirable dust levels (from 7,760 μg/m^3 to 2,420 μg/m^3); the difference was due to a lower percentage of silica in the respirable dust sample associated with the combined control (Document ID 0862, pp. 10-12). These ventilated chipping tools reduce worker exposures from both impact drills and jackhammers used to chip refractory materials.

Wet Methods

Wet methods can be successfully used to control silica exposures in a number of operations, including chipping, sawing, spraying, and handling dusty refractory materials, and are currently being used by some in the refractory repair service industry (Document ID 2348, Attachment 1, p. 22).

Studies have quantified the benefit of using wet methods to control respirable dust generated during chipping with handheld equipment. NIOSH investigated a water spray dust control used by construction workers breaking concrete with 60- and 90-pound jackhammers (Document ID 0865). A spray nozzle was fitted to the body of the chipping tool, and a fine mist was directed at the breaking point. Using both a direct reading instrument and a high-flow cyclone and filter media, NIOSH collected 10-minute readings with and without the spray activated, and found respirable dust concentrations were between 72 percent and 90 percent lower when the water spray was used (Document ID 0865, p. 6). NIOSH completed another study evaluating water spray devices to suppress dust created while jackhammering. The study reported a 77 percent reduction in exposures, from 380 μg/m^3 to 85 μg/m^3 (Document ID 0867, p. 8, 17).

Tool-mounted water spray devices can be manufactured using materials obtained from a hardware store and include a garden spray nozzle, tubing, clamps, and a control valve (Document ID 0741; 0838; 0914).

Two more sources also show the effect that water misting devices have on dust control. One study examined dust suppression using misting nozzles to reduce silica while brick cutting using a stationary saw (Document ID 0549, p. 505). Water-fed saws are readily available and effectively control dust during sawing of concrete, stone, and bricks. In comparison with free-flowing water, the respirable mass fractions of dust were reduced by 63 percent with the mist on low, 67 percent on medium, and 79 percent on high (Document ID 0549, p. 509). In another study, the use of a bench-top water-fed masonry saw was associated with a less-than-full-shift (340 minutes) result of 18 μg/m^3 for a worker cutting refractory brick (Document ID 0113, pp. 6, 9, 10).[119]

Water spray also is useful for suppressing dust during cleanup. One employer uses a garden mister to wet refractory debris in the bottom of the furnace, after chipping is completed (Document ID 1162). This step helps control dust as the waste is removed from the furnace. The same employer also tested high-pressure water blasting as a refractory removal method; the process controlled dust, although workers found it difficult to manage the amount of water released in the process (Document ID 1162). This method could be effective in cases where water can be captured effectively.

Workers must use caution when introducing water into a furnace. Some refractory materials crumble and become muddy or slippery when wet with excessive amounts of water (Document ID 1414, p. 366; 1161; 1365, p. 16-18). During partial furnace rebuilding, wetting un-removed brick may introduce a safety hazard. According to the United Automobile Workers (UAW), using water for cutting bricks could cause an explosion when firing a furnace because the bricks absorb too much moisture (Document ID 3582, Tr. 1843-1846). OSHA concludes that wet method controls, while not suitable for every furnace repair situation, may be the best option to control silica during total furnace rebuilds because all the material will be new and dry but other controls such as LEV for demolition and vacuuming for cleanup may be more suitable for partial repairs.

Work Practices

Work practices, such as limiting the number and location of operators working in a furnace at one time, can reduce refractory worker exposures during removal activities. NAIMA noted that its members restrict access to the furnace demolition and rebuild area to only those workers or contractors directly engaged with the project (Document ID 2348, Attachment 1, p. 22).

[119] This value is not included in the exposure profile because it was less than full shift.

Another beneficial work practice is modifying the use of equipment during demolition activities. A study reported a higher silica exposure level for a refractory worker operating in a position closer to the point of operation than a second refractory worker within a 1,100-pound holding furnace for molten aluminum. The worker who experienced higher exposure levels reportedly bent over to grab and toss the pieces of refractory material debris while the other worker operated the jackhammer. This put the lower worker's breathing zone closer to the jackhammer's point of operation and dust generation than the breathing zone of the jackhammer operator. The employer installed ventilated partial enclosures that reduced the workers' exposures substantially (Document ID 1178, pp. 508-509). This study shows that performing these demolition activities can produce elevated exposures, especially if the worker's breathing zone approaches the point of operation, which in this case was the jackhammer tip. Allowing for a pause in demolition for the second refractory worker to collect and discard demolished refractory material would also obviously reduce the amount of airborne silica in the worker's PBZ.

Regular maintenance of equipment and controls can also reduce refractory workers' exposures. For example, workers experienced an exposure reduction of approximately 90 percent when a foundry initiated several control measures, including a preventive maintenance program to ensure proper function of air guns and related equipment used to spray refractory furnace lining materials (Document ID 0121, p. 15). Preventive maintenance programs can also ensure that workers are not exposed to high levels of silica because of faulty equipment. In another foundry, a worker's silica exposure level decreased after a foundry replaced the missing tool restraint on a pneumatic chipper used to remove the refractory lining from a large ladle. The tool restraint eliminated the need for this worker to lean into the ladle where dust was generated to hold the chipping blade in place (Document ID 0576, pp. 719-720). This improvement to the tool, in conjunction with other controls, reduced the worker's exposure by 70 percent.

Combined Control Methods

Depending on the sources of respirable dust, a combination of control methods can reduce silica exposure levels more effectively than a single method. A routine cupola relining (removal and replacement) in the ferrous foundry industry demonstrates the benefit of a combination of controls by achieving a 92 percent reduction in the median exposure (Document ID 1365, p. 16-21). Before implementing controls, OSHA collected samples for three workers with 8-hour TWA results of 324 μg/m^3, 456 μg/m^3, and 583 μg/m^3 (Document ID 0121, pp. 43-47). This facility then implemented control measures to reduce exposures that included substitution of a refractory material with reduced silica and greater moisture content, improvement in equipment and materials to reduce malfunction and task duration, wetting of refractory material before removal, and assigned a consistent team of trained workers to the task. After the foundry made these changes, additional monitoring was conducted during three relining events. Four of five samples measured exposures between 30 μg/m^3 and 50 μg/m^3, with one exposure of 62 μg/m^3. The median was reduced from 456 μg/m^3 to 37 μg/m^3, a reduction of 92 percent (Document ID 0121, pp. 2, 5-7, 9, 12, 42-47).

A second report on a facility performing refractory relining also demonstrates the benefits of a combination of control measures (Document ID 0576, pp. 718-720). A full-shift silica result of 215 μg/m^3 was obtained while a worker chipped away the old refractory lining using faulty equipment, and then mixed the replacement refractory material (Document ID 0576, p. 719). According to the manufacturer's material safety data sheet, the ladle lining contained 56 percent silica. This report noted that the "pneumatic chipper lacked a tool retainer, requiring the worker to hold the chipping bit, putting the worker much closer to the source of the exposure than would have been necessary had the pneumatic chipper been equipped with a retainer" (Document ID 0576, p. 718). The foundry responded by holding a training meeting and seeking worker input on abatement actions, implementing a water control system to reduce dust generated during the pneumatic chipping process, purchasing and using chisel retainers (thereby eliminating the need for the worker to reach into the ladle during chipping), and purchasing and using a vacuum to remove dust and debris from the ladle (Document ID 0576, pp. 719-720). With these changes in place, exposure was reduced to 74 μg/m^3, representing a 66 percent reduction (Document ID 0576, p. 720).[120] OSHA has reason to believe that this

[120] The 8 hour TWA exposure was .67 mg/m^3, equal to 670 μg/m^3, and the sample contained 11 percent crystalline silica. The silica exposure was therefore 670 * .11 = 73.7 μg/m^3.

facility might have achieved still lower silica exposure levels by using LEV or tool-mounted vacuum suction to capture dust, or by managing fresh air flow past the worker's breathing zone.

4.19.4 Feasibility Finding

Based on the exposure profile in Table IV.4.19-B and other record evidence discussed above, OSHA concludes that exposure levels of 50 μg/m^3 or less have already been achieved for 66 percent of refractory-repair workers by implementing a combination of engineering and work practice controls.

The remaining refractory-repair workers will require additional controls to meet this level. These controls include:

- Increased reliance on remote and semi-automated methods for removing and replacing refractory materials.
- Use of portable exhaust ventilation units configured to capture dust as it is generated and design of ventilation to direct fresh air flow past the workers' breathing zone.
- Use of chipping equipment fitted with water mist nozzle or LEV-exhaust hood on the tool.
- Use of upgraded spray guns that allow workers better control of the refractory/water mix during spray application.
- Improved worker training.
- Substitution of high-silica refractories with low-silica-content refractory materials, or materials with a higher moisture content, or precast refractory shapes that minimize airborne silica exposures.

OSHA recognizes that in some instances respiratory protection may be needed, for example, when workers have to go inside furnaces to remove refractory materials by hand or where there is not enough room around the furnace to use automated methods.

OSHA concludes that refractory repair services can achieve silica exposure levels of 50 μg/m^3 or less for most refractory repair workers most of the time by using a combination of the controls described in this section. Accordingly, OSHA finds that the final PEL of 50 μg/m^3 is technologically feasible for the Refractory Repair industry.

4.20 SHIPYARDS (MARITIME INDUSTRY)

4.20.1 Description

The maritime industry encompasses the shipbuilding and repair industry (shipyards) as well as the marine cargo handling industry.[121] Abrasive blasting with silica-containing abrasive is a widely-recognized source of silica exposure in the maritime industry (Document ID 1144, p. 1; 1145; 0852, p. 3; 1365, p. 10-1). Other processes performed in the maritime industry that can result in worker exposure to silica are either construction-related activities or foundry operations, both of which are covered elsewhere in this technological feasibility analysis. Examples of such activities include milling road pavement; grinding, drilling, and sawing concrete or masonry structures; and using jackhammers and impact drills on concrete.

Facilities that repair ships and build boats are classified under the North American Industry Classification System (NAICS) codes 336611 (Ship Building and Repairing) and 336612 (Boat Building). Shipyard workers who repair and build ships/boats generally use abrasive blasting to clean rust, paint, and adhesions from metal surfaces and to etch such surfaces in order to leave a profile or anchor pattern for paint and coating adhesion.

In shipyards, abrasive blasting is the most effective and efficient means of surface preparation. In general, across all U.S. industries, the use of silica sand in abrasive blasting has declined substantially, from 1,500,000 metric tons in 1998 to 579,000 metric tons in 2008 (Document ID 1679, p. 17; 1211, p. 12). In the maritime industry, silica sand has been replaced with other abrasive media in many shipyard applications (Document ID 1427, p. 8). This move away from silica sand abrasive is not universal. While many larger shipyards, including those operated by the U.S. Navy, have switched to non-silica media, some smaller shipyards continue to use sand (Document ID 1680, p. 3; 1365, p. 10-2).

[121] OSHA does not anticipate silica exposure in maritime operations related to the operation of shipping lines for commercial use such as loading and unloading cargo ships.

Workers who perform abrasive blasting are classified as painters under the Bureau of Labor Statistics (BLS) Standard Occupational Classification (SOC) system. Attendants who assist abrasive blasters are classified as painter's helpers (Document ID 1706). In shipyards, these are the primary job categories in which employees are exposed to silica during abrasive blasting with silica-containing abrasive. However, any workers near such abrasive blasting operations have potential for substantial silica exposure. As in other industries that conduct abrasive blasting, maritime industry workers sometimes perform abrasive blasting in enclosed areas, such as in the ballast or bilge tanks or in the ship's holds. On other occasions the work is performed on the ship exterior, semi-enclosed in a dry dock.

Table IV.4.20-A
Job Categories, Major Activities, and Sources of Exposure of Workers in Shipyards (Maritime Industry) Industry (NAICS 336611, 336612)

Job Category*	Major Activities and Sources of Exposure
Painter	Using abrasive blasting equipment to remove paint and clean and etch surfaces to leave a surface profile for paint adhesion. • Dust generated from the use of silica-containing abrasive blast media. • Dust generated from abrasive blasting of silica-containing paint. Using abrading equipment to remove paint and rust and prepare surfaces for application of paint. • Dust generated from sanding silica-containing paint.
Painter's Helper	Dry sweeping residue generated from abrasive blasting operations. • Dust raised by sweeping spent abrasive material (housekeeping).

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility.
Sources: Document ID 0852; 0507; 1365; 1720, p. IV-334.

4.20.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.4.20-B includes 9 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for workers in the maritime industry. The median is 85 μg/m^3, the mean is 511 μg/m^3, and the range is 12 μg/m^3 (limit of detection (LOD)) to 3,100 μg/m^3. Table IV.4.20-B shows that, of the 9 samples, 5 (55.6 percent) are above 50 μg/m^3 and 4 (44.4 percent) exceed 100 μg/m^3.

To evaluate maritime workers' silica exposures, OSHA reviewed 7 personal breathing zone (PBZ) respirable silica exposure monitoring samples available from a NIOSH report on abrasive blasting in a shipyard (Document ID 0852, p. 7). OSHA inspection data from OSHA's Information System (OIS) provide 2 additional samples in NAICS code 336611 – one sample for "blasting and painting" and one for a "sandblaster" (Document ID 3958, lines 217, 332).[122] OSHA requested, but did not receive, additional exposure data for this industry. Thus, the limited exposure data in the record constitute the best available evidence on which OSHA can base the exposure profile for the maritime industry (shown in Table IV.4.20-B). OSHA notes that these pieces of data are generally consistent with the profile presented in Section IV-5.1 – Abrasive Blasters of this Final Exposure Analysis (FEA), after accounting for the differences in length of exposure and the type of media that is generally used.

The NIOSH report describes a facility engaged in the business of constructing marine vessels for oceanographic research (Document ID 0852). The company employs 1,000 workers, 2 to 20 of whom are exposed to silica daily. Painters perform sandblasting with beach sand and typically spend the balance of their shifts painting. The designated areas for abrasive blasting and painting movable parts have a hoisted screen curtain and rails to position pieces to be blasted. While NIOSH did not observe controls in place during its assessment, the facility indicated that the designated abrasive blasting/painting areas were selected so that prevailing winds would carry the generated aerosol away from the workers (Document ID 0852, pp. 3, 5). OSHA notes that the working conditions described in the NIOSH report, and the associated silica exposures, may not be representative of shipyard workers overall. Workers at this facility used beach sand containing a high percentage of crystalline silica, a practice also described by EPA at a small marine yard servicing boats averaging 125 feet in length (Document ID 0852, p. 4; 1202, pp. 38-39). In contrast, maritime workers in larger naval shipyards and facilities

[122] As noted in Section IV-2–Methodology, all sample results included in the exposure profile are 8-hour time-weighted averages (8-hour TWAs) calculated based on the assumption that the exposure continued at the same rate during any unsampled portion of the shift.

working under navy contracts do not use blast media with silica content greater than 1 percent (Document ID 1201, p. 43).

Workers employed by small, marina-based shipyards are more likely to have diverse duties, with abrasive blasting constituting only a small portion of their work shifts. These smaller maritime facilities typically service fishing vessels requiring routine repair and maintenance (Document ID 1202, p. 9). The U.S. Coast Guard estimates that 79,000 vessels could be engaged in fishing activities. Of these, 20,000 weigh 5 gross tons (GT) or more, and 59,000 are less than 5 GT (Document ID 0761).

Exposure Profile and Baseline Conditions for Painters

The exposure profile in Table IV.4.20-B includes 6 samples for painters in the maritime industry. The median is 31 μg/m^3, the mean is 679 μg/m^3, and the range is 12 μg/m^3 (limit of detection (LOD)) to 3,100 μg/m^3. Table IV.4.20-B shows that, of the 6 samples, 2 (33.3 percent) are above 50 μg/m^3 and 2 (33.3 percent) exceed 100 μg/m^3.

Existing OSHA standards applicable to shipyards require that abrasive blasters be provided with hoods and air-line respirators, or positive pressure air helmets, when blasting in enclosed spaces, or in the open with abrasives containing at least 1 percent silica; other suitable respiratory protection is required for other blasting activities (29 CFR 1915.34(c)(3)). Where blasting enclosures are used, they must be ventilated as described in 29 CFR 1910.94(a)(3). Based on these existing requirements and the NIOSH shipyard evaluation, OSHA finds that the use of compressor powered equipment with dry silica containing abrasive blast media and abrasive blasting respirators represent baseline conditions for blasters/painters in shipyards. OSHA also finds that the use of isolation by distance and partial screens around unventilated blasting areas are baseline controls for these workers (Document ID 0852, pp. 3-5). Painters typically perform abrasive blasting for 50 percent or less of every shift (Document ID 0852, p. 3).

Table IV.4.20-B summarizes the available silica exposure data for painters who perform abrasive blasting at maritime facilities. The data include four samples from the NIOSH report and two sample results from two recent OSHA inspections at maritime facilities (Document ID 3958). The median silica exposure for painters is 31 μg/m^3, and the mean is 679 μg/m^3, with a range of 12 μg/m^3 to 3,100 μg/m^3. The highest silica exposure occurred at the shipyard studied by NIOSH on a day when the painter spent 45 percent of his time sandblasting, 25 percent of his time preparing for sandblasting, and 20 percent of his time painting. The lowest exposure at this facility, 26 μg/m^3, occurred for the same painter on the following day when he spent 10 percent of his time sandblasting, 20 percent of his time preparing for sandblasting, and 70 percent of his time painting. The two other NIOSH sample results (36 μg/m^3 and 890 μg/m^3) involved a second painter who spent 70 percent of the shift sandblasting, 15 percent of his time preparing for sandblasting, and 15 percent of his time painting on both days (Document ID 0852, pp. 7, 9). The higher exposure level occurred on the second day, when 50 percent more silica sand was used. The amount of sand used on the second day was more representative of typical conditions at the facility (Document ID 0852, p. 5). Both painters performed sandblasting outdoors within a screen enclosure intended to decrease the spread of silica dust to other areas. Tasks and controls for the two OIS data points were described as, "blasting and painting, process enclosed," and "sandblaster, work performed in open air" (Document ID 3958, Rows 217, 332). Both OIS sample results were below the limit of detection (LOD) of 12 μg/m^3 and the type of blasting media used was not identified.

Exposure Profile and Baseline Conditions for Painters' Helpers

The exposure profile in Table IV.4.20-B includes 3 samples for painters' helpers in the maritime industry. The median is 160 μg/m^3, the mean is 175 μg/m^3, and the range is 85 μg/m^3 to 280 μg/m^3. Table IV.4.20-B shows that, of the 3 samples, 3 (100 percent) are above 50 μg/m^3 and 2 (66.7 percent) exceed 100 μg/m^3.

Painters' helpers perform dry sweeping of residue between the painters' abrasive blasting and painting activities. These tasks are performed wherever painting will occur, including in enclosed or confined spaces (e.g., a vessel engine room or tank) and outdoors on the deck of a ship (Document ID 0852, p. 6). Painters' helpers wear dust filtering respirators while dry sweeping (Document ID 0852, pp. 5-6).

The painters' helpers evaluated in the NIOSH report spent their entire shifts dry sweeping and using a hand brush (Document ID 0852, p. 6). The three sampling results for painters' helpers are summarized in Table IV.4.20-B. The median silica exposure for painters' helpers is 160 µg/m^3, and the mean is 175 µg/m^3, with a range from 85 µg/m^3 to 280 µg/m^3. The lowest exposure level was associated with the worker who swept the deck. The two higher values were obtained for two helpers who spent all or part of their shifts dry sweeping in an enclosed engine room (Document ID 0852, pp. 6-7).

Table IV.4.20-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Shipyards (Maritime) Industry (NAICS 336611, 336612)

	Exposure Summary			Exposure Range			Exposure Profile				
Shipyards (Maritime) Industry	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**		**<25 (μg/m³)**	**≥25 and ≤50 (μg/m³)**	**>50 and ≤100 (μg/m³)**	**>100 and ≤250 (μg/m³)**	**>250 (μg/m³)**
Painter	6	679	31	12	3,100		2 (33.3%)	2 (33.3%)	0 (0%)	0 (0%)	2 (33.3%)
Painter's Helper	3	175	160	85	280		0 (0%)	0 (0%)	1 (33.3%)	1 (33.3%)	1 (33.3%)
Shipyards (Maritime) Industry Total	**9**	**511**	**85**	**12**	**3,100**		**2 (22.2%)**	**2 (22.2%)**	**1 (11.1%)**	**1 (11.1%)**	**3 (33.3%)**

Notes: All samples summarized are personal breathing zone (PBZ) results and represent 8-hour time-weighted average exposures.
Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility.
Percentages may not equal 100 percent due to rounding.

4.20.3 Additional Controls

The exposure profile in Table IV.4.20-B shows that more than half (5 out of 9 samples) of painters and painter's helpers in the maritime industry have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. As the exposure profile indicates, painters and painters' helpers performing abrasive blasting operations using silica-containing abrasive in shipyards are potentially exposed to levels of silica well above 50 μg/m^3 unless additional controls are used. Additional controls are required not only to protect these workers, but also any workers adjacent to the blasting operation.

Additional Controls for Painters

Painters are potentially exposed to very high levels of silica when performing abrasive blasting using silica-containing abrasive. Since workers in this job category spend varying amounts of time performing blasting, exposures can range from below 50 μg/m^3 to above 3,000 μg/m^3. Thirty-three percent (two) of the six sample results for painters in Table IV.4.20-B are above 50 μg/m^3 and will require additional controls. The remaining 67 percent (four) of the six sample results are less than 50 μg/m^3. Workers who use silica-containing media to perform abrasive blasting in maritime industry facilities will benefit from the following exposure control options, which are outlined in IV-5.1 Abrasive Blasters and repeated here for convenience.

- Low-silica and silica-free abrasive blasting media substitutes that are less toxic than silica sand.
- Abrasive blasting with wet methods, dust suppressants, or other processes that reduce or eliminate dust generation.
- Automated and/or enclosed (shrouded) abrasive blasting equipment.
- Abrasive blasting cabinets for small and medium-sized parts.
- Enclosures, such as containment structures (which protect adjacent workers only).
- Local exhaust ventilation (LEV) of enclosures (with proper filtration to protect adjacent workers).
- Respiratory protection.

Use of Alternative Abrasive Media

To eliminate the hazards posed by using silica sand as the abrasive media, employers can select alternative blasting media that do not contain crystalline silica. For shipboard use, low-silica substitutes and silica-free blasting media, which are less toxic than silica sand, offer an important option for exposure control, particularly in areas where automated and semi-automated methods are impractical (for example, in most interior spaces and in spaces with small surface areas, multiple fittings, or corners and angles) (Document ID 0852, p. 5).

OSHA received many comments related to the use of alternatives to silica sand in abrasive blasting. Those comments are described more fully in IV-5.1 Abrasive Blasters. Ms. Peg Seminario, Director, Safety and Health Department of the AFL-CIO, urged OSHA to implement a ban on the use of silica sand in abrasive blasting (Document ID 4204, p. 76). Mr. Ian Bennitt, Manager, Government Affairs for the Shipbuilders Council of America (SCA), described efforts to reduce silica exposures in the shipbuilding and repair industry, stating that alternatives to dry abrasive blasting are effective in some circumstances:

> Within the shipbuilding and repair industry, there has been a concerted effort to eliminate occupational exposure to silica. In practice, shipyards have reduced or eliminated respirable crystalline silica from production processes, products, and services. A prime example of this has been the adoption of alternative media components for blasting operations…. Blasting techniques such as water blasting, dustless blasting, dry ice blasting and others have been tested and implemented in many shipyards (Document ID 2255, pp. 1-2).

Mr. Bennitt also noted, however, that “in some cases these alternative methods have proven unsuccessful in keeping up with production demands and providing competitive costs” (Document ID 2255, p. 2).

Many types of alternative abrasive blasting media are available for use as a substitute for silica sand in abrasive blasting. Alternative abrasive media containing less than 1 percent silica include garnet, staurolite, aluminum oxide, and slags of copper, coal, or nickel

(Document ID 3747, p. 14). Flynn and Susi (2004) suggest that crushed glass, specular hematite, and dolomite may be low-hazard alternatives to silica sand (Document ID 1717, p. 682). The International Safety Equipment Association (ISEA) describes steel shot as a safer, effective, and economical substitute for silica sand (Document ID 2212, Attachment 1, p. 4).

Some shipyards are already using alternatives to silica to meet customer specifications. For instance, in 1996, the U.S. Navy banned the use of silica sand, or any abrasive media containing more than 1 percent silica by weight, for abrasive blasting of ship hulls (see military specification MIL-A-22262B(SH) Amendment 2 (Document ID 1365, p. 10-2)).[123] Moreover, the American National Standards Institute (ANSI) Z9.4-1997 design standard on exhaust systems for abrasive blasting operations at fixed location enclosures prohibits the use of silica sand as an abrasive blasting agent in such operations (Document ID 0528, p. 1).

Ms. Sally Greenberg, Executive Director of the National Consumers League, noted that, in addition to the U.S. Navy, the Air Force, the Coast Guard, 23 state departments of transportation, and other countries (such as Great Britain, Germany, Sweden, and Belgium) have all banned the use of silica sand in abrasive blasting (Document ID 3588, Tr. 3752). Paul Mellon of Novetas Solutions testified regarding the growing use of alternative blasting media, noting that the annual tonnage of silica sand used for abrasive blasting operations decreased 67 percent from 1996 to 2007, primarily due to the use of alternative blasting media and high-pressure water-jet techniques (Document ID 3545, p. 4).

Evidence in the record suggests that several of the alternatives to silica sand may pose their own health hazards. Studies on abrasive blasting have noted that even blasting operations using media with low silica content, such as garnet, copper slag, and non-siliceous substrates, can result in elevated airborne concentrations of silica. In a NIOSH-sponsored study, 17 of 52 respirable samples showed detectable silica concentrations

[123] This specification supersedes one dated April 1993 restricting the use of abrasive blasting media containing greater than 1 percent silica.

when blasting on steel plate with garnet, with results as high as 6,800 µg/m^3; however, the geometric mean concentration (200 µg/m^3) was about 2 percent of the geometric mean concentration associated with blasting with silica sand (8,800 µg/m^3) (Document ID 0772, p. 117). This study did note that all respirable quartz samples were below the limit of detection for crushed glass, coal slag, nickel slag, olivine, specular hematite, copper slag with dust suppressant, and steel grit (Document ID 0772, p. 82). In this same study, 3 of 32 samples involving blasting with copper slag media showed detectable silica, with concentrations as high as 740 µg/m^3 (Document ID 0772, p. 83); however, the geometric mean level (140 µg/m^3) was 59 times lower than the geometric mean level associated with blasting with silica sand (8,800 µg/m^3) (Document ID 0772, p. 114).

In a follow-up study, all four samples involving blasting with garnet showed detectable silica, with concentrations ranging from 870 µg/m^3 to 7,280 µg/m^3, while no detectable silica concentrations were associated with copper slag media; blasting with silica sand led to silica concentrations ranging from 9,910 µg/m^3 to 50,052 µg/m^3 when blasting with silica sand (Document ID 0773, p. 45). This study found that the alternative media studied (coal slag, nickel slag, staurolite, copper slag, garnet, and steel grit) each resulted in higher geometric mean concentrations of at least four of ten toxic metals studied (arsenic, beryllium, cadmium, chromium, lead, manganese, nickel, silver, titanium, and vanadium), as compared to silica sand (Document ID 0773, pp. iii and 90). However, this study noted that only one abrasive from each generic category was studied, and that the potential for variability in toxic metals exposures between individual abrasives within a general category must be considered (Document ID 0773, pp. 89-90).

In another study, investigators measured geometric mean silica concentrations of 5,000 µg/m^3 and 6,900 µg/m^3 in the breathing zones of abrasive blasters removing paint from foot bridges using recycled coal slag or steel grit. The paint contained 5.9 percent to 9.6 percent silica by weight (Document ID 0802, p. D81 - D82). This study also indicated the presence of other toxic substances, even in clean abrasives (Document ID 0802, p. D-82).

Based on the studies in the record, OSHA has determined that while alternative blast media can be effective in reducing worker exposures to silica, alternative blast media must be carefully selected and evaluated for health hazards.

OSHA acknowledges that not every silica alternative will be practical in every circumstance. OSHA also recognizes, as described above, that many of the silica sand substitutes may increase levels of toxic dust other than silica. Based on its consideration of relevant comments and the information available to OSHA, the agency has determined that a ban on the use of silica sand is not warranted. Nonetheless, OSHA concludes that, in a great many cases, further reductions in silica exposures can be achieved through the use of alternative blasting media, and finds that substitutes can be an effective control in some situations. When employers are selecting appropriate controls for abrasive blasting operations, they must consider all potentially feasible controls – including substitution.

Wet Methods

Wet abrasive blasting methods will reduce the silica exposure levels of maritime workers who use silica sand. Wet abrasive blasting methods have proven to be effective in the construction sector. The exposure profile in Section IV-5.1 – Abrasive Blasters shows a median silica exposure of 251 μg/m^3, with a range of 12 μg/m^3 to 29,040 μg/m^3, for abrasive blasting operators performing dry, uncontrolled blasting without a booth or cabinet. In contrast, for abrasive blasting operators performing wet blasting without a booth or cabinet, the median silica exposure is 125 μg/m^3, and exposure levels range from 36 μg/m^3 to 407 μg/m^3. These values demonstrate the extent to which wet blasting can reduce exposure levels. It should be noted, however, that the construction industry data for both dry and wet abrasive blasting include samples collected under a variety of conditions, including some results obtained while workers used low-silica or silica-free abrasive blast media while blasting on silica-containing substrates, such as concrete.[124] The maritime exposure profile includes sample results associated with dry silica-containing blast media, which may be more typical of smaller shipyards and marinas.

[124] The construction industry abrasive blasting data represent 8-hour TWA exposure levels, calculated with the assumption that no additional exposure occurred during any unsampled portion of the shift.

Although there are some differences between the construction and maritime industries, the results from the construction industry showing the effectiveness of wet methods can offer valuable insight into the potential benefits of using wet abrasive blasting in the maritime industry.

Use of Dust Suppressant Additives

Dust suppressants are another control strategy that can be effective in reducing silica exposures when silica sand is used for abrasive blasting. NIOSH noted that a shipyard safety director described a 40 percent reduction in respirable silica exposures when abrasive sand containing dust suppressant materials was used. However, use of this control was discontinued, perhaps due to the increase in cost (from $20 to $26 per ton of blasting sand) (Document ID 0852, p. 5). Dust suppressant additives provide a limited amount of dust control during blasting with silica sand. For instance, during a study evaluating several types of abrasive media, silica sand abrasive was used to blast the side of an unpainted, rusted steel coal barge (Document ID 0773, p. 1). Silica exposures ranged from 9,910 µg/m^3 to 50,522 µg/m^3, with a geometric mean of 27,959 µg/m^3 (Document ID 0773, p. 45). When a dust suppressant was used with the silica sand abrasive, silica levels in four readings had a geometric mean of 19,040 µg/m^3 (ranging from 9,180 µg/m^3 to 28,200 µg/m^3), about 68 percent of the mean associated with the use of untreated silica sand (Document ID 0773, p. 45). Although these levels are still excessive, dust suppressant methods used in combination with other measures, such as ventilation and work practices, can help to reduce silica exposures when silica sand must be used as the blasting agent. Effective dust suppressant additives will also help reduce silica exposures when workers (e.g., painter’s helpers) handle abrasives before and after the actual abrasive blasting. OSHA did not receive comments or exposure information on dust suppressant additives and finds that they (in combination with other control measures) are useful in reducing workers’ exposure to silica.

Alternative Methods to Dry Abrasive Blasting

Many of the alternative methods for dry abrasive blasting (listed in Table IV.4.20-C, Alternative Controls) have been tested in shipyards, where the large expanses of near-flat surfaces available on ship decks and hulls provide optimal surfaces for comparative trials. Many of these methods effectively remove paint and eliminate worker exposure to silica by completely enclosing or eliminating the use of silica-containing blasting media or by eliminating the process of abrasive blasting (substituting another process, such as grinding paint off the surface).

Some of the alternative abrasive blasting methods also offer some reduction in airborne exposure to other contaminants (e.g., metals) from the surface coating being removed. For example, Flynn and Susi (2004) reviewed vacuum blasting and automated, robotic systems for removing lead-containing paint (Document ID 1717). Vacuum blasting demonstrates the potential value of a well-enclosed and well-ventilated process. Using this technology, worker lead dust exposures were controlled to a considerable extent, from a geometric mean of 4,200 μg/m^3 during open blasting to 55 μg/m^3 during vacuum blasting (a 98.6 percent reduction) (Document ID 1717, p. 685). Although these lead results cannot be translated directly to silica exposure levels, they suggest that much of the dust contaminated air was captured during the abrasive blasting. The exhaust ventilation on vacuum blasting systems would be expected to be even more effective in capturing respirable size particles (as compared to total dust), as respirable particles are smaller and are captured at a lower velocity and at a greater distance from the exhaust hood (Document ID 4149, p. 9; 3883, pp. 6-18 – 6-27).

Furthermore, automated and semi-automated versions of hydroblasting, centrifugal wheel blasting, and vacuum blasting equipment offer quality cleaning of flat or gently curved surfaces (such as exterior hulls) while allowing the workers performing the blasting to stand a good distance away from the surface being blasted. Each of these automated methods are challenged by corners, fittings, and sharp bends in the surface, where workers must still use mechanical stripping (needle gunning, grinding) or traditional abrasive blasting to finish the job (Document ID 0852, p. 6; 1365, p. 10-5). Additionally, these alternate methods result in different anchor patterns on the bare metal than traditional abrasive blasting, so workers require technical expertise to match alternate surface cleaning methods to the surface metal and paint system to be applied (Document ID 1717, p. 683).

Table IV.4.20-C, Alternative Controls Examples of Alternatives to Dry Abrasive Blasting	
Name	**Description/Comments**
Wet Abrasive Blasting	Can be used in most instances where dry abrasive blasting is used. Includes: 1) compressed air blasting with the addition of water into the blast stream before the abrasive leaves the nozzle, and 2) water jetting with the addition of abrasive into the water stream at the nozzle. Additives and rust inhibitors might be used.
Hydroblasting	High Pressure Water Jetting: Uses pressure pump, large volume of water, and specialized lance and nozzle. Pressures range from 3,000 to 25,000 pounds per square inch (psi). Can remove loose paint and rust; will not efficiently remove tight paint, tight rust, or mill scale. Can be used in most instances where abrasive blasting is used. Primary application is for an older surface rusted in a saline environment rather than for new steel. Rust inhibitors could be required to prevent flash rusting. Ultra-High-Pressure Water Jetting: Similar to high-pressure water jetting. Uses pressurized water from 25,000 to 50,000 psi. Removes tight paint and rust, but not mill scale.
Centrifugal Wheel Blasting	Uses a rotating wheel assembly inside an enclosure equipped with a dust collector. Abrasive is propelled outward from the rotating wheel and removes rust, paint, and mill scale. Abrasives are recycled and include steel shot, steel grit, cut wire, and chilled iron grit. Generates no airborne dust or high velocity particles.
Vacuum Blasting	Uses standard blast nozzle inside a shroud (head) that forms a tight seal with the work surface. Vacuum is applied inside shroud during blasting to remove dust and debris. Abrasives are recycled and include aluminum oxide, garnet, steel shot, steel grit, and chilled iron grit. When used properly, cleans effectively with minimal dust.
Dry Ice Pellets	Dry ice blast cleaning with solid carbon dioxide. Waste is minimized and includes paint chips and rust. Storage and handling costs can be substantial.
Thermal Stripping	Uses a flame or stream of superheated air to soften paint, allowing for easy removal. Generates one waste stream (i.e., waste paint). Effective for small parts; not suitable for heat-sensitive surfaces. Very labor intensive.
Chemical Stripping	Uses hazardous chemical strippers such as methylene chloride-based or caustic solutions. Effective for small fiberglass, aluminum, and delicate steel parts. Requires adequate ventilation and other safety measures. Generates multiple waste streams (i.e., contaminated rinse water and waste strippers).
Mechanical Stripping	Involves chipping, grinding, sanding, or scraping the coating off small parts or surfaces through the use of needle guns, chipping hammers, sanders, and grinders. Generates paint waste and airborne dust. Some power tools are equipped with dust collection systems.
Sources: Document ID 1202; 0775, pp. 4-5; 0575, pp. 36-37, 40-41, 43.	

A NIOSH study (ECTB 233-110) noted that switching to factory pretreated steel in the mid-1990s eliminated the need for some shipyard abrasive blasting. To reduce the need to remove yard corrosion by abrasive blasting, the shipyard purchased steel that had been coated with a zinc antioxidant after treatment in a steel shot blast machine. The resulting steel requires less abrasive blasting at the shipyard (Document ID 0852, p. 5).

As described above, a variety of technologies are available as alternatives to open air dry abrasive blasting. Available literature, also described above, leads OSHA to conclude that these methods are feasible and effective in reducing exposures to respirable crystalline silica in many instances.

Enclosures and Local Exhaust Ventilation (LEV)

Enclosing blasting operations is a common technique for preventing exposures among workers not directly involved in blasting operations. The NIOSH shipyard evaluation described the use of partially enclosing screens to reduce bystander exposures (Document 0852, pp. 3-5). Similarly, one of the OSHA shipyard inspections reported in OIS noted that process enclosure was used for abrasive blasting (Document ID 3958, Row 217).

When enclosures are used, they must be properly ventilated to avoid extremely high silica exposures for the person performing the abrasive blasting. For example, in an evaluation of bridge repair, NIOSH found elevated short-term airborne silica results of 820 $\mu g/m^3$, 1,730 $\mu g/m^3$, and 2,960 $\mu g/m^3$ (with sample durations of 93, 96, and 93 minutes, respectively) for area samples collected inside an unventilated enclosure used to confine dust generated during the blasting process (Document ID 0910, p. 5). OSHA's existing Ventilation Standard at 29 CFR 1910.94 contains requirements for abrasive blasting in shipyards. Among other things, the standard includes specifications for blast-cleaning enclosures, exhaust ventilation systems, air supply and air compressors, and operational procedures.

The record supports OSHA's determination that enclosures and LEV reduce silica exposure. NIOSH researchers found that when blasting ceased, ventilation rapidly reduced the high levels of dust that had been produced by abrasive blasting in ventilated enclosures (Document ID 0212, p. 15). And while the exposure data in the record do not provide precise measurements of the extent to which silica exposures associated with abrasive blasting are reduced in ventilated enclosures, evidence in the record, coupled with basic ventilation principles, indicates that use of ventilated enclosures results in reduced exposures among operators that work within the enclosures. In hearing testimony, Ms. Lauren Bailey of the National Automobile Dealers Association (NADA) described the use of LEV with spot abrasive blasters:

> It is not uncommon for dealership auto body shops to use ventilated spot blasters for dust control purposes regardless of the media being used since such devices offer the advantage of abrasive capture and recycling and have a cleaner workplace environment. The use of ventilated blasters, like ventilated sanders, helps to minimize any potential dust exposures (Document ID 3587, Tr. 3722).

Similarly, the AFL-CIO submitted a World Health Organization document on airborne dust to the record, which explains that enclosures are usually coupled with exhaust ventilation to remove contaminants from the workplace (Document ID 4072, Attachment 15, p. 97).

Portable blast-cleaning equipment and temporary containment structures must have sufficient exhaust ventilation to: 1) prevent a build-up of dust-laden air and reduce the concentrations of hazardous air contaminants, 2) prevent any leakage of dust to the outside, and 3) provide prompt clearance of dust-laden air from the enclosure when blasting has ceased (Document ID 0528, pp. 5, 9; 3883, p. 13-142). Exhaust ventilation systems must be constructed, installed, inspected, and maintained according to 29 CFR 1910.94. The exhaust air from blast-cleaning equipment must be discharged to the outside (away from other workers and the public) through an appropriate dust collector to protect the workplace, the environment, and the surrounding community from hazardous air contaminants. The dust collector should be set up so that the accumulated dust can be emptied and removed without contaminating other working areas.

Additionally, another control method for workers who abrasively blast smaller, removable parts is the use of ventilated enclosures (e.g., ventilated abrasive blasting cabinets), which will isolate the abrasive blasting media and limit (or eliminate) worker exposures to silica.

Respiratory Protection

OSHA recognizes that, even with implementation of feasible engineering and work practice controls, respiratory protection may be necessary in some circumstances to protect abrasive blasting operators in the maritime industry from silica exposures above 50 µg/m^3. Maritime employers following 29 CFR 1915.34(c)(3)(i) protect abrasive blasters from a wide range of hazards by equipping these workers with hoods and NIOSH-certified airline respirators or positive-pressure air helmets. In contrast, when abrasive blasters are working in the open and using synthetic abrasive blasting media that contains less than 1 percent silica, employers may use appropriate filter type respirators in accordance with 29 CFR 1915.154 (which states that respiratory protection for shipyard employment is covered by the general industry Respiratory Protection Standard at 29 CFR 1910.134). Employers will need to consider the silica PEL of 50 µg/m^3 when determining whether a respirator offers adequate protection. Ms. Julie Tremblay of 3M noted in written comments that blasting respirators come with assigned protection factors (APFs) of 25 and 1000. Emphasizing the importance of proper respirator selection in accordance with OSHA's Respiratory Protection Standard, she stated that "without considering the performance (APF) of the respirator, some workers could be overexposed to silica" (Document ID 2313, p. 1). OSHA agrees with Ms. Tremblay's concern that a respirator with an APF of 25 or higher may be needed for abrasive blasting operations in some cases, depending on factors such as the silica content of the media, the task duration, and whether the blasting is performed in the open or in an enclosed area.

Additional Controls for Painters' Helpers

As presented in the exposure profile in Table IV.4.20-B, all three sample results for painters' helpers exceed 50 µg/m^3; therefore, additional controls will be necessary to reduce exposures among painters' helpers. In the PEA, OSHA estimated that the same controls for, and alternatives to, dry abrasive blasting with silica sand outlined for painters would benefit the painters' helpers (regardless of the helpers' duties) to at least the same extent as those methods benefit the painters themselves. No comments were received in the rulemaking record disputing this estimate. Automated, enclosed (e.g., isolating), or shrouded dry abrasive blasting methods, which employ some form of vacuum suction device to capture the media, will produce less dust and debris, resulting in less cleaning by the helpers. Wet methods, such as wet abrasive blasting, will limit the spread of dust and prevent silica dust from becoming airborne to the extent that the helpers can clean up the spent media while it is still damp. Low-silica substitutes and silica-free blasting media that is less toxic than silica sand will generate dust with lower silica content and reduce painters' helpers' exposures during cleaning.

Improved housekeeping methods are of critical importance to reduce exposures among painters' helpers. The dry sweeping of spent abrasive blasting media and debris can be a significant source of silica exposure for painters' helpers. For example, the NIOSH shipyard evaluation found exposure levels of 85 $\mu g/m^3$, 160 $\mu g/m^3$, and 280 $\mu g/m^3$ for workers who spent the entire sampling period dry sweeping material from surfaces, using a hand broom or a whiskbroom (Document ID 0852, p. 3). Dry sweeping material will create higher airborne dust levels than other methods (such as vacuums, shovels, and scrapers); indeed, NIOSH recommended the use of a filtered vacuum system rather than dry sweeping (Document ID 0852, p. 6).

Using vacuums, shovels, and scrapers to clean surfaces introduces less dust into the air than dry sweeping. A study of Finnish construction site workers (Riala (1988)) compared the silica exposures for workers dry sweeping with exposures for workers using alternate cleaning methods (Document ID 1163). When compared with dry sweeping, worker exposures were approximately three times lower when the workers used squeegees to scrape surfaces and approximately five times lower when workers used vacuums (Document ID 1163, p. 217). Additionally, when wet abrasive blasting is implemented as a control, moisture in the abrasive media will continue to suppress dust as long as workers dispose of or recover the abrasive before it dries. OSHA expects that exposure reductions seen in the construction industry can be replicated in shipyards.

Based on the information presented here and in IV-5.1 – Abrasive Blasters, OSHA concludes that silica exposure levels among painters' helpers can be reduced by providing high-efficiency particulate air (HEPA)-filtered vacuums for cleaning. NIOSH recommends vacuuming with an approved HEPA-filtered vacuum, or using wet cleaning methods, to minimize worker exposures to hazardous air contaminants (such as asbestos, silica, and heavy metals) during housekeeping activities in numerous industries (Document ID 1365, pp. 19-25, 23-6). Furthermore, as discussed previously, when vacuum blasting was used for an abrasive blasting task, lead exposure levels among painters were reduced by 98.6 percent (Document ID 1717, p. 685). A HEPA-filtered vacuum uses similar suction and filtration technology without an internal blasting component so will capture settled dust even more efficiently. Even if a HEPA vacuum is assumed to capture dust only 85 percent effectively, it would reduce the highest painters' helper's silica exposure level from 280 μg/m^3 to 42 μg/m^3.

4.20.4 Feasibility Findings

OSHA has determined that a PEL of 50 μg/m^3 is technologically feasible for the maritime industry. Although it is not feasible to reduce painters' exposures to 50 μg/m^3 when conducting abrasive blasting operations most of the time without the use of respirators, evidence in the record demonstrates that it is feasible to reduce painters' helpers' exposure to 50 μg/m^3 most of the time with HEPA-filtered vacuums. As noted above, workers in the maritime industry may also be exposed during foundry activities; as explained in Chapter 4.8.4 – Captive Foundries, OSHA has determined that it is feasible to reduce exposures during most operations in captive foundries to 50 μg/m^3, most of the time. The record evidence indicates that shipyard foundries face similar issues controlling silica as other typical small foundries (e.g., cleaning the cast metal) and that shipyard foundries cast items in a range of sizes, from small items like a ship's plaque to large items like the bow structure for an aircraft carrier (Document ID 1145; 3584, Tr. 2607). OSHA did not receive comments indicating that foundries in shipyards would require any unique controls to reduce exposures, and therefore believes that exposures in shipyard foundries can also be reduced to 50 μg/m^3 in most operations, most of the time. Accordingly, OSHA has determined that 50 μg/m^3 is feasible for most silica-related activities performed in the maritime industry.

Even if captive foundries are excluded from consideration, OSHA considers the standard to be feasible for shipyards with the use of respirators by painters doing abrasive blasting. OSHA recognizes that, consistent with its hierarchy of controls policy for setting methods of compliance, respirator use is not ordinarily taken into account when determining industry-wide feasibility. Neither this policy nor the "most operations most of the time" formulation for technological feasibility is meant to place OSHA in a "mathematical straitjacket" (*Indus. Union Dep't, AFL-CIO v. Am. Petroleum Inst.*, 448 U.S. 607, 655 (1980) ("*Benzene*") (stated with respect to the "significant risk" finding, which the Supreme Court recognized is "based largely on policy considerations" (*Benzene*, 448 U.S. at 655 n.62)). No court has been confronted with a situation where an industry has two operations (or any even number), of which one can achieve the PEL through engineering controls and the other (or exactly half) can achieve it most of the time only with the use of respirators. However, the same court that formulated the "most operations most of the time" standard "also noted that '[i]nsufficient proof of technological feasibility for a few isolated operations within an industry, or even OSHA's concession that respirators will be necessary in a few such operations, will not undermine' a showing that the standard is generally feasible" (*Amer. Iron & Steel Inst. v. OSHA*, 939 F.2d 975, 980 (D.C. Cir. 1991) (*Lead II*), (quoting *United Steelworkers of Am., AFL-CIO-CLC v. Marshall*, 647 F.2d 1189, 1272 (D.C. Cir. 1980) ("*Lead I*")). It further recognized the intended pragmatic flexibility of this standard by stating that "[f]or example, if 'only the most technologically advanced plants in an industry have been able to achieve [the standard] — even if only in some of their operations some of the time,' then the standard is considered feasible for the entire industry" (*Lead II*, 939 F. 2d at 980 (quoting *Lead I*, 647 F.2d at 1264)). In this instance, OSHA has determined that it makes sense to treat painters performing abrasive blasting in shipyards as an outlier for which the PEL established for all other covered industries is feasible, even conceding that respirators will be necessary. If abrasive blasting were the predominant activity that occurs in shipyards, there might be justification to set a separate, higher PEL for shipyards. But as in construction (for which supplemental respirator use is also contemplated for abrasive blasting operations), abrasive blasting is one of many activities that occurs; substitution of non-silica blasting materials is an option in many cases; few, if any, painters spend entire days or weeks doing blasting operations and thus needing respirators for the duration; and lowering the standard from 250 μg/m^3 to 50 μg/m^3 does not threaten the economic viability of the industry. Under these circumstances, OSHA concludes that it may find the standard feasible for shipyards rather than raise the PEL for this single industry because it can only achieve the uniform PEL with respirators or, alternatively, not be able to revise the previous PEL of 250 µg/m^3 at all.

4.21 STRUCTURAL CLAY

4.21.1 Description

Silica-containing materials are the primary ingredients in the manufacture of structural clay products, which include bricks, clay tiles, and ceramic tiles. Facilities manufacturing structural clay products were classified in the 2007 six-digit North American Industry Classification System (NAICS) codes: 327121, Brick and Structural Clay Manufacturing; 327122, Ceramic Wall and Floor Tile Manufacturing; and 327123, Other Structural Clay Product Manufacturing. OSHA analyzed the facilities classified in NAICS codes 327121, 327122, and 327123 together, based on the similarity of materials, processes, and worker activities associated with potential exposure to silica throughout the majority of these facilities.[125]

Structural clay products manufacturing typically begins with crushing, grinding, and screening silica-containing raw materials such as clay and shale. Traditionally, there are three ways to form and shape structural clay products: extrusion, molding, and dry-pressing. For molding and extrusion, the processed raw materials are mixed with water in a mill to form wet clay or slurry. Next, the wet clay is either pressed into a mold or, more commonly, extruded through a die and cut into shape with a wire-cutter. Dry pressing, an alternate method for forming high-density products (e.g., floor tiles), uses clay slurry that is spray-dried to a low-moisture compactable powder, then compressed in a mold (Document ID 1365, p. 3-2).

Regardless of the forming method, the resulting clay products can be coated or glazed with silica-containing coating mixtures at various stages in the shaping process depending on the final appearance of product desired. For example, a sand mixture is sometimes applied directly to the mold and is often sprayed or sprinkled on the formed product shape. The formed products are dried, fired in kilns, and then packaged. Structural clay products typically require no further processing after the forming, coating, and firing steps are complete. Workers do not normally cut, grind, sand, or saw the

[125] The applicable 2012 NAICS code is 327120, Clay Building Material and Refractories Manufacturing (which consolidates the three codes 327121, 327122, and 327123 into a single NAICS code).

finished products, except perhaps to separate units cast as groups (Document ID 1365, p. 3-6).

The Whitacre Greer Company stated that the following employee types would be directly affected by the rule; grinders, kiln firemen, unloaders, maintenance, shipping and blending, press operators, and plant supervision (Document ID 3731, p. 1). OSHA agrees and has determined that based on the comments received, available literature and exposure monitoring data presented in site visit reports, NIOSH reports, and OSHA Special Emphasis Program (SEP) reports, workers in all phases of structural clay products manufacture have potential for silica exposure (Document ID 1365, p. 3-2).

The primary job categories with potential for exposure are: material handler, grinding operator, and forming line operator. To evaluate the exposure conditions effectively, these job categories have been further broken down into subcategories. Material handlers are split into three categories—loader operator, production line handler, and post-production handler—depending on the type of material handled (raw material, shaped but unfired product, or fired product). Forming line operators are split by job activity into three categories as well: pug mill operators, coatings blenders, and formers.[126]

Material Handlers

Material handlers classified as *loader operators* oversee the transfer of the raw materials from both off site to storage piles or bins and within the facility to the processing equipment. Typically this work is done with the use of a front end loader although some facilities utilize pneumatic conveyor systems for the transfer of raw material from storage silos. Additionally, these workers may use forklifts to transfer bulk bags of materials (Document 1365, p. 3-5).

After products are formed, *production line handler*s transfer unfired product to racks or kiln cars which move the product through the kiln and dryers.[127] After firing and drying is

[126] In the exposure profile contained in Table IV.4.21-B, formers have been further divided into the subcategories of clay powder formers, wet clay formers, automated coatings applicators and manual coatings applicators.

[127] This process is often referred to as hacking in the brick industry.

complete, *post-production handlers* remove the products from the kiln cars and/or racks[128] either by hand or with the use of lifts and automated equipment; and oversee the product through the inspection and packaging process. Post production works may also utilize forklifts to transport finished products throughout the facility (Document 1365, p. 3-5).

Grinding Operators

Grinding operators oversee the automated machinery responsible for the crushing, grinding and screening of raw materials. Typically these workers monitor equipment from enclosed and ventilated control rooms; however, grinding operators enter the process area multiple times a shift to maintain equipment, to clear jams caused by rocks and debris, to ensure that storage bins and hopper are full, and to clean spillage in the area (Document 1365, p. 3-5).

Forming Line Operators

Forming line operators perform several functions perform several functions. Those classified as *pug mill operators* monitor the equipment, commonly called a pug mill that blends and mixes the raw materials together with water. For this process, raw clay or shale is typically transferred from the grinding process to the milling area by conveyor belts. When needed for dry-press molding, the pug mill operator will also spray dry the clay mixture. After milling, the processed material exits by conveyor to the forming area (Document 1365, p. 3-5 – 3-6).

Coatings blenders prepare crystalline silica-containing coatings by manually emptying bags or boxes of sand into mixer hoppers, then operating sand driers, mills, and mixers to create the coatings applied on the production line. These workers also often spend a portion of their shift performing tasks associated with the formers' job category on the production line (Document 1365, p. 3-6).

Workers in the *formers* category are responsible for shaping the product. At most brick manufacturing and some tile manufacturing facilities *wet-clay formers* oversee equipment

[128] This process is often referred to as de-hacking in the brick industry.

that forces mixed clay through a die to form an extruded column that is cut by an automated wire-cutter. At other facilities, operators known as *clay powder formers* oversee machinery that presses wet or powdered clay into molds. Some formers also shape specialty products by hand. After the product is formed, *coatings applicators* monitor coatings application equipment; which applies a silica-containing mixture or slurry onto the product surface (Document 1365, p. 3-6).

See Table IV.4.21-A for a description of the job categories, major activities, and sources of silica exposure for workers in the structural clay products industry.

4.21) Structural Clay

Table IV.4.21-A Job Categories, Major Activities, and Sources of Silica Exposure of Workers in the Structural Clay Industry (2007 NAICS 327121, 327122, 327123)	
Job Category	**Major Activities and Sources of Exposure**
Material Handler	
Loader Operator	Transferring raw materials (e.g., clay, shale) from storage piles to processing equipment or storage bins via front-end loader. • Dust from open transfer of silica-containing raw materials via front-end loader. • Dust re-suspended by passing traffic (e.g., spilled materials, settled dust). • Dust from conveyors and drop points.
Production Line Handler	Transferring unfired, shaped products within the production line (e.g., to dryers, kilns) using manual, power assisted, or automated processes. • Dust generated by spilled or broken product crushed under wheels. • Dust released from products during handling. • Dust from adjacent processes (e.g., forming line operators, sand coating application).
Post-Production Handler	Transferring finished, fired products through post-production inspection, packaging, and yard areas manually or using lifts and automated equipment. • Dust released during open transfer of products manually or by lift truck. • Dust disturbed by passing traffic (e.g., spilled materials, settled dust, yard dust).
Grinding Operator	
	Operating and maintaining raw material processing equipment, such as crushers, grinders, screens, and driers; performing housekeeping activities. • Dust generated during manual maintenance and operation of crushers, grinders, screens, and raw material driers. • Dust from housekeeping activities (e.g., dry sweeping, shoveling silica-containing materials).
Forming Line Operator	
Pug Mill Operator (including all raw clay-finishing processes)	Mixing dry clay with water to form wet clay to be extruded or molded; spray-drying clay slurry to create compactable clay powder. • Dust from transferring dry material into pug mills and related equipment. • Dust from spray-drying of clay and associated conveyors.
Coatings Blender	Preparing and transferring sand-based coatings to add pigment and texture to bricks. • Dust disbursed during open, manual emptying of bags of silica-containing materials into hoppers. • Dust generated by sand drying, mixing, and milling equipment used to create coatings.
Former (including manual and automated Coatings Applicators, Clay Powder Formers and Wet Clay Formers)	Forming product by hand or machine (molded or extruded products); applying coatings to products manually or monitoring automated application equipment • Dust released during manual or automated application of silica-containing coatings (e.g., sand) to products. • Dust that becomes airborne while sand-coating bags are emptied and compacted for disposal.
Note: Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility. Source: Document ID 1365, p. 3-4; 1720, p. IV-346; 3731, p. 1.	

4.21.2 Exposure Profile and Baseline Conditions

<u>*Introduction*</u>

The exposure profile in Table IV.4.21-B includes 135 full-shift personal breathing zone (PBZ) samples of respirable crystalline silica for workers in the structural clay industry. The median is 46 µg/m^3, the mean is 97 µg/m^3, and the range is 10 µg/m^3 (limit of detection (LOD)) to 1,028 µg/m^3. Table IV.4.21-B shows that, of the 135 samples, 64 (47.4 percent) are above 50 µg/m^3 and 36 (26.7 percent) exceed 100 µg/m^3.

To evaluate silica exposures of structural clay production workers, OSHA reviewed monitoring data on full-shift personal-breathing-zone (PBZ) respirable quartz exposure from five OSHA SEP inspection reports[129] on brick manufacturing facilities and three NIOSH control technology and exposure assessment reports on brick manufacturing (Document ID 0161;0137; 0232; 0239; 0235). In addition, OSHA reviewed one report from a site visit to a ceramic tile manufacturing facility (Document ID 0202).[130]

The exposure profile for the structural clay industry includes 135 samples, three of which were added from OSHA's OIS database (Document ID 3958).[131] The addition of these data points did not change the distribution of the samples in a significant way. As a result, the conclusions drawn from the exposure profile are not appreciably different from the conclusions presented in the PEA.

---

[129] OSHA SEP Inspection Reports 300530805, 302005772, and 302547674, are all contained within OSHA SEP Inspection Report 300523396 (Document ID 0161).

[130] As noted in Section IV-2–Methodology, all results included in the exposure profile are 8-hour time-weighted averages (8-hour TWAs) derived from samples of 6-hours or longer, assuming the exposure concentration during any unsampled portion of the shift was the same as the concentration during the period sampled. Unless explicitly stated otherwise, all results discussed in the additional controls section meet the same criteria. Assumptions made in calculating 8-hour TWAs are discussed in Section IV-2–Methodology.

[131] A total of 17 samples for 2007 NAICS 327122 appear in the OIS data. Five samples from Frost Tile & Marble Co., (inspections 626738 and 900993) were excluded because the job tasks performed were more closely associated with the cut stone industry. Summitville Tiles, Inc., had four samples collected and analyzed for cristobalite, quartz and tridymite, which resulted in 12 individual data points. All of the cristobalite and tridymite values were zero; therefore, they were not included as individual results, only the quartz values were added. Of those four samples, one worker was performing task unrelated to brick manufacturing, resulting in only three samples being added to the exposure profile (438.1 µg/m^3, 75.9 µg/m^3, 12.0 µg/m^3).

Baseline conditions include the numerous activities at structural clay facilities that produce silica dust, which can be re-suspended in the air and contribute to workers overall exposure. Dust arises while workers handle quantities of dry, dusty raw materials (clay, sand, and other minerals), use equipment for grinding raw materials and finishing clay (mills, mixers, spray driers), mix coatings and tend clay coating processes, and move unfinished and finished products through the plant.[132] Dust becomes airborne during production processes, and then settles on surfaces.

For each of the job categories listed in Table IV.4.21-B and included in the exposure profile, and for the structural clay industry as a whole, OSHA concludes that Table IV.4.21-B represents baseline conditions.

Exposure Profile and Baseline Conditions for Material Handlers

The exposure profile in Table IV.4.21-B includes 64 samples for material handlers. The median is 21 μg/m^3, the mean is 42 μg/m^3, and the range is 10 μg/m^3 (limit of detection (LOD)) to 258 μg/m^3. Table IV.4.21-B shows that, of the 64 samples, 17 (26.5 percent) are above 50 μg/m^3 and 6 (9.4 percent) exceed 100 μg/m^3. Loader operators and material handlers working on the production line tend to have higher maximum and median exposure levels than material handlers working in post-production areas, who handle finished goods. The three subcategories within the material handler's job category (loader operators, production line handlers, and post-production handlers) are discussed in the following subsections. All three subcategories can be subject to silica exposure when passing vehicles crush spilled raw materials or broken product and disturb settled dust.

[132] NIOSH collected 38 samples at a brick manufacturing facility, 16 of which exceeded 50 μg/m^3. Seven of these results also exceeded 100 μg/m^3. NIOSH listed the primary sources of exposure as traffic passing over ground clay and shale in the grinding plant, loader dumping and spillage in the same area, conveyor spillage, dry broom sweeping of kiln cars, and various activities associated with the sand applied to bricks for texture and pigment. NIOSH described the strengths and weaknesses of housekeeping at this facility as follows: "Extensive efforts were made at housekeeping in this facility. The notable exception was in the C plant grinding area, which had significant accumulations of settled dust. [In the other areas] dry sweeping with brooms and shovels was common, with the powered sweeper used in some plant areas and the yard. Hi-Vac systems (Model 230) were installed in both the B and C plants for the cleaning of kiln cars. The vacuum systems were not equipped with [high-efficiency particulate air] HEPA filters. Workers used shovels to remove the largest pieces of brick, followed by dry sweeping, and then vacuuming of the cars" (Document ID 0235). This facility had also installed a number of engineering controls.

Exposure Profile and Baseline Conditions for the Loader Operators Subcategory

The exposure profile in Table IV.4.21-B includes 7 samples for loader operators in the structural clay industry. The median is 56 µg/m^3, the mean is 58 µg/m^3, and the range is 11µg/m^3 (limit of detection (LOD)) to 157 µg/m^3. Table IV.4.21-B shows that, of the 7 samples, 4 (57.1 percent) are above 50 µg/m^3 and one (14.3 percent) exceeds 100 µg/m^3. The highest exposure, 157 µg/m^3, is associated with a loader operator in a ceramic tile facility who dumped dry materials into a hopper and monitored a partially enclosed and ventilated conveyor. Visible dust was released from the loader bucket, hopper, and conveyors, and the worker performed operations with the loader windows open for a portion of the sampling period (Document ID 0202, p. 9). In contrast, exposures of 14 µg/m^3 and 10 µg/m^3 were obtained for loader operators at another facility moving crushed shale and schist from storage piles to hoppers. The floor was wet from the rain and visible dust was not “particularly evident” which may have contributed to the lower exposures (Document ID 0232, p. 4).

In the PEA, OSHA preliminarily determined that while front end loader operators frequently work in enclosed cabs, the cab enclosures are not always properly maintained or consistently used as an exposure control measure. For example, at three facilities, workers operated cabs with ventilation systems turned off or windows left open, or allowed dust to accumulate in cabs (Document ID 1365, p. 3-15). A loader operator working in an area where a dust suppressant foam system blanketed raw materials on conveyors had an exposure level of 56 µg/m^3 (Document ID 0239, pp. 6, 8, 14). NIOSH noted an accumulation of dust on the loader cab interior, suggesting that results could be lower (e.g., at 50 µg/m^3 or less) if the cab interior had been kept clean (Document ID 0239, p. 7).

Additionally, loader operators frequently spend a portion of the shift outside the cab as they monitor raw material conveyor systems. These partially enclosed conveyors can emit silica dust when facilities have not enclosed and ventilated transition points, applied dust suppressant, or adjusted for optimal dust control. In addition, nearby raw material processing equipment (crushers, hammer mills, dry-pans, and screens) is typically partially open, allowing silica dust to escape, despite some effort to provide exhaust ventilation for the equipment (Document ID 1356, p. 3-15).

OSHA did not receive comments specifically disputing the assessment of baseline conditions. Therefore, in this final economic analysis (FEA) OSHA concludes that baseline conditions for loader operators in this industry typically involve ventilated, but poorly maintained or improperly used cab enclosures on all front-end loaders and that dust from nearby processes can contribute to elevated exposures when monitoring conveyor systems. Thus, OSHA anticipates that lower exposure levels can be attained by improving/upgrading controls that are already in place.

Exposure Profile and Baseline Conditions for the Production Line Handlers Subcategory

The exposure profile in Table IV.4.21-B includes 20 samples for production line handlers. The median is 42 μg/m^3, the mean is 69 μg/m^3, and the range is 12 μg/m^3 (limit of detection (LOD)) to 258 μg/m^3. Table IV.4.21-B shows that, of the 20 samples, 9 (45 percent) are above 50 μg/m^3 and 4 (20 percent) exceed 100 μg/m^3. The highest concentrations occurred when workers moved dry, unfired product (Document ID 1365, p. 3-9; 0137, p. 103). During the transportation of unfired brick product throughout the kiln area, the wheels on the forklift (or squeeze lift) crushed a mixture of high-silica spilled and broken product, which became suspended in the air causing a significant source of exposure (Document ID 1365, p. 3-9; 0137, pp. 48, 80, 103).

At a different facility, NIOSH observed silica exposures of 80 μg/m^3 and 64 μg/m^3 for a production material handler who also transported products into and out of kilns with a forklift (Document ID 1365, p. 3-9; 0239). The floors were covered with washed limestone pea gravel (a low-quartz aggregate) and aluminum plates to reduce crystalline silica dust generation. However, dust was still generated by brick breakage during firing (Document ID 1365, p. 3-9; 0239, p. 8).

Workers with low exposures include those controlling the flow of bricks from the molding machine (12 μg/m^3 and 21 μg/m^3) and transfer car operators moving bricks between the manufacturing area and the kilns and drying ovens (four exposures ranging from 17 µg/m^3 to 21 µg/m^3). At this facility the product was sprayed with water from manual or automatic nozzles and the material handlers performed this work either by hand or using automated equipment (Document ID 1365, p. 3-10; 0232, p. 7).

Belden Brick Company submitted data that they shared with OMB and SBA in 2010, to the docket (Document ID 2378, p. 5). For manual hacking, 68.2 percent of samples had exposures over 50 µg/m^3 with 50.0 percent above 100 µg/m^3; and for machine hacking 66 percent of the samples were above 50 µg/m^3 with 19.8 percent falling between 50 and 100 µg/m^3. The data submitted did not contain any individual sampling values nor did it include any description of the working conditions and controls in place; therefore, OSHA was not able to incorporate these results into the exposure profile. However, these exposures are consistent with the baseline working conditions for production line handlers reflected in the final exposure profile in Table IV.4.21-B, which shows that 45 percent of the production line handlers have exposures above 50 µg/m^3.

In the PEA, OSHA reported that production line handlers typically work without task-specific exposure controls. Local exhaust ventilation (LEV) is sometimes associated with nearby processes, such as conveyor belts and coatings application; however, dust control is incomplete, and those processes still contribute to silica exposure of production line handlers (Document ID 1365, p. 3-16). No comments were received disputing this finding; therefore, OSHA finds that baseline conditions for production line handlers in this industry typically involve work near processes with incomplete dust control.

Exposure Profile and Baseline Conditions for the Post-Production Handlers Subcategory

The exposure profile in Table IV.4.21-B includes 37 samples for post-production handlers. The median is 15 µg/m^3, the mean is 25 µg/m^3, and the range is 10 µg/m^3 (limit of detection (LOD)) to 119 µg/m^3. Table IV.4.21-B shows that, of the 37 samples, 4 (10.8 percent) are above 50 µg/m^3 and 1 (2.7 percent) exceed 100 µg/m^3. Silica exposure levels tend to be lower for workers handling kiln-fired structural clay products than for the other two material handler subcategories. After firing, the clay is substantially harder than in earlier parts of the manufacturing process, and thus handling creates less dust (Document ID 1720, p. IV-351; 1365, p. 3-10).

The exposure profile represents a variety of operations that are typical for post-production workers in this application group. Nine workers (24 percent) monitored automated unloading or packaging equipment. These workers had consistently low exposures, ranging from 12 μg/m^3 to 29 μg/m^3. Another 19 workers (51 percent) manually unloaded fired bricks. These workers generally had higher exposures, ranging from 10 μg/m^3 (the LOD) to 119 μg/m^3, with four results exceeding 50 μg/m^3. Finally, nine post-production workers (24 percent) operated forklifts or other heavy equipment to move stacks of fired and packaged bricks around the yard. Exposures for these forklift operators were all below 50 μg/m^3, ranging from 12 μg/m^3 to 44 μg/m^3 (Document ID 0137, p. 122; 0202, p. 11; 0232, p. 11; 0235, pp. 13-14; 0239, p. 14).

A report by NIOSH found that a forklift operator using an enclosed, ventilated cab in addition to yard dust management, had an exposure of less than or equal to 12 μg/m^3 (LOD) (Document ID 1365, p. 3-10; 0235, p. 6). Another facility that frequently sprayed water in the plant yard reduced all of its forklift operator exposures to below 50 μg/m^3 (four results less than or equal to the LOD [16 μg/m^3] and one result of 43 μg/m^3) (Document ID 1365, p. 3-10; 1720, p. IV-351; 0239, p. 8, 12). Additionally, forklift speed was restricted at this facility reducing the amount of dust disturbed by traffic (Document ID 1365, p. 3-10; 0239, p. 9). Many facilities occasionally sprinkle water on heavily traveled routes through outdoor brickyards to suppress dust (Document ID 1365, pp. 3-10, 3-17).

Of the 19 results for workers manually unloading bricks, 12 (63 percent) are associated with some type of additional control (water spray nozzles, fans to remove dust on bricks prior to reaching the operator, or clean air supply blown in the worker's PBZ) (Document ID 0202, p. 11; 0232, p. 11; 0235, p. 13). However, using these controls for manual operations was not always effective; an unloader supplied with clean air had an exposure of 119 μg/m^3. NIOSH reported that the ducts blew clean air into workers breathing zones, but nearby fans may have disturbed the airflow patterns (Document ID 1365, p. 3-10;

0235, p. 13). The post-production handler results associated with automated processes in place (including some obtained in areas where wet methods are also used) are all below 50 μg/m³.

Exposure for post-production handlers in some plants may also occur when tumbling brick. This process is used to give the brick the appearance of being aged or reclaimed. However, the use of this process varies by plant. During the public hearings, Belden Brick stated that it does not do any post-fired tumbling at all. Their brick is only molded (Document ID 3586, Tr. 3481). Brian Ogle with General Shale reported that they tumble fired brick but explained that it was a very dusty operation and that LEV must be set up to remove dust around the kiln tunnel after tumbling fired brick (Document ID 3586, Tr. 3480). Representatives from the Whitacre Greer Company stated that like General Shale, they tumble brick after it has been fired using an old cement mixer with dust controls on it (Document ID 3586, Tr. 3480-3481).

According to the data submitted by Belden Brick Company, 58.5 percent of workers manually unloading (dehacking) kiln cars had exposures over 50 μg/m³ and 26.9 percent were above 100 μg/m³ (n=171), while only 23.3 percent of the samples for dehackers, which OSHA assumes is other than manual dehacking and therefore the worker has less interaction with the process,[133] were above 50 μg/m³ (Document ID 2378, p. 5). The data submitted did not contain any individual sampling values nor did it include any description of the working conditions and controls in place that would allow OSHA to determine whether these exposure results are representative of baseline working conditions for post-production handlers. However, these summary data suggest that OSHA's exposure profile may underestimate the baseline exposures of post-production materials handlers.

During the public hearings, representatives from the brick industry testified that plant workers in arid climates occasionally experience elevated exposures due to dust storms (Document ID 3577, Tr. 714; 3586, Tr. 3465-68). Presumably, the storms would affect

[133] OSHA bases this assumption on similar results between the manual hackers and the machine hackers at the same facility. Where the 50 percent of the workers who manually load (hacking) had exposures above 100 μg/m³ while only 19.8 percent of samples for machine loading was above 100 μg/m³.

only those workers working outdoors. No information, however, was submitted to the docket explaining the frequency of storms, the typical time duration these storms last, the levels of respirable silica dust experienced in these storms, or any existing modification to work practices when dust storms occur. Although Acme Brick described a storm resulting in zero visibility, it seems unlikely that work would still continue under those circumstances (Document ID 3755, Tr. 714). General Shale admitted that they have never sampled to determine what the final exposures for an 8-hour shift where a dust storm occurs might be (Document ID 3586, Tr. 3465-68).[134] Because the final exposure profile reflects a variety of conditions, including low exposure levels in facilities with conscientious dust controls even in the yard areas, OSHA concludes that the profile reflects a range of weather conditions and that no adjustment is required for dust storms.

Based on this information, OSHA has determined that baseline conditions for post-production workers typically include the use of automated equipment, and that most post-production handler's work with some type of task-specific engineering control. However, these controls are often not well implemented. In addition, some facilities use water in the yard and on heavily traveled routes through outdoor brickyards to suppress dust.

Overall Exposure Profile and Baseline Conditions for All Material Handlers

In the PEA, OSHA determined that across the industry, the baseline conditions are best represented by the cross section of facilities reviewed for the exposure profile. No comments were received disputing this determination. Therefore, in the FEA, OSHA concludes that the best description of current baseline exposures includes all results summarized for this job category in Table IV.4.21-B; and the median of 21 μg/m^3, a mean of 42 μg/m^3 for all material handlers and a range of 10 μg/m^3 (LOD) to 258 μg/m^3 represent their baseline exposure.

Exposure Profile and Baseline Conditions for Grinding Operators

The exposure profile in Table IV.4.21-B includes 17 samples for grinder operators. The median is 91 μg/m^3, the mean is 162 μg/m^3, and the range is 12 μg/m^3 (limit of detection

[134] Refer to section FEA Chapter X - Environmental Impacts for a more detailed discussion of environmental factors which affect exposures.

(LOD)) to 628 μg/m^3. Table IV.4.21-B shows that, of the 17 samples, 12 (70.5 percent) are above 50 μg/m^3 and 8 (47 percent) exceed 100 μg/m^3. These values are based on 17 readings for grinding operators obtained from four OSHA SEP inspection reports (Document ID 0137; 0161),[135] three NIOSH reports (Document ID 0232; 0235; 0239) and the OSHA Information System (OIS) (Document ID 3958).

Three of the highest full-shift exposure levels (628 μg/m^3, 410 μg/m^3, and 362 μg/m^3) were all associated with a single production plant and remained high despite efforts on the part of the facility to enhance dust collection at the grinder and improve ventilation and housekeeping in the control room (Document ID 0161). The results might have been influenced by newly installed milling equipment, which reportedly generated more dust and finer particles than had been evident before the installation. OSHA, however, does not have access to results from the period before the new mill was installed for comparison. Additionally, OSHA reported elevated sample levels for workers in all three job categories (10 out of 11 samples were over 100 μg/m^3) suggesting that dust was poorly controlled throughout this facility (Document ID 1365, p. 3-11; 0161). The fourth exposure of 438 μg/m^3 taken at another facility is also associated with a grinder with inadequate ventilation (Document ID 3958, Row 610).

Two of the lowest exposures for grinder operators of ≤18 μg/m^3 (LOD) and 24 μg/m^3, taken on two different days, were associated with one operator who worked from an enclosed, ventilated control room for 90 percent of the shift (Document ID 0235, pp. 10, 13-14; 1365, p. 3-36). For the remaining 10 percent of the time, the operator monitored machinery, removed material from the grinder teeth and performed dry sweeping under the conveyors (Document ID 0235, p. 10; 1365, pp. 3-11 – 3-12). The facility had a troughed conveyor system with raised edges designed to reduce the amount of spillage (Document ID 0235, p. 7). A second operator at the same facility had an exposure result of 169 μg/m^3 while operating additional enclosed grinding and screening equipment in a separate building where substantial spillage occurred. Although a control room was available, this second operator spent most of the shift (85 percent) cleaning the grinding

[135] OSHA SEP Inspection Report 300523396 also contains inspections 302005772 and 302547674, which were conducted at the same facility (Document ID 0161).

machinery by manually removing rocks and shoveling debris in the area. NIOSH noted several exposure sources in the second area including conveyor spillage and re-suspension of settled dust by front end loaders (Document ID 0235, pp. 4, 9-10, 14; 1365, p. 3-12).

Grinding operators at six manufacturing facilities used for this exposure profile performed tasks within the grinder area. Typical conditions associated with this job category include the use of ventilated control rooms for the grinding operator for at least part of the shift, open conveyors, and enclosed and ventilated grinding equipment (Document ID 1365, p. 3-5). The most substantial exposures occur when grinding operators exit control rooms and approach the grinder equipment to clean and maintain equipment and perform housekeeping activities (e.g., manually remove rocks from grinder teeth, and sweep or shovel spilled debris from floors). In the PEA, OSHA made the assumption that grinding operators perform these tasks intermittently (up to eight times per day) and respirable quartz levels in the grinding area often are elevated to extreme levels and thus are the primary source of exposure for grinder operators. This assumption was supported by comments from the brick industry. Acme Brick and the Brick Industry Association stated that their grinding operators are in and out of the control booth all day and spend approximately 50 percent of their time outside of the control room (Document ID 3577, Tr. 733-34, 743; 3586, Tr. 3450). It was further explained that exposures are elevated in this area due to the raw materials sticking to conveyor belts and that dust levels can remain high in spite of extensive dust collection (Document ID 3577, Tr. 742; 3586, Tr. 3449). Poorly constructed control rooms can also obviously become contaminated with silica and contribute to worker silica exposures.

The Belden Brick Company submitted summary sampling data for grinder operators in their facilities (Document ID 2378, p. 5). Over 58 percent of the samples from grinding operators had exposures greater than 50 $\mu g/m^3$ and 17.8 percent were above 100 $\mu g/m^3$. The data submitted did not contain any individual sampling values, nor did it include any description of the working conditions and controls in place that would allow OSHA to determine whether these exposure results are representative of baseline working conditions for grinding operators. However, these summary data are consistent with

OSHA's exposure profile which indicates that approximately 70 percent of the grinders have exposures greater than 50 µg/m^3 and 47 percent were above 100 µg/m^3.

Based on supplemental information, and the conditions described for this job category described above in this subsection, OSHA has determined that the baseline conditions for grinding operators across this industry are best represented by the range of results summarized in the exposure profile (Document ID 2378; 3577). Thus, their baseline exposure level is represented by the median exposure for this job category (91 µg/m^3), ranging from 12 µg/m^3 (the LOD) to 628 µg/m^3.

Exposure Profile and Baseline Conditions for Forming Line Operators

The exposure profile in Table IV.4.21-B includes 54 samples for forming line operators. The median is 76 µg/m^3, the mean is 142 µg/m^3, and the range is 12 µg/m^3 (limit of detection (LOD)) to 1,028 µg/m^3. Table IV.4.21-B shows that, of the 54 samples, 35 (64.9 percent) are above 50 µg/m^3 and 22 (40.8 percent) exceed 100 µg/m^3. Four of the 54 results (501 µg/m^3, 690 µg/m^3, 794 µg/m^3, and 1028 µg/m^3, all from the same facility) also exceed 500 µg/m^3. Silica exposures primarily occur when workers perform open transfer of clay and coatings ingredients into hoppers and mills, operate mixing and milling equipment, and apply sand-based coatings to products.

Exposure Profile and Baseline Conditions for the Pug Mill Operators Subcategory

The exposure profile in Table IV.4.21-B includes 7 samples for loader operators. The median is 226 µg/m^3, the mean is 312 µg/m^3, and the range is 41 µg/m^3 (limit of detection (LOD)) to 1,028 µg/m^3. Table IV.4.21-B shows that, of the 7 samples, 6 (85.8 percent) are above 50 µg/m^3 and 5 (71.5 percent) exceed 100 µg/m^3. The highest value among the data available to OSHA for this industry (1,028 µg/m^3) was obtained for a forming line operator monitoring a pug mill equipped with a poorly maintained exhaust-ventilated enclosure (Document ID 1365, pp. 3-12, 3-37; 0161). The inspection report noted that the enclosure doors did not seal properly and there was no exhaust ventilation in place (Document ID 0161, p. 56). After the inspection, the facility repaired the enclosure around the primary pug mill, installed a second pug mill with a better-sealed exhaust-ventilated enclosure and added a greater quantity of water to the clay mix to reduce dust emissions (Document ID 0161, pp. 602, 1048). During a later inspection, an exposure of 214 µg/m^3 was observed for an operator monitoring this second mill (an exposure 79 percent lower than the first reading). The report also noted that the old pug mill still continued to be a major source of silica dust due to the lack of improved ventilation at that source and may have contributed to the elevated exposure for the worker at that mill (Document ID 0161, pp. 1048-1049, 1052).

Two silica exposure results (226 µg/m^3 and 337 µg/m^3) were obtained for ball mill and spray drier operators at a ceramic tile manufacturing facility who prepared clay powder to be compressed into tiles (Document ID 1365, p. 3-13; 0202, p. 9). These workers had adjacent workstations in the same room where visible dust occasionally entered when the ball mill was charged with fired tile scrap. Dust also entered when the operator brushed spilled material away from the mill hatch. Furthermore, an automatic LEV system associated with the storage hoppers functioned improperly, and the spray-drying equipment constantly emitted fine dust into the surrounding room as the clay powder was sized (sorted in a cyclone-type separator), transferred, and conveyed through the process.[136] Dust release from vertical conveyors adjacent to the spray drier was reduced with enclosures. Air samples obtained in other production processes suggested that dusty air leaking from this area (through doors and open conveyor passages through the walls) contributed to worker exposure farther down the production line (e.g., material handlers and forming line operators). Although a control room was available, and the spray-drier operator spent 10 percent of the shift there, the door was frequently open and the room was unventilated. The floor, walls, windows, and equipment inside the control room were coated with a light layer of dust (Document ID 1365, pp. 3-13; 0202, pp. 9, 24- 26).

Detailed information is not available for the two lowest results (41 µg/m^3 and 70 µg/m^3) associated with the pug mill operator subcategory; however, these workers may have

[136] At times, the airborne dust was sufficient to reduce visibility. Furthermore, the facility provided information indicating that 30 percent of the particles in the milled clay processed through the drier were less than 4 µg in size, suggesting that a substantial portion of the clay particles were in the respirable size range (Document ID 0202, p. 9).

spent a portion of their shift performing other task such as brick cutting (Document ID 0137, p, 129-130, 158).

Exposure Profile and Baseline Conditions for the Coatings Blenders Subcategory

The exposure profile in Table IV.4.21-B includes 10 samples for coating blenders. The median is 77 μg/m^3, the mean is 97 μg/m^3, and the range is 17 μg/m^3 (limit of detection (LOD)) to 225 μg/m^3. Table IV.4.21-B shows that, of the 10 samples, 8 (80 percent) are above 50 μg/m^3 and 3 (30 percent) exceed 100 μg/m^3. The highest exposures (225 μg/m^3 and 190 μg/m^3) are associated with a worker operating a sand dryer and coatings mixer in a brick coatings preparation room. LEV was present at the dryer and at transition points between the particulate screen, bucket elevator, and weight bin; at the bag dumping station for the mixer; and at the transfer point between the mixer and skid tub (Document ID 0235, p. 13). However, the dryer LEV was poorly aligned with the hopper and operated at air velocities less than one-half of the 250 feet per minute recommended by the American Conference of Governmental Industrial Hygienists (ACGIH) for toxic materials (Document ID 1365, p. 3-13; 1607). At the same facility, another worker dumping bags and mixing coatings for a different production line had a much lower exposure of only 17 μg/m^3 (Document ID 0235, p. 13). Although information on the controls associated with this other production line is not available, NIOSH noted that this sand preparation area was smaller, serving only one production line with a part-time operator, while the first served two production lines (Document ID 1365, p. 3-13; 0235, p. 5). A respirable silica exposure result of 68 μg/m^3 was obtained for an employee dumping bags of glaze ingredients under similar conditions at a ceramic tile manufacturing facility (Document ID 1365, p. 3-14; 0202, p. 11). LEV on the bag dumping station was judged inadequate as settled dust obstructed air flow through the slotted hood (Document ID 0202, p. 19).

Exposure Profile and Baseline Conditions for the Formers Subcategory

As Table IV.4.21-B indicates, the 37 exposure samples for formers, the subcategories of forming line operators (Clay Powder Formers, Coating Applicators- Automated, Coatings Applicators – Manual, and Wet Clay Formers) who spend the entire shift at forming stations (without milling or mixing materials), range from 12 μg/m^3 to 794 μg/m^3, with a median of 70 μg/m^3 and a mean of 122 μg/m^3. Twenty-one samples (56.7 percent) exceed 50 μg/m^3, and 14 samples (37.8 percent) exceed 100 μg/m^3.

The exposure profile in Table IV.4.21-B includes 10 samples for Forming Line Operators (Wet Clay Formers). The median is 19 μg/m^3, the mean is 27 μg/m^3, and the range is 13 μg/m^3 (limit of detection (LOD)) to 78 μg/m^3. Table IV.4.21-B shows that, of the 10 samples, 1 (10 percent) is at or above 50 μg/m^3 and none exceed 100 μg/m^3. The formers who primarily work with wet clay only (molding and extrusion processes, no coatings application), identified as Forming Line Operators (Wet Clay Formers) on Table IV.4.21-B have the lowest range of exposures. The exposure profile in Table IV.4.21-B includes 3 samples for Forming Line Operators (Clay Powder Formers). The median is 144 μg/m^3, the mean is 158 μg/m^3, and the range is 141 μg/m^3 (limit of detection (LOD)) to 188 μg/m^3. Table IV.4.21-B shows that, of the 3 samples, 3 (100 percent) are above 50 μg/m^3 and 3 (100 percent) exceed 100 μg/m^3. In contrast, the three exposure samples for formers dealing with pressing dry clay powder (pressing operations, no coatings application), identified as Forming Line Operators (Clay Powder Formers) on Table IV.4.21-B, worked at a ceramic tile facility; they had higher exposures, ranging from 141 μg/m^3 to 188 μg/m^3. An automated air jet that blew residual clay powder from the molds several times per minute resulted in substantial silica in the air, contributing to these workers' exposures (Document ID 1365, p. 3-14; 0202, p. 27). Data are not available to determine whether clay powder pressing operations have elevated exposures in the absence of air spray cleaning; however, formers making specialty shapes also had substantial exposure from frequent dry sweeping/brushing of the work table and dry unfired tiles (Document ID 1365, p. 3-14; 0202, p. 27).

According to the summary data submitted by Belden Brick Company, 80.7 percent of samples for machine brick molder had exposures over 50 μg/m^3 (n=114), and 49.1 percent were above 100 μg/m^3. Fifty-two percent of extruded brick operators experienced exposures over 50 μg/m^3 (n=185), while 70.6 percent who hand-molded brick were over 50 μg/m^3. As noted previously, the data submitted did not contain any individual sampling values nor did it include any description of the working conditions and controls in place; thus OSHA is unable to determine whether these exposures data are representative of baseline working conditions for formers (Document ID 2378, p. 5). Although these summary data suggest that OSHA's exposure profile may underestimate the exposures of formers, there is no means of determining the extent of the possible underestimation

Coatings application operations (especially sand coating) are associated with some of the highest exposures in this industry (only pug mill operators have higher exposure levels). The exposure profile in Table IV.4.21-B includes 15 samples for Forming Line Operators (Coating Applicators - Manual). The median is 102 μg/m^3, the mean is 199 μg/m^3, and the range is 12 μg/m^3 (limit of detection (LOD)) to 794 μg/m^3. Of the 15 samples, 10 (66.7 percent) are above 50 μg/m^3 and 8 (53.3 percent) exceed 100 μg/m^3. The four lowest exposures for manual coatings application were associated with manual slurry application rather than dry mix coatings (Document ID 0232, pp. 4-5, 11-12; 0235, pp. 5-6, 11). Not surprisingly, higher exposures were reported for workers dumping bags of dry silica-containing materials, especially sand. Formers using automated coatings equipment experienced somewhat lower exposures, but seven of the nine samples (77.8 percent) still exceeded 50 μg/m^3 (Document ID 0202, p. 11; 0232, pp. 11-12; 0235, pp. 13-14). Based on this information, OSHA finds that, except for workers primarily handling (wet) clay slurry, all forming line workers routinely experience high exposure levels (greater than 50 μg/m^3), principally from working with dry sand or dry clay (Document ID 1720, p. IV-354; 1365, pp. 3-13 – 3-14).

Formers typically work near local exhaust ventilation hoods, which are generally associated with the automated dry coatings application equipment. Other engineering controls are not normally present on the forming line (Document ID 0232, p. 6; 0573). For example, in contrast to coatings blending areas, the hoppers along the forming line into which workers dump dry coating materials are not fitted with exhaust ventilation. LEV is not normally available at the workstations where formers apply coatings by hand, either to molds or to product (Document ID 0161, pp. 22, 56). In addition, due to the warm conditions in facilities operating drying ovens and kilns, workers often use pedestal or ceiling fans for comfort, which can disturb settled dust and disrupt the function of ventilation systems (Document ID 0232, pp. 2, 5; 0572). Workers also commonly (at least daily) clean the forming line floors by dry sweeping and using shovels to clean up spilled material as necessary which can contribute to exposures (Document ID 1365, pp. 3-12 – 3-14; 3-37 – 3-41).

Overall Exposure Profile and Baseline Conditions Forming Line Operators

The exposure profile in Table IV.4.21-B includes 7 samples for Forming Line Operators (Pug Mill Operators). The median is 226 μg/m^3, the mean is 312 μg/m^3, and the range is 41 μg/m^3 to 1,028 μg/m^3. Table IV.4.21-B shows that 6 of the samples (85.7 percent) exceed 50 μg/m^3, 5 (71.4 percent) exceed 100 μg/m^3 and 3 (42.9 percent) exceed 250 μg/m^3.

Forming line operators work under various conditions depending on the work practices and control technology at the facility. OSHA has determined that across the industry, baseline conditions are best represented by the cross section of facilities reviewed for the exposure profile. OSHA finds that the best description of current baseline exposures of forming line operators includes the full dataset available to OSHA for this job category (summarized in Table IV.4.21-B). Therefore, the median of 76 μg/m^3 for all forming line operators represents their baseline exposure.

Table IV.4.21-B Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Structural Clay Industry (2007 NAICS 327121, 327122, 327123)

Notes: All samples summarized are personal breathing zone (PBZ) results representing 8-hour time-weighted average exposures. Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the facility. Percentages may not add to 100 percent due to rounding. Sources: Document ID 1720; 3958; 0137; 0161; 0202; 0232; 0235; 0239.											

4.21.3 Additional Controls

Additional Controls for Material Handlers

The exposure profile in Table IV.4.21-B shows that 26.6 percent (17 out of 64 samples) of material handlers have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Information presented in the exposure profile (Table IV.4.21-B) indicates that the median exposure level for all material handlers is 21 μg/m^3, and these data range from 10 to 258 μg/m^3. The data summarized for material handlers are not distributed equally across all three subcategories. Although Table IV.4.21-B shows that less than 30 percent of material handlers in this industry experience exposure levels of more than 50 μg/m^3, 57 percent of loader operators and 45 percent of production line handlers currently have silica exposures exceeding 50 μg/m^3 and therefore require additional controls. Among data for post-production handlers less than 14 percent exceeded that level.

Brian Ogle with General Shale stated that their company does not have any problem with controlling exposures when handling the finished product on the packaging end, and that exhaust ventilation normally suffices; however, LEV is not enough to consistently control exposures during raw material processing alone (Document ID 3586, Tr. 3450). OSHA agrees that a single control alone may not adequately reduce exposures. It is through the use of a combination of controls (enclosures, housekeeping, etc.) that the Agency believes that exposures for material handlers can be reduced to below the PEL in most instances.

The following paragraphs describe additional controls suitable for material handlers. Since the sources of exposures may vary depending on the processes being used, a facility may find that some of the engineering controls discussed will not be applicable to their specific needs.

Local Exhaust Ventilation and Enclosed Conveyor Systems

To obtain reductions in silica levels in raw material handling areas, the primary control methods target dust emissions from hoppers, conveyors, and transfer points associated with material handlers' duties. Such control methods include covering conveyors and augmenting ventilation at existing enclosed transfer points to meet the ACGIH recommended air velocity of 150 to 300 feet per minute (fpm) across all openings in the enclosures (Document ID 3883, pp. 10-67; 1365, pp. 3-21, 3-24; 0202, p. 14; 0161, pp. 56, 1550-1555; 1607).[137] NIOSH described an enclosed conveying system associated with grinding equipment, pug mills, silos, and mixers at a brick manufacturing facility with ventilation at the transfer points (Document ID 0235, pp. 7-9). During an inspection at a brick manufacturing facility OSHA observed elevated exposures to silica dust during material transfer in the grinding plant (Document ID 0161, pp. 409, 936). The sole source of exposure for the worker in the grinding plant was three conveyors in the rear of the machine (Document ID 0161, p. 590). An enclosed conveyance system was installed and has substantially reduced exposures (Document ID 0161, p. 183).

Enclosed conveyors with exhaust ventilation have been implemented effectively on similar conveyor systems in the foundry industry for the movement of sand and clay used for mold material in metal casting processes. Because of the similarities in the process (equipment, material type and flow), OSHA has determined that these systems can be equally effective in the structural clay industry (Document ID 0018, pp. 52, 93). Foundry sand systems operators working in areas where sand transport systems were enclosed and where machines that process sand and clay (materials also used by the structural clay industry) were fitted with exhaust ventilation, experienced some of the lowest exposures in the foundry industry, e.g., two exposures of 13 μg/m^3 (LOD) for a sand-systems operator (sand mullor) controlling equipment that had both the belts and sand elevator fully enclosed (Document ID 0018, pp. 52, 93).

[137] ACGIH (2010, Chapter 13.50) recommends a minimum air flow of 150 feet per minute (fpm) across bin and hopper openings for manual loading operations; however, ACGIH also recommends air velocity of one-and-a-half to two times that rate (i.e., 225 fpm to 300 fpm) when conditions create conditions more dusty than during manual loading. The need for increased air velocity depends on the material flow rate (a front-end loader will add materials at a much greater material flow rate than manual transfers), dustiness (the material at this site was apparently very dusty), and the height the material falls (influenced both by hopper design and by material handler work practices). Furthermore, ACGIH recommends that the enclosure be "large enough to accommodate the 'splash' effect." For some dust controls, ACGIH suggests increasing the baseline air flow rate from 150 fpm to 250 fpm when the materials handled include toxic dusts.

NIOSH and OSHA evaluated pneumatic and enclosed systems to isolate the storage and transport of dry sand in two foundries. The four exposures for the molder job category from these foundries include two results of 13 μg/m³ (LOD) and one each of 20 μg/m³ and 23 μg/m³ (Document ID 0268; 0501, p. 6).[138] At another foundry, OSHA reported a 65 to 70-percent reduction in exposures (from 140 μg/m³ to 50 μg/m³ and 42 μg/m³) after the facility made improvements to sand delivery systems and exhaust ventilation systems throughout the facility (Document ID 0132, pp. 104-109, 113-118, 138-146, 163-172, 181, 192-195, 197-199, 238, 242-243). Based on these findings OSHA expects that the addition of enclosures and ventilation at dust emission points would provide for similar reductions in the structural clay industry.

If exposure levels remain elevated, another type of ventilation system is available for material handlers who spend a portion of the shift at a fixed location. A combination "push-pull" ventilation system—designed to remove (pull) contaminated air from near the source, while supplying (push) a similar amount of clean air behind or above the worker's head—has been demonstrated to be very effective for other types of dust. Heinonen et al., determined in an experimental study (using dusty flour) that compared with general ventilation alone, breathing zone total dust concentrations were reduced by 98 percent from 42,000 μg/m³ to 1,000 μg/m³ or less when the work surface was fitted with exhaust ventilation (at the front, side, or as a downdraft) in combination with local clean air supply above the worker's head (Document ID 1365, pp. 3-21 – 3-22; 1393). Although this study tested high concentrations of total dust, OSHA expects this type of "push-pull" ventilation system, which is a common form of LEV, would be similarly effective for reducing levels of respirable silica dust in the breathing zone of structural clay workers (in this case, to be considered "clean air," the air provided to the area around the worker would be free of silica). OSHA notes that for such a system to function, competing air from pedestal fans (often used for cooling workers in hot

[138] In the ERG contractor report, molder activities are described as monitoring and operating equipment in which the sand molds are produced, manually handling cured sand mold sections and working near sand transport systems. This sand often contains 100 percent quartz. (Document ID 1365, pp. 2-27 – 2-29).

climates) must be eliminated; however, the temperature (e.g., air-conditioning) of the provided air can be adjusted for worker comfort.

A system similar to this was used on the packaging line (and also at a forming station) at a facility evaluated by NIOSH. Reported exposures had a median of 62 μg/m^3 for stackers in the packaging line and 70 μg/m^3 for formers. NIOSH noted that the prohibition of dry sweeping materials would further reduce exposures (Document ID 0235, pp. 6, 8, 12).

Reduced Spillage and Adhesions Associated With Conveyors

Conveyor belts, even if not fully enclosed, can be modified with raised sides (e.g., using troughed belts or V-rollers) to reduce spilled material that also can contribute to silica exposure levels. In addition to the benefit of reducing occupational exposures, less spillage also translates to minimizing the loss of product or raw material and increased productivity for the employer. NIOSH reported that the brick manufacturing facility that used LEV on various milling, mixing, and storage equipment (mentioned previously) also used alternative trough conveyors to reduce the amount of raw materials lost from the conveyor belts associated with the raw material grinding equipment. At this facility, the "B Plant" grinding room conveyors were equipped with a ¾ inch raised edge that minimized material spillage. Workers in this area who spent only a small portion of the shift (10 percent) performing clean-up activities had exposures below the PEL (≤15 (LOD) and 24 μg/m^3) and (Document ID 0235, pp. 6-7, 10). A second worker in a separate grinding area in the same facility, which did not have this type of conveyor installed, had a sample result of 144 μg/m^3. This worker spent a larger portion of their shift, almost 85 percent, cleaning up material (Document ID 0235, pp. 6, 10).

A second facility visited by NIOSH installed full-width belt scrapers on its feed belt conveyors, which carried screen clay through the production facility to the pug mill (Document ID 0239, p. 8). The scrapers, in addition to water sprays, prevented the clay from clinging to the belt, drying out and continuing to be a source of silica exposure as the conveyor moved. Troughing idlers were also added to prevent spillage of the screen clayed as it moved overhead (Document ID 0239, p. 8). Although sampling results exceeded the PEL, the overexposures could have been due primarily to shoveling spilled clay from the floor. NIOSH recommended using a vacuum to further reduce exposures, an additional control discussed at more length below (Document ID 0239, p. 12).

Dr. Garth Tayler, Technical Director, Acme Brick Company agreed with OSHA that material frequently sticks to the conveyor belts during material transfer resulting in spillage and accumulation on the ground (Document ID 3577, Tr. 742; 3586, Tr. 3447-3449). OSHA expects that the installation of belt scrapers to reduce the amount of material that clings to the belt will reduce material spillage or re-suspension. Use of these scrapers prevents the clay from drying out on the belts and re-aerosolizing as the conveyor continues to move (Document ID 0235, p. 8). Although the benefit of this control method by itself has not been quantified, it can be part of the overall control package used to limit silica exposures, as demonstrated by the fact that just 1 of 32 samples (3 percent) exceeded 100 μg/m^3 in the plant (compared with 28 percent for the industry as a whole, as indicated by Table IV.4.21-B) (Document ID 0235, p. 8).

Housekeeping

Poor housekeeping can contribute substantially to worker exposure levels in all material handling areas. Housekeeping that minimizes the amount of spilled materials and settled dust in areas of vehicular traffic reduces silica exposure that occurs when those sources are crushed or disturbed by passing traffic (including machinery operated by material handlers).

In one facility evaluated by NIOSH, exposures in the two separate grinding rooms were substantially less for operators in the grinding area that had good housekeeping practices (Document ID 0235). The “C plant” had what NIOSH described as “major accumulations (2 to 3 inches) of settled dust on the floor” and was associated with an exposure result of 144 μg/m^3 (Document ID 0235, p. 5). Grinding operators at the same facility in the “B Plant” had substantially lower results of ≤15 (LOD) and 24 μg/m^3 (Document ID 0235, pp. 6-7).

At a different facility evaluated by NIOSH, the grinding room operator spent a portion of the shift sweeping and shoveling (40 percent). NIOSH noted that the facility had implemented a number of various engineering controls and work practices already but suggested that replacing the broom with a vacuum cleaner equipped with a filter selected based on the particle size of the dust would eliminate this as a source of silica dust and further reduce exposures (Document ID 0239, pp. 7, 10, 12).

Thorough initial cleaning in association with improved housekeeping procedures to maintain cleanliness and prevent the accumulation of dust can reduce exposures. For example, a thorough cleaning in a brick manufacturing facility removed "several inches" of dust from floors, as well as from all structural and equipment surfaces (Document ID 1365, pp. 3-19 – 3-20; 0571). Post-cleaning air samples indicated a "dramatic" decrease in exposure levels (in some cases, a greater than 90-percent reduction, to levels less than 50 μg/m^3) for workers in areas where dusty materials were transported or handled. This thorough cleaning also allowed the facility to identify and prioritize specific sources of dust for future control efforts (Document ID 0571).

Enclosed Cabs

For facilities where elevated exposures persist for material handlers using vehicular material handling equipment (e.g., loader operators), well-sealed, air conditioned cabs maintained under positive pressure with filtered air provide an effective control option. The information summarized in the ERG contractor report suggests that most front-end loaders used in this industry are equipped with cabs (Document ID 1365, p. 3-16). During the public hearings, Bill Latham and Tom Brown with Acme Brick confirmed the availability of environmental cabs on front-end loaders in the structural clay industry. They commented that their loader operators use front-end loaders with enclosed cabs that are air conditioned and equipped with HEPA filters (Document ID 3586, Tr. 3442). Although Acme Brick did not submit any sampling data to the docket, Mr. Brown stated that the majority of their employees currently experience exposures below 50 μg/m^3 (Document ID 3577, Tr. 760-761).

Enclosed cabs have been shown to be highly effective in agriculture and mining industries as reflected in data from Hall et al. (Document ID 0719). Agricultural workers are routinely exposed to respirable dust and the agricultural industry has an interest in protection against respirable and total dust. Hall et al., tested two cabs manufactured or retrofitted to comply with the controls recommended by the American Society of Agricultural Engineers'[139] S525–*Engineering Control of Environmental Air Quality* (ASAE S525) standard criteria. The data from Hall et al., suggest that a 94 to 98.5-percent reduction in respirable dust[140] (inside, compared with outside the cab) can be achieved on tractors (a type of heavy equipment) fitted with well-sealed, air-conditioned, and filtered cabs (Document ID 0719, p. 51).[141]

Operators working in heavy equipment cabs designed to meet ASAE S525 standards should experience exposure reductions in the same general range as described by Hall et al. OSHA estimates that for the loader operators currently experiencing exposures between 50 and 100 $\mu g/m^3$ (approximately 40 percent of all operators in this industry), use of well-controlled cabs would reduce exposures to levels at or below 50 $\mu g/m^3$; while operators currently exposed to average concentrations between 100 and 200 $\mu g/m^3$ (approximately 14 percent of loader operators) would achieve exposure levels of less than 100 $\mu g/m^3$. Lighter equipment, such as forklifts, might achieve a lower reduction, but a functional air conditioning system and careful maintenance should offer exposure reductions, in OSHA's judgment, of at least 50 to 90 percent as compared with the 94 to 98.5 percent reductions described above .This estimation was used in the PEA (citation), and no commenters disputed it.

OSHA's estimate of percentage reductions is buttressed by studies of enclosed cabs in the mining industry. The Mine Safety and Health Administration (MSHA) found that for

[139] In 2005, the American Society of Agricultural Engineers (ASAE) changed its name to the American Society of Agricultural and Biological Engineers (ASABE).

[140] The cabs were found to offer exposure reductions of 98.5 percent (manufacturer's factory-made cab) and 94 percent (retrofit cab) for particles smaller than 1.0 µm. When tested against particles 3.0 µm and larger, the cabs were found to provide even greater protection. Although more than half of the mass of respirable particles is usually particles greater than 3 µm, a portion of respirable particles are often smaller. Therefore, OSHA has used the reductions for the smaller particles to ensure workers are fully protected, although this means that OSHA is underestimating the benefit these tractor cabs likely offer workers exposed to respirable particles.

[141] "At least three criteria must be met for a cab to fulfill properly its function: pressurization, minimum penetration with respect to the main pollutants, and cleaned airflow rate."" (Document ID 0550, p. 3). The precise reduction depends on cab pressurization to exclude particles, particle penetration through filters, and clean airflow rate.

loaders, bulldozers, and trucks used by the surface and underground mining industry, where workers were exposed to high levels of mineral dust containing silica, sealed cabs reduced (total) silica exposure levels by 42 to 99 percent (original equipment or retrofit). In most cases, when a loader or truck cab had a filtered ventilation system meeting the requirements of ISO standard 10623, silica exposure reduction was 91 percent (Document ID 0821, pp. 3-6).[142] Cabs offered less effective dust control (less than 80 percent reduction) when seals were poorly maintained or air filtration inadequate; that is, metal mesh filters rather than higher efficiency paper filters were used in the cab air filtration system (Document ID 0871, pp. 2, 6). However, MSHA concluded that "a cab without additional controls provides some additional protection to the worker, because it protects the worker from peak concentrations" (Document ID 0821, p. 4). MSHA also concluded that housekeeping practices should include vacuuming or wet wiping the cab interior daily (Document ID 0871, p. 4). Some loaders tested by MSHA (Caterpillar models 992G, 992C and 980F) were similar to the model used by a structural clay facility evaluated by NIOSH (Caterpillar model 950F), demonstrating that these filtration systems can be implemented for equipment used in the structural clay industry (Document ID 0235).

Although these cabs require regular maintenance to function properly, OSHA estimates that appropriately fitted and maintained cabs would offer an exposure reduction of at least 90 percent (the low end reported for larger equipment) for material handlers, including those using front-end loaders (Document ID 1365).

Using Low-Silica Gravel on Floors

Use of low-silica materials on floors driven on by equipment can reduce silica exposures. In the kiln area of one structural clay facility, the wheels on a lift that was transporting product crushed a mixture of high-silica gravel floor covering and spilled broken product. Plant personnel reported that the material on the floor contained up to 98 percent silica content, which became a source of exposure when dust from the crushed material became airborne. The highest result (258 μg/m^3) for material handlers is attributed to this

[142] ISO standard 10623 provides for a 50 Pascal (0.20 inches of water) cab pressure and a minimum 25 cfm of intake airflow into the cab (Document ID 0821, p. 1).

exposure source (Document ID 0137, PDF p. 115). Another facility, described by NIOSH, used “washed limestone pea gravel” (a low-silica stone) on kiln floors, instead of the original brick chips and dust, as the wheels on mobile equipment tend to pulverize the material and were contributing to worker silica exposure in the enclosed kiln (Document ID 0239, p. 8). Workers covered the pea gravel with aluminum plates to provide thermal protection, improve forklift traction, and reduce dust. Results of 57 to 60 $\mu g/m^3$ were associated with material handlers who worked on the pea gravel surface but also performed dry sweeping and spent half the shift handling unfired dry clay (two additional sources of silica exposure). NIOSH commented that the potential for silica exposure remained, due to bricks that broke during firing (Document ID 0239, p. 8). OSHA notes that it might be necessary to replace the pea gravel frequently to avoid increasing amounts of broken product accumulating in the gravel where it will be crushed by passing in-plant vehicles.

Wet Methods, Dust Suppressants, and Conducting Operations on Damp Clay

When possible, wet methods are a particularly effective means of controlling silica, as water spray can help capture airborne dust, and damp surfaces release less dust than dry surfaces.

Brian Ogle with General Shale expressed concern regarding the use of wet methods due to the physical specifications of the product and machinery, stating “because of the nature of that raw material, we're forced to utilize heaters and devices that displa[ce] [*sic*] large volumes of air at high velocity just so we can process our raw material and make brick. The slightest change in moisture content changes the maintenance related activities, the settings and even the exposure limits in those areas. This is a fancy and complicated way of saying that if we increase moisture content of the raw material; we're not going to be able to make brick” (Document ID 3586, Tr. 3380).

OSHA acknowledges that wet methods may not be appropriate to use in all circumstances such as the pre-production material handling described by Mr. Ogle. Where appropriate, however, their implementation has been shown to reduce exposures. In addition, water sprays are most effective at particle capture when the droplet size and dust particle diameter match, which also results in minimal water usage (see Section IV-4.11 – Landscaping Services for further discussion of the use of wet methods to control dust).

In the structural clay industry, use of wet methods has been shown to reduce respirable silica dust exposures well below the PEL. A NIOSH study demonstrates the effectiveness of wet methods. This study reported six exposure results, all less than 30 µg/m^3 (ranging from 11 µg/m^3 (the LOD) to 29 µg/m^3) for four post-production material handlers who operated *automated* product handling equipment equipped with spray nozzles to unload fired products from kiln cars (Document ID 1365,p. 3-22; 0232, pp. 5, 7, 8, 11). At the same facility, NIOSH also collected an additional six samples indicating similar exposure levels (ranging from 11 µg/m^3 (the LOD) to 36 µg/m^3) for material handlers working in an area where directional water-spray nozzles were used to reduce dust released from fired products before the products were *manually* unloaded (Document ID 1365, p. 3-22; 0232, pp. 5, 7, 8, 11). The spray heads could be triggered by the material handlers or set to operate automatically. An additional water hose with hand sprayers also was available for manual dust control. This report demonstrates how facilities can use both automatic and manual water sprays to optimize dust control and achieve modest exposure results to control dust from fired products (Document ID 1365, p. 3-21; 0232, pp. 5, 7, 8, 11).

Wet methods also can reduce exposures where silica-containing dust in the yard contributes to the overall exposure levels of material handlers. Dust suppressants or frequent wetting using a water spray truck can limit the amount of dust that becomes airborne. For example, a brick manufacturing facility sprayed the yard (product storage area) with water five times per day. Five of the six results obtained for material handlers operating in the area were below the LOD (16 µg/m^3 in this case), while one result was 43 µg/m^3 (Document ID 1365, p. 3—10; 0239, pp. 8-14). Another example that suggests that wet methods can significantly reduce exposures, exposures of 14 µg/m^3 and 10 µg/m^3 were obtained for loader operators at another facility moving crushed shale and schist from storage piles to hoppers. The floor was wet from the rain and visible dust was not “particularly evident” which may have contributed to the lower exposures (Document ID 0232, p. 4).

Dust suppressants, such as foam sprays, can also be applied to hoppers and conveyors to prevent silica dust from becoming airborne as raw materials are transferred between work areas. This method is in use at a structural clay facility visited by NIOSH. A foam suppression system with four spray heads was installed on the conveyor supplying the loading hopper of the pre-crusher. The loader operator working in the area had a silica result of 56 μg/m^3, despite visible dust accumulations in the loader cab which may have contributed to the exposure (Document ID 0239, pp. 6-8, 11, 14).[143]

Another way to reduce exposures to silica dust, while transporting unfired clay is to transport or manipulate the clay objects while they are still slightly damp rather than fully dried. For example, if bricks are handled (to transfer or further process them) while still slightly damp, they will be less dusty, and material handlers (and other production workers) will experience less silica exposure. A review of the data available to OSHA shows that airborne silica concentrations for damp clay operations range from less than or equal to 12 μg/m^3 (LOD) to 77 μg/m^3, with a median exposure of 22 μg/m^3. In contrast, manual operations of dried clay are associated with exposures ranging from 64 μg/m^3 to 215 μg/m^3, with a median exposure of 104 μg/m^3 (Document ID 1720; 0235; 0239). These results support the conclusion that work involving dried clay is dustier than work involving damp clay. OSHA acknowledges that even when workers can perform manual operations on damp clay, the clay eventually must be allowed to dry (e.g., prior to kiln firing). At a site visited by NIOSH, however, wet bricks were stacked onto the kiln carts and allowed to dry in place before firing, eliminating the need to transfer them dry (Document ID 0239, p. 5). Furthermore, spilled damp clay must be cleaned up before it dries and becomes an ongoing source of exposure.

Automation

Automated material handling and transfer equipment will also mitigate exposures. Another review of the exposure data available to OSHA (see Table IV.4.21-B) shows that post-production material handlers performing the tasks of unloading kilns and stacking

[143] The foam application system consisted of “a drum of citrus-based surfactant, a control panel, hoses, a manifold, and four spray heads. This system worked by blanketing the surface of the conveyed material with foam, preventing the generation of silica-containing aerosols” (Document ID 0239, p. 8).

finished structural clay products had lower exposure levels when they used automated material handling equipment (all nine results less than 50 μg/m^3, with eight of those results also less than 25 μg/m^3) than did workers performing this work by hand (Document ID 1365, p. 3-23; 1720, p. IV-359; 0202, p. 11; 0239, p. 11). For manual work, 21 percent of 19 total results exceeded 50 μg/m^3 and one exceeded 100 μg/m^3. Automatic material handling tools include kiln unloading equipment, automated transfer, and stacking and bundling or strapping equipment (Document ID 1720, p. IV-359). OSHA acknowledges that retrofitting to accommodate automating material handling in existing facilities may not be feasible in all cases.

Additional Comments Regarding Controls

General Shale expressed concern that adjacent worksites and non-asphalt roads can be very dusty and can contribute to exposures (Document ID 3586, Tr. 3465-68). Implementation of the controls listed above, such as enclosed cab for workers in vehicular equipment, misting and fogging systems and yard wetting practices which may need to extend to roadways, will control exposures. OSHA understands that workers may continue to be exposed to dust from outside sources, but expects that those sources will not contribute significantly to respirable silica dust exposures in the workplace. For rare instances such as dust storms in arid climates, workers may need to be placed in respiratory protection or if possible adjust the workload to avoid the storm. Please refer to the discussion in FEA Chapter X – Environmental Impacts.

Additional Controls for Grinding Operators

The data summarized in Table IV.4.21-B show that 29 percent of grinding operators' exposures are already at or below 50 μg/m^3. OSHA finds that additional controls are needed to reduce the exposures of the remaining 71 percent of grinding operators in the structural clay products industry. Those controls as discussed further below include well-enclosed and well-ventilated control rooms; enclosures, LEV, and water sprays on grinding equipment, conveyors and storage units; and regular cleaning of the grinding areas using HEPA vacuums.

Eliminating the Use of Compressed Air for Cleaning

As discussed in the PEA, using compressed air for cleaning is an ongoing source of silica exposure for grinder operators. No comments from the structural clay industry were received on the use of compressed air for cleaning. Accordingly, for reasons discussed below, OSHA has reaffirmed its conclusion that facilities eliminating the use of compressed air for cleaning can reduce the exposure levels of grinder operators in the structural clay industry.

NIOSH consistently cites the elimination of compressed air for cleaning when recommending methods to reduce silica exposures in this and other industries, such as the concrete products, refractory products, and foundry industries, which also use substantial quantities of sand and clay- and concrete-based materials (Document ID 0232, p. 10; 0236, pp. 6, 10; 0266, p. 13; 0898, p. 14; 1381, p. 10).

The use of compressed air was shown to have a significant impact on worker silica exposure levels in foundries (Document ID 1365, pp. 2-29 - 2-36, & *passim*). Due to the large number of results available for foundry cleaning/finishing operators, it was possible for the OSHA contractor ERG to examine exposures associated with the use of compressed air on exposure levels (Document ID 1365, pp. 2-69 - 2-70). ERG found that 26 results for cleaning/finishing operators working at five foundries where NIOSH or OSHA had observed the use of compressed air to blow sand and clay molding material (similar to the silica-containing mineral dust found in structural clay facilities) off metal castings or equipment were associated with exposure levels having a median of 487 μg/m^3 compared with a median of 72 μg/m^3 for all finisher/operators. Furthermore, all 26 results (100 percent) were 230 μg/m^3 and higher (Document ID 1365, p. 2-75). In light of the ERG and the NIOSH analyses and recommendations, OSHA concludes that the use of compressed air contributes to high exposures above the preceding and final PEL.

Acme Brick along with the concrete product industry commented that there are locations where vacuums and brooms cannot be utilized and that “the only alternative in these locations is compressed air to blow material out to where it can be collected” (Document ID 2023, p. 5). Acme acknowledges that this approach generates significant dust but that it occurs "on a very periodic basis,* * *. is necessary, and there is currently no engineering control available to address this situation" (Document ID 2023, p. 5). Although Acme Brick's comment appears to be primarily concerned with the cost of the vacuums, OSHA agrees that there may be places, for example, under certain pieces of equipment and in tight spots that cannot be easily accessed by vacuums. As reflected by Acme Brick's comment, however, these circumstances are "periodic" and not therefore usual. Work practices could be implemented during the period compressed air is required that would protect workers, including moving workers not involved with cleaning away from the area, and protecting the workers using compressed air with respirators. The area could then be vacuumed to collect any dust dispersed by blowing before normal activities resumed. Additionally, some of the locations where vacuuming is not possible may be appropriate for the limited use of wet methods to move the material where it can be swept up damp or vacuumed.

OSHA therefore has determined that vacuuming using appropriately filtered vacuums in all or almost all circumstances instead of the use of compressed air will substantially reduce exposures among grinding operators during cleanup activities.

Housekeeping

Another control is diligent housekeeping using HEPA-filtered vacuums and dust suppressants to prevent settled dust from accumulating in grinding areas and control rooms, reducing the likelihood of the dust being re-suspended. The use of HEPA-filtered vacuums and dust suppressants to clean in the grinding areas rather than dry sweeping and shoveling will also reduce the airborne re-suspension of silica-containing dust. A NIOSH report indicates that dry sweeping and shoveling of "fine material" in the grinding area is a notable exposure source that can be eliminated by using a vacuum cleaner equipped with an appropriate filter (Document ID 0239, p. 10; see also Document ID 0232, p. 10; 0236, pp. 6, 10; 0266, p. 13; 0898, p. 14; 1381, pp. 10, 12). Where the facility has allowed significant quantities of dust to accumulate, as previously described under additional controls for material handlers, a thorough initial cleaning can dramatically reduce exposures (Document ID 0571). At the facility described previously, the exposure level of most workers was reduced dramatically, in some cases by over 90 percent, to levels of 50 μg/m^3 or less (Document ID 0571).

While industry representatives agree that vacuum systems can reduce exposures to silica during cleaning activities, their use is not widespread. As one industry representative commented, "[d]espite the obvious value of vacuum systems, only 25 percent of responding companies * * * have implemented those as a control strategy. This limited reliance on vacuum systems is likely due to the fact that they typically collect from only individual discreet areas of an operation" and because "dust/debris is not limited to one or two locations in the plant, fixed location vacuum collection points are not realistic" (Document ID 2023, p. 4). However, some companies use mobile vacuum systems to address this concern. According to Acme Brick, "a few producers * * * have reported the implementation of HEPA semi-mobile central vacuum systems (Demarco or similar) that are used daily between and during shifts as needed" (Document ID 2023, p. 4).

Additionally, modified work practices for housekeeping can be beneficial for further reducing exposures. Acme Brick stated that they have modified their work practices (including housekeeping) so that they do not conduct cleanup activities while the plant is operating. "We know that silica takes a long time to settle, so we normally don't do any clean up or anything until way after the shift is completed" (Document ID 3577, Tr. 742-743). This practice allows the operator to remain in the control booth for the majority of the shift, reducing the likelihood of exposures from the operating equipment.

Operator Control Booth

Operator control booths (or rooms) can limit silica exposures to low levels (often below the LOD) during the time that the operator spends in the booth (Document ID 1365, pp. 3-23 – 3-24). Control booths are widely used for grinder operators in the structural clay industry; however, these booths are not necessarily maintained optimally to limit worker silica exposure levels. As explained below, to provide a low-exposure environment, a control booth must be well-sealed, supplied with clean air, under slight positive pressure to help keep dusty air out, and regularly cleaned to remove any dust that is tracked in.

At a structural clay facility visited twice by OSHA, an area sample collected inside a ventilated control room used by the grinder operator resulted in an average silica concentration of 116 μg/m^3 (Document ID 0161, p. 452). Before OSHA's next visit, the facility sealed gaps around the main entrance door to the control room, which reduced airborne silica levels inside the room to one-tenth the original level. A 6-hour area sample taken on the second visit showed an average respirable quartz concentration of 11 μg/m^3 inside the control room, suggesting that the room provided a substantial level of protection for any worker inside (Document ID 0161).

During the two visits, OSHA also collected personal samples for the grinder operator. The silica exposure level of the grinder operator was 362 μg/m^3 during OSHA's initial visit and fell to 101 μg/m^3 during OSHA's second visit, a 72 percent reduction.[144] Although the report does not indicate the relative amount of time the operator spent in the control room on the two sampling dates, the report attributes this reduction in the grinder operator exposure level to the improvements in the control booth (Document ID 0161, pp. 219, 1285).

Exhaust Ventilation

The use of effective exhaust ventilation systems for clay grinding machines is another option for reducing worker exposures. Although no information specific to the structural clay industry is available, OSHA identified two studies that evaluated exhaust ventilation systems for activities analogous to grinding operations, that is, rock crushing, which often involves a similar action to this type of grinding, and raw clay processing in mining activities, which is as dusty as structural clay. A LEV system installed at a rock crushing plant processing rock containing as much as 60 percent silica was associated with reductions of silica ranging from 20 to 79 percent (Document ID 1365, pp. 3-24 – 3-25). In another study by the U.S. Bureau of Mines, a total mill ventilation system for a clay processing facility that performed crushing and screening operations was associated with an average respirable dust reduction of 40 percent throughout the facility. OSHA expects

[144] On the first sampling date the grinder operator exposure is assumed to have been concurrent with the area sample in the control room. The second grinder operator sample is known to have been obtained concurrently with the second area sample collected in the control room (Document ID 0161).

that similar reductions (approximately 40 percent) in respirable dust levels in structural clay products facilities would result in reduced silica exposures for grinding operators (Document ID 1365, p. 3-25).

Commenters expressed skepticism about the feasibility of LEV. During the public hearing, a representative for General Shale stated, without explanation, that their raw material processing buildings where the grinding operators work “do not provide for the practical use of local exhaust ventilation” or “bag houses” in the raw material processing areas (Document ID 3586, Tr. 3379-3380). He acknowledged, however, that LEV was effective in the mill and final packaging areas (Document ID 3586, Tr. 3450). Other participants at the hearing discussed their use of ventilation in the grinding areas to reduce exposures. Brian Ogle of General Shale testified that “maybe a 50,000 cfm bag house might work in these buildings” but they had not yet looked into it (Document ID 3586, Tr. 3357, 3380). He also stated that “local exhaust ventilation is about what you're going to do” to reduce exposures (Document ID 3586, Tr. 3486-3487). These types of controls for grinding are not uncommon as Rami Katrib representing United Steelworkers (USW) quoted from employers “ … processes typically have point source exhaust systems to collect particulates containing the crystalline silica. In addition, we use work practices such as misting …” (Document ID 3584, Tr. 2537).

Others commented that dust control technologies, including bag house dust collectors, cartridge filter dust collectors, and even mobile units, are used to reduce dust in grinding areas (Document ID 3577, Tr. 743; 3586, Tr. 3450; 2363, p. 2).

Combination of Engineering Controls

In the PEA, OSHA opined that most facilities would need to implement a combination of properly implemented and maintained controls to reduce exposures to at or below the PEL of 50 μg/m^3 for grinding operators (Document ID 1720, p. IV-365). A NIOSH evaluation describes a combination of engineering controls that reduced worker exposure during grinding operations (Document ID 0232). At the facility evaluated, troughed conveyors reduced the spillage of raw materials as the materials were transferred to the grinding equipment; enclosed grinding machinery minimized dust release during the grinding process; a covered conveyor reduced dust release from ground materials as they were transferred to storage silos; and sealed bins prevented dust release from the storage units (Document ID 0232, pp. 4, 6-7). This facility also used raw materials with a higher water content (20 percent) (Document ID 0232, p. 4) than the facilities described in other NIOSH reports (9 percent to 13 percent) (Document ID 235, p. 4; 0239, p. 7). NIOSH obtained exposure readings of 67 $\mu g/m^3$ and 13 $\mu g/m^3$ for the grinding operator at this facility (Document ID 0232, pp. 5, 11-12). These values are substantially lower than the median of 98 $\mu g/m^3$ for this job category (see Table IV.4.21-B). Although the report does not indicate conditions that would explain the difference between these two readings, it recommends against the use of compressed air, suggesting that compressed air was used for cleaning and that its use contributed to worker silica exposures (Document ID 0232, pp. 8, 10). The information presented in this section regarding the use of compressed air. OSHA finds that both these levels would likely have been lower and less than 50 $\mu g/m^3$ if the workers had not used compressed air for cleaning.

Another control that can be implemented in combination with other controls is conveyor belt scraper, which removes material that sticks to the conveyor belts during material transfer. NIOSH observed the use of full-width belt scrapers at a facility where the feed belt conveyors carried screened clay through the production facility to the pug mill (Document ID 0239, p. 8). As discussed earlier, the use of the belt scrapers, in addition to water sprays, prevented clay from clinging to the belt and drying out, preventing it from being a source of silica exposure as the conveyor moved the raw materials (Document ID 3577, Tr. 742; 3586, Tr. 3449).

The use of a combination of controls to reduce exposures was supported by representatives from the brick industry during the public hearings. “No one solution is a fix,” stated one representative. “Basically we develop solutions through engineering, containment, suppression, collection, ventilation, best management practices, education, and training.” He added, “When you have an issue, depending on what it is, you might end up having to put an enclosure over this portion, a fogging system here, ventilation at this end, because you can't just do one thing because it's not going to fix the problem.

And, that is why our engineering department is part" of the team developing controls (Document ID 3577, Tr. 710-711, 745-746).

Although five to twenty percent of Acme Brick grinders experienced higher exposures during the period May 2003 to June 2007 at one of its plants, the industry representative commented that through the use of a combination of controls it was able to control the majority of its employees' exposures to at or below 50 μg/m^3 (Document ID 3577, Tr. 760-61; 3730, pp. 1-2).

In light of the studies and comments, OSHA has concluded that using a combination of controls, the structural clay industry will be able to limit exposure to most grinders at structural clay facilities to at or below the PEL most of the time.

Additional Controls for Forming Line Operators

The exposure profile in Table IV.4.21-B shows that 64.8 percent (35 out of 54 samples) of forming line operators have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for overexposed workers. While General Shale commented that exposures in its mill rooms where forming line operator work are typically below 100 μg/m^3 due to the use of local exhaust ventilation and the existence of moisture in the material (Document ID 3586, Tr. 3450), OSHA's exposure profile represents that exposures of Forming Line Operators substantially exceed the PEL. The final exposure profile, Table IV.4.21-B, reflects that only 35 percent of forming line operators currently experience exposure levels at or below 50 μg/m^3. As is the case for material handlers, the data for this job category are not equally distributed across all three subcategories; only 14 percent of pug mill operators, 20 percent of coatings blenders, and 0 percent of clay powder formers, experience exposures at or below 50 μg/m^3. The only forming line operators that consistently have exposures at or below 50 μg/m^{3}are the wet clay formers with 90 percent of their exposures below 50 μg/m^3.

Since only 35 percent of Forming Line Operators experience exposures at or below the PEL, additional controls are needed to reduce the exposures of the majority of the workers in this job category. Additional controls include enclosed and automated transfer of crystalline silica-containing materials, well-ventilated bag dumping stations, well-enclosed and well-ventilated milling and mixing equipment, and the use of a combination of supply and exhaust ventilation systems in the coatings application areas.

Similar to other job categories in this application group, the use of a combination of controls will be necessary to reduce exposures for forming line operators. Acme Brick reports using fogging systems,[145] suppression surfactant, ventilation, enclosures over the conveyors, belt scrapers and adjusting belt speeds to reduce exposures to at or below 50 μg/m^3 (Document ID 3577, Tr. 743,745-746). This testimony supports OSHA's conclusion that a combination of controls will be most effective.

Local Exhaust Ventilation

Ventilated, sealed, bag dumping stations can capture silica dust during coatings preparation activities performed by some forming line operators (coating preparers and formers). To be effective, the stations require properly ventilated enclosures, which capture dust released during both bag emptying and bag disposal. OSHA has not identified any structural clay products facilities using bag dumping stations that effectively controlled dust generated by bag emptying and disposal. Comparable respirable quartz exposure monitoring data exist, however, for workers using bag dumping stations to empty 50-pound bags of silica-containing materials at a paint manufacturing facility (Document ID 0199, pp. 12-13). The activities and bags dumped are similar to those existing at structural clay facilities. A bag dumping station with fully functioning LEV was found to reduce silica exposure by at least 95 percent (from 363 μg/m^3 to 12 μg/m^3) (Document ID 0199, pp. 7-8). The stations consisted of hoppers topped with grates enclosed by LEV hoods. After each bag was emptied, the worker released it, and suction automatically pulled the bag into the ventilation system and transferred it to an enclosed storage area. Bag dumping stations with other types of ventilated bag disposal equipment should be equally effective as long as they capture dust as the bags are compressed. Ventilated bag dumping and bag disposal stations are readily

[145] Fogging nozzles produce a very fine water mist (a droplet size distribution ranging from submicron to micron) (Document ID 1596,; 3472).

available from commercial sources (Document ID 1224; 0581; 0594; 1429; 0680 and 1212).

These types of controls have been successfully implemented as demonstrated by Acme Brick who reports that in extrusion areas they have enclosures and LEV (Document ID 3586, Tr. 3449).

Automated Coatings Transfer System

Automated material transfer equipment can also help reduce dust released as hoppers are filled (e.g., hoppers that hold sand coatings distributed onto bricks along forming lines). For example, at a facility inspected by OSHA, an 86-percent reduction in respirable quartz exposure readings occurred after management installed an enclosed, automated sand transfer system (Document ID 1365, p. 3-26; 0161). Initially, a reading of 501 $\mu g/m^3$ had been obtained for a forming line operator who manually cut open and emptied 120 50-pound bags of silica sand into a hopper at an unventilated sand charging station. After the inspection, the facility installed an automated system with enclosed conveyors to transfer sand to the hopper from a storage silo. During a subsequent inspection, a reading of 70 $\mu g/m^3$ was obtained for an operator who monitored the automated transfer system (Document ID 1365, p. 3-26; 0161).The inspection report observed that sand leaked from the conveyor leading to the hopper because the conveyor was not the correct size. OSHA expects that with tightly sealed, correctly-sized components, exposures could be reduced further using this type of equipment.

Housekeeping

Housekeeping can either minimize silica exposure (when settled dust is effectively removed) or contribute to worker exposure by causing spilled or previously settled dust to become airborne (Document ID 1365, 3-4, 3-15, 3-25; 0235, p. 9). And therefore it is essential that housekeeping is done in a manner that minimizes silica re-entrainment into the air. As discussed previously in regard to additional controls for material handlers in this industry, considerable exposure reduction was associated with thorough cleaning in areas where raw materials were handled (Document ID 1365, p. 3-20; 0571). A facility observed by NIOSH reported that a regular schedule of afterhours cleaning using a walk behind sweeper, brooms and a HEPA vacuum, has reduced the accumulation of product materials in the brick production facility (Document ID 0239, p. 8). OSHA finds that thorough cleaning and rigorous housekeeping offer the same benefit (exposure reductions of 90 percent, in many cases to less than 50 μg/m^3) in other plant areas that have accumulated dust. Much of the dust is of similar origin, so it can be expected to behave similarly. Once emissions from grinding and conveying equipment have been reduced, eliminating this source of exposure is as effective in the grinding area as in other material handling areas.

Combination of Engineering Controls

As mentioned previously, the use of a combination of controls to reduce exposures was supported by representatives from the brick industry during the public hearings (Document ID 3577, Tr. 710-711, 746).

Pug mill operators and formers on the forming line are exposed to silica dust released as dry materials fall into the hopper and mill. Mixers with doors that seal well and enclosed, ventilated mixer hoppers can limit this dust release. For example, the installation of a mixer equipped with a ventilated enclosure, and improved water feed system was associated with a 79 percent reduction in respirable quartz exposure readings for a tile manufacturing facility (Document ID 0161, pp. 1048,1052). This exposure reduction was achieved after an initial reading of 1,028 μg/m^3 (the highest among the data available to OSHA for this industry) was obtained for a forming line operator who monitored a mixer equipped with poor LEV and a partial enclosure (Document ID 0161). The enclosure had several openings, and its doors did not seal properly, allowing dust to escape back into the work area. Later, the facility installed another mixer with an improved enclosure and a water-feed system to wet the materials during mixing. A reading of 214 μg/m^3 was obtained for an operator who primarily monitored the second mixer (Document ID 0161, p. 1048). Although this level still exceeds allowable limits, it represents a notable decrease in worker exposure level. If the facility had made ventilation improvements to the original pug mill still operating in the area, improved ventilation of the mixer hopper to the levels recommended by ACGIH, for example, it is likely the exposure would have been reduced even further.

4.21.4 Feasibility Findings

Based on the exposure profile in Table IV.4.21-B and other record evidence discussed above, OSHA finds that the standard is technologically feasible for the different categories of structural clay workers and additional controls previously discussed are used. Several commenters expressed concern that compliance with the PEL may not be achievable and that it is “difficult, if not impossible, in some of the locations” (Document ID 3577, Tr. 706, 742; 2378, p. 4; 3731, p. 1; 2085, p. 3; 2004, p. 2). However, others acknowledge that the difficulty in reducing exposures is dependent on the type of clay and shale being used and how easily it breaks into respirable sized particles (Document ID 3577, Tr. 706; 3586, Tr. 3356; 2085, pp. 2, 3).

In its written comments, however, Acme Brick acknowledges that compliance with the PEL of 50 μg/m^3 is technologically feasible (Document ID 2023, p. 6). During the public hearings, Garth Tayler and Tom Brown with Acme Brick stated that the majority of workers in their facility currently are exposed to silica levels below 50 μg/m^3 and that they have received samples back with results below the LOD, which they reported as 0.28 μg. When exposures above 50 μg/m^3 occur, respiratory protection is worn until engineering controls which lower the exposure to levels at or below 50 μg/m^3 are implemented. To ensure that exposure are reduced, Acme Brick continues to incorporate controls until three samples below 50 μg/m^3 are achieved (Document ID 3577, Tr. 725-726, 755-757, 760-761). These comments show that, with the right combination of controls to control all sources of silica exposure, achieving the PEL is technologically feasible.

Feasibility Finding for Material Handlers

Based on Table IV.4.21-B, OSHA concludes that more than 70 percent of material handlers already experience exposure levels of 50 μg/m^3 or less. The same level of 50 μg/m^3 or less can be achieved for the remaining 29 percent of workers in this job category most of the time by using a variety of situation-specific controls. Based on the information presented earlier in this section, OSHA has determined that the controls necessary for this job category include covering, ventilating, and modifying conveyors;

augmenting ventilation at transfer points; using well-maintained environmental cabs (for loader operators); installing push-pull ventilation (for workers performing manual transfers); using water sprays where practical (storage yards, roads, in areas where workers handle kiln-fired finished product); and performing thorough cleaning as needed.

Although most exposure control methods for material handlers are universally beneficial for all workers in this job category, some of the controls discussed previously are more appropriate for certain material handler subcategories than others. The following paragraphs summarize the control methods suitable for workers in the material handler subcategories. OSHA has also determined that some facilities may need to use a combination of engineering controls to reduce exposures to the PEL. Based on the information on additional controls presented in this section, describing in detail the effectiveness of each control, OSHA concludes that the control methods listed below will reduce the exposures of most material handlers to levels of 50 μg/m^3 or less most of the time

Loader Operators Subcategory: The primary controls for loader operators are LEV and suitable enclosures at receiving hoppers, conveyors (including conveyors designed to limit spillage), and transfer points to reduce exposure during the monitoring of material. Other controls include rigorous housekeeping to reduce the re-suspension of settled material and well-sealed enclosed cabs with air conditioning and air filtration systems.

Production Line Handlers Subcategory: Exposure control methods for this subcategory of material handlers include using low-silica stone (e.g., limestone) in place of high-silica gravel on kiln floors (where it can be crushed). Workers can also handle formed clay products in a slightly damp, rather than fully dried state, which is less dusty. These workers will also experience a reduction in exposure when housekeeping is improved and the exposure levels of other workers in the immediate area are better controlled (e.g., forming line operators and the associated sand application processes).

Post-Production Line Handlers Subcategory: Most material handlers in the post-production line already experience exposure less than the PEL. For those workers who experience exposure above 50 μg/m^3, additional controls for this group of workers include wet methods (water spray on fired product and in the yard), improved housekeeping and automation.

Based on the information presented in this subsection, OSHA concludes that the control methods listed above will reduce the exposures of most material handlers to levels of 50 μg/m^3 or less most of the time.

Feasibility Finding for Grinding Operators

Based on Table IV.4.21-B, OSHA concludes that exposure levels of 50 μg/m^3 or less have already been achieved for 29 percent of grinding operators. The silica exposures of most of the remaining 71 percent of grinding operators can be controlled to the PEL most of the time by using a combination of controls, including well-enclosed grinding equipment, conveyor enclosures, dust suppressants or water spray on raw materials, covered or troughed conveyors, tightly sealed storage units, and thorough cleaning.

This conclusion is supported by the study of a facility that used a combination of troughed conveyors, enclosed grinding machinery, covered conveyors, sealed bins, and raw materials with higher water content to achieve exposures of 67 μg/m^3 and 13 μg/m^3 for a grinding operator (Document ID 0232). OSHA has determined that exposures persisting above 50 μg/m^3 are usually associated with poor housekeeping practices like the use of compressed air or with poorly sealed equipment that leaks dust.

Based on the information on the effectiveness of additional controls discussed in detail above, OSHA finds that the exposure levels of most grinding operators can be controlled to 50 μg/m^3 or below most of the time with a combination of controls. These controls include a thorough initial cleaning if necessary to reduce accumulated dust levels and implementing a routine cleaning schedule to keep levels low. The controls also include the use of the following: enclosed, well-ventilated control rooms; enclosed grinding equipment; dust suppressants or water spray on raw materials; enclosed or troughed conveyors; and tightly-sealed storage units.

Elevated exposures can still occur during discrete activities such as opening the grinder housing doors. In cases where a grinder must inspect the area inside the sealed doors enclosing the grinder, the operator must deactivate the grinder and let the LEV evacuate dusty air before opening the doors. If this is not possible, the operator must wear respiratory protection to inspect the grinder. If the ventilation system is running and the grinder is turned off (but not evacuated), a respirator that provides an applied protection factor (APF) of 10 (e.g., a half-face piece respirator) should offer adequate protection under the PEL of 50 μg/m^3 [146] (Document ID 1720, pp. IV-366-377).

Based on the exposure profile in Table IV.4.21-B and other record evidence discussed above, OSHA finds that the PEL of 50 μg/m^3 is technologically feasible for grinders in the structural clay industry.

Feasibility Finding for Forming Line Operators

Based on the data shown in Table IV.4.21-B, OSHA concludes that 35 percent of forming line operators already experience results of 50 μg/m^3 or less. Employers of the remaining 65 percent of forming line operators can achieve exposure levels at or below 50 μg/m^3 for most of these workers by a combination of control measures. These controls include thorough, regular housekeeping, starting with thorough initial cleaning if needed; well-ventilated and enclosed mills, mixers, hoppers, and conveyors; tightly-sealed storage units; enclosed, automated sand transfer systems or bag dumping stations with LEV; exhaust-supply ventilation at workstations; and the elimination of compressed air for cleaning. Wet-clay formers will also experience reduced silica exposure when the silica exposures associated with adjacent activities (e.g., pug mill operators and sand coating activities) are reduced. Based on the information presented on additional controls and their effectiveness, OSHA concludes that with few exceptions (as discussed below for pug mill operators) forming line operators' exposures can be reduced to 50 μg/m^3 or less most of the time with the use of the controls listed below. Accordingly, OSHA finds that the PEL of 50 μg/m^3 is technologically feasible for forming line operators in the structural clay industry.

[146] If the grinder remains running, a higher level of respiratory protection will likely be required (e.g., a full-face piece respirator with an APF of 50).

Although most exposure-control methods for forming line operators are effective for all workers in this job category, some of the controls discussed above are particularly appropriate for certain subcategories. The following paragraphs summarize the control methods suitable for workers in the individual forming line operators' subcategories.

Pug Mill Operators Subcategory: The primary controls for this group of workers include improved enclosures for clay finishing equipment (mills, spray driers, conveyors), LEV fitted to the equipment enclosures, and water-feed systems that help reduce dust by wetting the dry clay. In work areas where dust has accumulated, improved housekeeping also helps reduce silica exposure levels.

Coatings Blenders Subcategory: For this subcategory, which prepares coatings mixtures for structural clay products, the primary control is LEV at sand transfer and dumping stations (particularly in the form of bag dumping stations, bag disposal equipment, and LEV for mixing equipment).

Formers Subcategory: Workers in this subcategory tend equipment that shapes bricks and applies sand coatings for tint or texture. Where the sand hopper is at the production line, these workers will also benefit from LEV in the form of a ventilated bag dumping station or batch-receiving hopper and bag disposal units. Where sand-based coatings are delivered from the coatings blending area by conveyor, enclosed and ventilated conveyors will be required. In both cases, formers will require coating sand application zones with LEV that enclose the coating process and capture silica dust before it spreads through the work area.

As mentioned in the additional controls section (IV-4.21.3), exposure levels may not be consistently reduced for some forming line operators, such as operators of pug mills and related clay finishing equipment, if they cannot spend at least 33 percent of the shift in a well-sealed control room. In order to keep these workers' exposures at or below the PEL of 50 $\mu g/m^3$, based on the exposure levels that can be expected for most of the shift (67 $\mu g/m^3$ or less), the supplemental use of respirator protection may be necessary.

Overall Feasibility Finding

Based on the information described in this section, OSHA concludes that the exposures of all material handlers and all forming line operators, except operators of pug mills and related clay finishing equipment, can be controlled to levels of 50 μg/m^3 or less most of the time. Exposures of most grinder operators and most production line handlers working with pug mills and related equipment also can be controlled to levels of 50 μg/m^3 or less most of the time, but these workers will likely require respiratory protection for certain activities, such as equipment inspections. OSHA therefore finds that the final PEL of 50 μg/m^3 is technologically feasible for the Structural Clay Industry.

4.22 HYDRAULIC FRACTURING

4.22.1 Description

Hydraulic fracturing is a process used to extract natural gas and oil deposits from shale and other tight geologic formations. While hydraulic fracturing has been in existence for around 60 years, innovative technology has emerged in the last 10 to 15 years that has made hydraulic fracturing a viable option for the extraction of gas or oil (Document ID 3589, Tr. 4086-87). Workers in the oil and gas industry pump fracturing fluid, composed of a base fluid (usually water with chemical additives) and a proppant (usually sand with a high crystalline silica content) into the well bore under extremely high pressures (e.g., 7,000 psi to 9,000 psi) to hold the fractures in the shale formation open after the pressure is released (Document ID 1538, pp. 1-2). The high pressures fracture the shale or rock formation, allowing the gas and oil trapped in the formation to flow into the well. Use of this process has increased significantly in recent years due to new horizontal drilling and multistage hydraulic fracturing technologies that improve access to natural gas and oil deposits (Document ID 1720, p. A-3). At the same time, there is increasing awareness of the hazards of this process, particularly that of exposure to RCS, which first came to widespread attention in 2010 as a result of a NIOSH report, Field Effort to Assess Chemical Exposures in Gas and Oil Workers (Document ID 1541)

Once well drilling is complete, the delivery of proppant to the wellhead used for hydraulic fracturing occurs in steps. Initially, sand truck drivers deliver sand to the site and pneumatically pump it from trucks into sand movers that store sand. Once the sand is placed in the sand movers, workers regulate the flow of sand out of the sand mover onto a series of associated conveyor belts, which carry the sand to a hopper from which the sand is metered into a blender. At the end of the process, the sand, water, and chemical additives are mixed together in the blender before the sand-laden fracturing fluid is pumped through a high-pressure manifold into the well (Document ID 1720, p. A-4).

Silica sand used as a proppant contains a high percentage of crystalline silica, typically ranging from 60 to 100 percent depending on the source (Document ID 1525, p. 1; 1529, p. 1). When silica sand is used as a proppant in hydraulic fracturing, high airborne concentrations of respirable silica dust can occur as workers deliver, convey, and mix large volumes of sand with fracturing fluid (Document ID 1720, p. A-3).

Hydraulic fracturing crews frequently spend several days performing active hydraulic fracturing at a site where a well has several zones, with additional days for equipment setup and removal on the days before and after hydraulic fracturing. The time spent in this process can be longer when multiple wells are located at the same site (Document ID 1538, p. 2). Once the job is complete, the crew moves to another site, where the process is repeated. During hydraulic fracturing several dozen workers can be on the site, but most work occurs outside the central sand-handling zone, which is only occupied by fracturing sand workers. The number of fracturing sand workers typically ranges from a half-dozen to two dozen, depending on the size of the project and whether multiple hydraulic fracturing crews are involved. A crew of 10 to 12 workers is typical (Document ID 3828, p. 348).

For the purpose of characterizing exposures to respirable crystalline silica, OSHA has organized activities at hydraulic fracturing sites into three main job categories: fracturing sand workers; ancillary support workers; and remote/intermittent support workers. Table IV.4.22-A provides information on these job categories and their sources of exposure. Fracturing sand workers have the highest potential for exposure and include approximately half of the crew, while ancillary support and remote/intermittent workers spend limited time in the immediate area where sand is being handled and thus have lower exposure levels (Document ID 1541; 1542; 1543; 1544; 1545; 1546).

Based on workplace observations and air monitoring surveys at 11 hydraulic fracturing sites, NIOSH researchers identified seven primary points of dust emissions from hydraulic fracturing equipment or operations. These included the following locations or equipment:

- Dust emitted from “thief” hatches (open ports on the top of the sand movers used to allow access into the bin);
- Dust ejected and pulsed through side fill ports on the sand movers during refilling operations;

- Dust released from the transfer belt under the sand movers;
- Dust released from operations of transfer belts between the sand mover and the blender;
- Dust released from the top of the dragon’s tail (end of the sand transfer belt) on sand movers;
- Dust created as sand drops into, or is agitated in, the blender hopper and on transfer belts;
- Dust generated by on-site vehicle traffic, including sand trucks and crew trucks, by the release of air brakes on sand trucks, and by winds.

(Document ID 3828, p. 355). Table IV.4.22-A shows how these seven primary and two other secondary sources of exposure relate to the three job categories. Dr. Gerhard Knutson, a ventilation consultant who testified on behalf of the U.S. Chamber of Commerce (Chamber), agreed with OSHA’s identification of exposure sources (Document ID 2264, p. 7-8; 3576, pp. 449-450).

;Table IV.4.22-A
Job Categories, Major Activities, and Sources of Exposure of Workers in the Industry Providing Support Activities for Oil and Gas Operations (NAICS 213112)

Job Category*	**Major Activities and Sources of Exposure**
Fracturing Sand Workers in the Central Area (e.g., sand mover operator, conveyor belt tender, blender tender, water operator, pump truck operator)	Operate and tend equipment in the central sand-handling area on hydraulic fracturing sites • Dust ejected from the thief hatches on the top of the sand movers (source #1 above). • Dust ejected from the side fill ports on the sand movers (source #2 above). • Dust released from the conveyor belt under the sand movers (source #3 above). • Dust released from conveyor belt operation between sand mover and blender (source #4 above). • Sand released at the top of the end of the sand belt on the sand movers (source #5 above) • Dust created as sand drops into or is agitated in the blender hopper (source #6 above).
Ancillary Support Workers (e.g., chemical truck operator, hydration unit operator)	Operate or tend equipment that is at a fixed location on the perimeter or slightly removed from the central sand-handling area, such as chemical trucks and hydration units. • Dust disbursed from processes operated by fracturing sand workers in the central sand-handling area. • Sand and aggregate on the ground, crushed by heavy equipment and disturbed by passing vehicles (source #7 above). • Accumulated dust in vehicle and equipment cabs occupied by drivers and operators.
Remote/Intermittent Support Workers (e.g., roving operator, ground guide, sand coordinator, mechanic, QA technician, fueler, wire-line crew)	Active over a wide area of the site, primarily outside the central sand handling area, but may include brief, occasional excursions into the central sand-handling area. These workers may spend time at a primary base location (truck, trailer) away from sand-handling. • Dust disbursed from processes operated by fracturing sand workers in the central sand-handling area. • Sand and aggregate on the ground, crushed by heavy equipment and disturbed by traffic on the site (source #7 above). • Dust released inside trailer while QA/QC technicians sieve sand to check sand quality. Normally only QC technicians are exposed in these instances because they are the only workers in the trailer while this work is performed.

*Job categories are intended to represent job functions; actual job titles may differ and responsibilities may be allocated differently, depending on the facility.

4.22.2 Exposure Profile and Baseline Conditions

In the PEA, OSHA reviewed 83 8-hour time-weighted average (TWA) personal breathing zone (PBZ) respirable quartz results for workers at hydraulic fracturing sites. These samples were taken by NIOSH during a project conducted in collaboration with the oil and gas industry to investigate hazards at hydraulic fracturing sites. NIOSH conducted exposure monitoring at eleven hydraulic fracturing worksites in five states (seven sites in Colorado and individual sites in Arkansas, North Dakota, Pennsylvania, and Texas) as part of an industry-wide effort to identify and characterize exposures to vapors, gases, particulates and fumes among gas and oil field workers (Document ID 1541; 1542; 1543; 1544; 1545; 1546; 3828). The NIOSH report was one of the first comprehensive evaluations of respirable crystalline silica in hydraulic fracturing (Document ID 2177, Attachment B, p. 4).

In developing the final exposure profile, Table IV.4.22-B, OSHA added 31 recent exposure monitoring results obtained through OSHA's Information System (OIS) (Document ID 3958). These samples were taken during eleven compliance inspections conducted between 2011 and 2014 in Pennsylvania, Texas, Wisconsin and Colorado. These measurements were added to the exposure profile presented in the PEA, bringing the total number of exposure measurements to 114, from 22 different worksites.

The sampling data from the NIOSH site visits and the OIS database indicate that high exposures to respirable crystalline silica occurs at most hydraulic fracturing operations. The exposure profile in Table IV.4.22-B for respirable crystalline silica in the hydraulic fracturing (gas and oil extraction) industry includes 114 full-shift, PBZ samples. The median exposure is 111 μg/m^3, the mean is 272 μg/m^3, and the range is 6 (limit of detection (LOD))[147] to 2,570 μg/m^3. Of the 114 samples, 79 (69.3 percent) are above 50 μg/m^3, and 34 (29.8 percent) are above 250 μg/m^3.

[147] Results reported as "none detected" are assigned a value equal to the LOD. The LOD is determined individually for each sample based on the volume of air sampled and the method used to analyze the sample. Therefore, the limit of detection varies between samples. See Section IV-2–Methodology for additional information on LODs.

Respirable dust at these sites contained a relatively high percentage of silica. Among the 88 samples for which this information is available from all NIOSH site visits, more than half had greater than 41 percent silica in the sample with a range of 6 to 100 percent silica (Document ID 1541; 1542; 1543; 1544; 1545; 1546). Among the 34 OIS samples, the percent silica content averaged 33 percent with a range of 16 to 71 percent.

NIOSH site visits indicate that dust controls were either absent or that efforts to implement engineering controls were ineffective:

> NIOSH observed ineffective efforts to use engineering controls at some sites. Cotton (muslin) cloth sacks were attached to the ends of fill ports on sand movers, possibly to contain or capture dust ejected from the fill ports during bin filling. NIOSH determined the sacks to be ineffective; the bags were torn or degraded and visible dust was emitted during bin filling. Similarly, muslin bags atop thief hatch covers were not effective because dust was observed leaking from the bags during operation (Document ID 2177, Attachment B, p. 5).

Additionally, while some personal protective equipment (PPE) was being used at hydraulic fracturing locations, it was not always used properly:

> Workers at those sites used personal protective equipment (PPE) including filtering-face piece respirators, half-face elastomeric respirators, full face air-purifying respirators (APRs) with P-l00 cartridges, and combination acid gas/P-100 cartridges. However, NIOSH determined that PPE use was ineffective because most workers wearing respirators had visible facial hair that was in contact with the sealing surface of the respirator, did not understand how to properly wear or store the respirators, and did not participate in a formal respiratory protection program (Document ID 2177, Attachment B, p. 5).

The descriptions of working conditions from the NIOSH reports indicate that baseline operating conditions involve very high exposures with few engineering controls in place. From their field studies, Esswein et al. observed that dust controls for hydraulic fracturing operations are “only now emerging” given that the nature and severity of the hazard was just recently recognized by the industry (Document ID 3828, p. 355).

The American Petroleum Institute (API) asserted that OSHA's exposure profile does not adequately represent the wide range of conditions that can be encountered at hydraulic fracturing sites (Document ID 2301, pp. 3, 30-36). Similarly, the Marcellus Shale Coalition (MSC) commented (Document ID 2311, pp. 2-3) that the exposure profile provided in the PEA failed to reasonably characterize the hydraulic fracturing industry. Both API and MSC contended that other geological basins had as much or more widespread fracking than the ones sampled by NIOSH (Document ID 2310, p. 30; 2311, p. 3). However, they provided no explanation why geological basin would affect the exposure levels. API acknowledged that it does not have data to indicate that the topography differences of basins affect exposures (Document ID 3589, Tr. 4126). Additionally, Chamber of Commerce witness Dr. Knutson testified that he has seen industry exposure monitoring data from hydraulic fracturing sites other than the data in the record, and that he did not see a marked difference between this industry data and the data in OSHA's exposure profile (Document ID 3576, Tr. 500). Dr. Knutson testified that he was unable to submit this industry data to the record due to confidentiality agreements (Document ID 3576, Tr. 500).

The 114 samples of respirable crystalline silica in the final exposure profile (Table IV.4.22-B) were collected from 22 different worksites. NIOSH collected samples in diverse seasons and weather conditions, with temperatures ranging from 30º to 113º Fahrenheit (Document ID 3828, p. 350, Table 1). Elevations of the worksites ranged from 300 feet to over 5000 feet (Document ID 3828, p. 350).[148]

NIOSH visited single and multi-well site locations during single and multiple-stage well fracturing projects (Document ID 3828, p. 350). These sites included single stage "re-fracs" (rejuvenating old wells), multistage hydraulic fracturing, and "zipper-fracs" (multiple parallel wells) (Document ID 1578, p. 6).[149]

[148] The Site 5 report described "gusty wind" conditions on site, "between 5 and 7 mph" (Document ID 1545). Sites 1, 4, 5, and 6 were sampled during summer, Site 2 was sampled during winter, and Site 3 was sampled during spring (Document ID 1541; 1542; 1543; 1544; 1545; and 1546).

[149] Simultaneous or "zipper" hydraulic fracturing involves "two or more parallel wells [that] are drilled and then perforated in alternate intervals along the well bores and fractured at the perforations (Document ID 1528).

These varied environments represent a wide range of working conditions and, based on the available evidence, OSHA considers this range of exposures to be typical of the industry. Thus, OSHA has determined that the 114 samples in the exposure profile are the best available to characterize exposures in hydraulic fracturing. Most of the samples are from NIOSH reports. NIOSH stated that the sites sampled are typical of hydraulic fracturing sites across the industry (Document ID 3579, Tr. 226-28) and “included geographic, topographic, climatic, altitude, and environmental diversity” (Document ID 3828, p. 350).

API commented that OSHA improperly assumed that the NIOSH samples represented uncontrolled exposures, noting that wet methods were used on some sites due to rainfall, and enclosures were used at some sites (Document ID 2301, p. 41). OSHA does not consider natural rainfall to be an engineering control for the purpose of complying with the engineering controls provision of the standard. Additionally, NIOSH stated that rain was present only for short periods and it never interfered with sampling or completion of operations (Document ID 3828, p. 350). Regarding the use of enclosures, NIOSH stated that some fracturing sand workers operated machinery from closed and open cabs and these workers had elevated exposures even when these workers remained in cabs most of the day. Furthermore, NIOSH stated that blender trucks had enclosed cabs but none of these had High Efficiency Particulate Air (HEPA) filtration or positive pressurization (Document ID 3828, p. 354), making the cabs ineffective as silica controls.

API also criticized OSHA’s inclusion of samples from NIOSH site visit 6, which used ceramic proppant that contained less than 1 percent quartz. API argued that these samples are unrepresentative (Document ID 2301, pp. 30-31). An alternative proppant (e.g., ceramic media) is used occasionally at sites where conditions benefit from the proppant’s unique properties (e.g., strength, shape, size, uniformity) (Document ID 3828, pp. 348, 350). OSHA disagrees that including exposure results from this site is inappropriate. Eight of the 114 sample results (7 percent) came from NIOSH’s survey of this site; 93 percent of samples were collected at sites that used silica sand. According to API, silica sand accounts for 90 percent of the proppant used in the industry is silica sand

(Document ID 2301, p. 31). Therefore, OSHA does not believe that inclusion of the sample results from site 6 renders the exposure profile unrepresentative of the industry.

Halliburton commented that NIOSH did not measure exposures with accepted sampling devices, using a high-flow rate sampler that is "biased toward the collection of large, non-respirable dust particles," which would lead to exposures being overstated (Document ID 2302, p. 4). OSHA examined this issue, and in particular the BGI GK2.69 dust samplers used by NIOSH, and concludes, based on recent studies, that the sampler conformed to the international convention for particle-size selective samplers (i.e., ISO/CEN) with acceptable bias (see Section IV-3 – Feasibility of Measuring Respirable Crystalline Silica Exposures at the Final Rule's PEL and Action Level). Although this sampler is not listed among those included in NIOSH's Method 7500 for crystalline silica (Document ID 0901), NIOSH stated in its post-hearing submission that "the bias…against the ISO respirable convention…was not considered excessive" (Document ID 4233, p. 4). Therefore, OSHA concludes that the GK2.69 sampler has been adequately tested for performance against international convention, that NIOSH's use of the high-flow sampler for these field studies was appropriate, and therefore that the data generated by NIOSH should not be eliminated from the exposure profile.

API, through the National Service, Transmission, Exploration & Production Safety (STEPS) Network's Respirable Silica Focus Group, began collecting respirable silica exposure data associated with hydraulic fracturing in May 2013 (Document ID 3589, Tr. 4068-69, 4074-75; 4072, Attachments 32, 37). During the public hearings, OSHA requested additional data to reflect the industries assessment of current exposures in hydraulic fracturing, but no additional exposure monitoring data were submitted to the record (Document ID 3589, Tr. 4123-24).

Accordingly, OSHA is relying on the sampling data from NIOSH that was the basis of the preliminary exposure profile, supplemented by the more recent OIS data collected by OSHA and submitted to the record, for its final exposure profile. OSHA concludes that the exposure data available to determine baseline conditions represent a wide variety of locations and environmental conditions. OSHA considers this data to be the best available evidence to characterize exposures during hydraulic fracturing.

Exposure Profile and Baseline Conditions for Fracturing Sand Workers

Fracturing sand workers include sand mover operators, conveyor belt tenders, blender tenders, water operators, and pump truck operators (Document ID 3828, pp. 348-354). The exposure profile in Table IV.4.22-B for fracturing sand workers includes 70 samples; 51 of these samples are from the six NIOSH reports on hydraulic fracturing sites, and 19 exposure results are from the OSHA Information System (OIS) database (Document ID 1541, pp. 11-12; 1542, pp. 7-9; 1543, pp. 8-11; 1544, pp. 9-12; 1545, pp. 11-13; 1546, pp. 12-13; 3958). The median exposure is 159 μg/m^3, the mean is 373 μg/m^3, and the range is 10 μg/m^3 to 2,570 μg/m^3. Of the 70 samples, 58 (82.9 percent) exceed 50 μg/m^3, 48 (68.6 percent) exceed 100 μg/m^3, and 29 (41.4 percent) exceed 250 μg/m^3.

The worker with the highest full-shift sample result (2,570 μg/m^3) worked near sand movers while tending sand conveyor belts in hot, dry, breezy weather at a location where respirable dust samples contained 30 to 65 percent quartz (Document ID 1541, pp. 1, 4, 12). The next four highest exposures (2,000 μg/m^3, 1,950 μg/m^3, 1,100 μg/m^3, and 1,010 μg/m^3) occurred during sand moving operations (Document ID 1543, p. 8-9; 1545, p. 11). At these three sites where exposure levels exceeded 1,000 μg/m^3, the extremely high silica exposure levels were associated with worker positions immediately down-wind of points from which sand dust was released (e.g., thief hatches, conveyors, sand hoppers) (Document ID 1541, p. 5; 1543, p. 4; 1545, p. 2).

The baseline working conditions for fracturing sand workers presented in Table IV.4.22-B represent largely uncontrolled work processes using dry sands from various sources (Document ID 1541; 1542; 1543; 1544; 1545; 1546; 3958). The more recent exposure data from the OIS database provide no indication that exposure controls were used at the time these samples were collected (Document ID 3958).

Exposure Profile and Baseline Conditions for Ancillary Support Workers

Ancillary support workers operate or tend equipment, such as chemical trucks and hydration units that are at fixed locations on the perimeter or slightly removed from the central sand-handling area.[150] The exposure profile in Table IV.4.22-B for ancillary support workers includes 8 samples. Six of these samples are from the NIOSH site visits, and two are from the OIS database (Document ID 1542, p. 7 sample 2-05; 1543, pp. 8, 10, samples 3-10 and 3-21; 1544, pp. 9-10, 12, samples 4-08, 4-19, 4-26; 3958, Rows 180, 188). The median exposure is 64 μg/m^3, the mean is 195 μg/m^3, and the range is 9 μg/m^3 (LOD) to 820 μg/m^3. Of the 8 samples, 4 (50 percent) are above 50 μg/m^3, and 3 (37.5 percent) exceed 100 μg/m^3.

The highest exposure level for a worker in this job category (820 μg/m^3), obtained for a hydration worker, was more than three times the next highest level for a hydration worker (240 μg/m^3), obtained at the same worksite, but likely on a different day (Document ID 1543, pp. 8, 10). In contrast, hydration worker results were 9 μg/m^3, 26 μg/m^3, and 44 μg/m^3 at a second site where fracturing sand worker exposures reached 983 μg/m^3 (Document ID 1544, pp. 9-10, 12).

The elevated measurement suggests that the most highly exposed ancillary support worker spent more time in close contact with fracturing sand workers and their exposure sources than would normally be the case (Document ID 1543, pp. 8, 10). OSHA has concluded that unusual exposure patterns can result from workers temporarily assigned to another job duty (in this case fracturing sand worker), upset conditions, or from individual work practices, any of which could cause an ancillary support worker to spend more time than usual in the extremely dusty fracturing sand work area.[151]

Ancillary support workers typically work at fixed positions outside the central sand-handling area. Nonetheless, the primary sources of exposure for ancillary support

[150] Hydration workers employ hydration units to prepare fracking fluid.

[151] In its observations of a hydraulic fracturing site, NIOSH stated that these high exposures could be explained in part by weather conditions and equipment configurations and relative locations of workers (i.e., workers stationed in path of airborne dust) (Document ID 1543, p. 4). Additionally, NIOSH recommended limiting the number of workers, or time spent by these workers, in areas of high silica concentrations in order to reduce worker exposures (Document ID 1543, p. 6).

workers appear to be from proximity to the sand movers controlled by the fracturing sand workers (Document ID 1578, pp. 21-30). OSHA concludes that variable wind and weather conditions as reported in the NIOSH site visits (Document ID 3828, p. 350) carry airborne silica from the central work area where all of the largely uncontrolled primary sources of exposure are located. This migration of silica dust causes exposure for ancillary support workers, as demonstrated by Table IV.4.22-B (Document ID 1542, p. 4; 1543, p. 5; 1544, p. 4). Silica dust accumulated in the vehicle cabs and silica-containing sand on the ground disturbed by vehicle traffic can also contribute to ancillary support worker exposure (Document ID 1543, pp. 6-7; 1544, pp. 5-6; 3828, p. 354). The exposure profile represents ancillary support worker exposure on sites operating under poorly controlled conditions (Document ID 1542, p. 2; 1543, p. 2; 1544, p. 2).

Exposure Profile and Baseline Conditions for Remote/Intermittent Support Workers

Remote or intermittent support workers are active over a wide area of the site, primarily outside the central sand-handling area, but their work may include brief, occasional excursions into the central sand-handling area. Job descriptions include roving operator, ground guide, sand coordinator, mechanic, quality assurance (QA) technician, fueler, and wire-line crew.

The exposure profile in Table IV.4.22-B for remote/intermittent support workers includes 36 samples. Twenty-six of these samples are from six NIOSH reports (Document ID 1541, pp. 11-12; 1542, pp. 7-9; 1543, pp. 8-11; 1544, pp. 9-12; 1545, pp. 11-13; 1546, pp. 12-13), and an additional 10 samples are from the OIS database (Document ID 3958, Rows 191, 197, 877, 878, 879, 881, 901, 1080, 1081, 1082). The median exposure is 50 μg/m^3, the mean is 91 μg/m^3, and the range is 6 μg/m^3 (LOD) to 630 μg/m^3. Of the 36 samples, 17 (47.2 percent) are above 50 μg/m^3, and 8 (22.2 percent) exceed 100 μg/m^3.

The remote/intermittent support workers typically had substantially lower exposures compared to fracturing sand workers and ancillary support workers. Although these workers' exposures are intermittent, their duties take them near moving vehicles that disturb dust and into the central sand-handling area as they guide sand delivery trucks into positions near sand movers. The single sample for a QA technician was less than 25 μg/m^3, as was one of the three samples obtained for mechanics (the other two samples for mechanics were between 50 μg/m^3 and 100 μg/m^3) (Document ID 1543, pp. 8-9, 11; 1546, p. 12).[152]

This group of workers' exposure can occur due to emissions from the central sand-processing areas and also from aggregate crushed on the ground by passing heavy equipment (Document ID 3828, p. 354). Similar to the other job categories, remote/intermittent support workers mostly perform their activities without engineering controls.

Some remote/intermittent support workers, such as QA technicians who sieve sand as part of quality testing, handle silica-containing materials in a manner that could be a meaningful source of exposure if performed on a large scale. However, OSHA has no evidence suggesting that these workers experience significant exposure from the small-scale, short-term testing activities they perform at hydraulic fracturing sites.

[152] NIOSH did not document the QA technician's activities. However, it is reasonable to assume that sieving of small samples of sand was part of the worker's activities during sampling since it is one of the tasks involved with this job.

Table IV.4.22-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Workers in the Gas and Oil Extraction (Hydraulic Fracturing) Industry (NAICS 211111, 211112, 213111, 213112)

	Exposure Summary			**Exposure Range**			**Exposure Profile**				
Gas and Oil Extraction (Hydraulic Fracturing) Industry	**N**	**Mean (μg/m^3)**	**Median (μg/m^3)**	**Min (μg/m^3)**	**Max (μg/m^3)**		**< 25 (μg/m^3)**	**≥ 25 and ≤ 50 (μg/m^3)**	**> 50 and ≤ 100 (μg/m^3)**	**> 100 and ≤ 250 (μg/m^3)**	**> 250 (μg/m^3)**
Fracturing Sand Workers	70	373	159	10	2,570		6 (8.6%)	6 (8.6%)	10 (14.3%)	19 (27.1%)	29 (41.4%)

4.22.3 Additional Controls

The exposure profile in Table IV.4.22-B shows that 69 percent (79 out of 114 samples) of workers sampled in the hydraulic fracturing industry have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. The workers with the highest baseline exposure are fracturing sand workers: Eighty-three percent (58 out of 70) of fracturing sand workers are currently exposed to 8-hour TWA levels above 50 μg/m^3, while 48 percent (21 out of 44) of the ancillary support workers and remote/intermittent workers are currently exposed at levels above 50 μg/m^3.

To limit workers' exposure to silica, emissions need to be eliminated or reduced from each source of dust emissions identified by NIOSH and described in Table IV.4.22-A. Fracturing sand workers will benefit the most from such a control strategy, because they operate in closer proximity to sources that are producing elevated exposures, especially exposures from thief hatches, blender hoppers, and conveyor and transfer belts. Addressing these sources will benefit all of the workers present at a site (Document ID 1541; 1542; 1543; 1544; 1545; 1546).

OSHA has determined that effective control methods include local exhaust ventilation (LEV) systems, enclosure and partial enclosure of material transfer points and conveyors, enhanced material transfer systems, use of dust suppressants, and use of control booths, along with improved work practices and administrative controls. In some situations, substitution of silica sand with ceramic proppant may also be feasible. Kenny Jordan of the Association of Energy Service Companies (AESC) testified that the controls he has observed include baghouses, augur movement of the sand in closed-loop systems, misting systems, and clean-up systems (Document ID 3589, Tr. 4101-4103). An individual site or company may need to choose one or more of the potential controls to adequately control all potential sources of exposure.

Local Exhaust Ventilation (LEV)

In general terms, LEV is highly effective when designed to capture dust at the release point and with sufficient suction (pressure and volume) to overcome competing forces, such as turbulence, leakage, other sources of air flow, and dust particles in motion. Captured air released in the work area needs to be treated with an appropriate air-cleaning device to prevent respirable particles from recirculating back into workers' breathing zones (Document ID 3883). LEV with a tight-fitting or partial enclosure is a control option for all the major sources of dust released from sand-handling equipment in hydraulic fracturing work zones (Document ID 1530, p. 3; 1537, pp. 9-10; 1570, pp. 8-10; 4072, Attachment 36, p. 9). Dr. Knutson of Knutson Ventilation, testifying on behalf of the Chamber, stated that he is currently exploring controls for clients in the hydraulic fracturing industry, including "looking at local exhaust ventilation as a major tool" in controlling respirable silica (Document ID 3576, Tr. 545).

As discussed below, the record contains several examples of effective dust control in hydraulic fracturing through ventilation systems. The record shows that adoption of this technology is already well underway in the industry, in large part because it is needed to come into compliance with the preceding PEL. In many cases its adoption will also result in compliance with the new PEL, but even where it does not, relatively minor adjustments or add-on controls will be needed to achieve that compliance.

KSW Environmental LEV Systems

This control is a powered LEV system built for the purpose of controlling dust emissions from the transfer of fracturing sand (Document ID 1570, p. 5). Specifically, the ventilation system controls airborne dust generated on top of the sand mover (thief hatches), transfer points between sand mover and t-belt (conveyor belt between sand mover and hopper), and transfer from the t-belt to the hopper (Document ID 1570, pp. 8-10). This control is commercially available now, and the manufacturer specifies that its LEV systems have been used at hundreds of worksites since 2009 (Document ID 1570, p. 5).[153]

[153] In the PEA, this control was cited as "FracSandDC, 2012". In 2012, KSW Environmental acquired the exclusive license to the Frac Sand Dust Control, LLC systems and technology, along with the business and name. Dupre Energy Services is the parent company of KSW Environmental (Document ID 1570, p. 6).

KSW Environmental has performed PBZ sampling for fracturing sand workers to evaluate the effectiveness of its LEV systems (Document ID 1530, p. 11).[154] Samples were collected on two days for workers operating the blender/hopper, t-belt, and dust control (located on top of the sand movers) (Document ID 1570, p. 14).

Although the record does not include the individual exposure results, the manufacturer reported that none of the six samples exceeded 50 μg/m^3 as an 8-hour TWA (Document ID 1570, p. 22). The manufacturer also shows images comparing the difference in dust generation when the controls were reportedly turned off and then on (Document ID 1570, p. 7). The images clearly show that visible airborne dust has been greatly reduced when the LEV system was used. In a June 19, 2014 presentation to STEPS, KSW Environmental reported that its LEV system reduced silica exposures, with all 12 samples below 50 μg/m^3 (Document ID 4204, Attachment 1, p. 35, Fn. 21; 4222, Attachment 2, p. 6).[155]

The KSW Environmental presentation also reported that four additional customer tests resulting in 76 PBZ samples showed that all worker exposures to silica were below 100 μg/m^3; these results were only reported as "yes" or "no" responses, and no individual PBZ values were reported. KSW Environmental reported that there were an additional 50 PBZ samples taken. Although the individual sample results were not provided to KSW Environmental, the manufacturer reported that, as a result of these tests, customers began selecting KSW Environmental as the preferred vendor for dust control. KSW Environmental explained that its technology now operates all around the United States including Pennsylvania, West Virginia, Ohio, Colorado, Wyoming, Oklahoma, and Texas. KSW Environmental stated that its goal is to reduce exposures to 25 μg/m^3 or less by enhancing the existing system, training customers and improving work practices, and

[154] These samples were collected using NIOSH method 7500 (Document ID 1570, p. 20).

[155] In their post-hearing briefs, both AFL-CIO and API referenced and provided the hyperlink to KSW Environmental's June 19, 2014 presentation to the Silica Focus Group: http://www.nationalstepsnetwork.org/docs_respirable_silica/june_19_2014/KSWE-STEPS-Meeting-6-19-14-REV-A.pdf (Document ID 4204, Attachment 1, p. 35, Fn. 21; 4222, Attachment 2, p. 6). OSHA therefore considers this publically-available presentation part of the record.

developing supplemental controls (Document ID 4204, p. 35, Fn. 21, pp. 3-4 of slide presentation).

The exhaust ventilation system manufactured by KSW Environmental is capable of achieving 45,000 cfm, with temporary or permanent shrouding at the blender/hopper (Document ID 4204, p. 35, Fn. 21; 4222, Attachment 2, p. 6, n. 21). KSW Environmental also addressed some work practices that may reduce exposures. Some of these included fixing damaged truck hoses (material transfer) and avoiding leaning over or standing in the hopper, leaning over the conveyor belt, leaning into hatches to view sand levels, and overfilling sand movers (Document ID 4204, p. 35, Fn. 21, pp. 11-15 of slide presentation).

OSHA received comments from industry questioning the effectiveness of the KSW Environmental ventilation system. API commented that there is limited air monitoring data demonstrating the effectiveness of the KSW Environmental system (Document ID 2301, p. 49; 4222, Attachment 2, pp. 6-7). API noted that at the June 19, 2014, STEPS Respirable Silica Focus Group meeting, KSW Environmental reported that 12 samples of respirable crystalline silica were below 25 $\mu g/m^3$, but that no information was provided regarding job category, sampling conditions, duration, sampling methods, or type of proppant used (Document ID 4222, Attachment 2, p. 7).

OSHA concludes that there is adequate information on the exposure samples taken by KSW Environmental to judge the results as credible. In a submission to the record, KSW Environmental reported that samples were collected for workers located near blender/hopper, t-belt, and thief hatches (referred to as “dust control operator,” “blender operator,” and “crow’s nest or T-belt operator”) (Document ID 1570, p. 14), which are among the major sources of dust emissions. KSW Environmental reported that sampling was conducted on two consecutive days with temperatures ranging from 37 to 74 degrees Fahrenheit, humidity ranging from 40 to 93 percent, and with variable wind directions and speed (Document ID 1570, p. 13). KSW Environmental also reported that these samples were collected using NIOSH method 7500 (Document ID 1570, p. 20). The samples were collected at a site in West Virginia located along a ridge extending into a valley, at an elevation of 1,180 feet (Document ID 1570, p. 11).

API commented that members that have used the KSW Environmental ventilation system have reported significant durability and workability concerns (Document ID 4222, Attachment 2, pp. 7-8). API listed three main concerns: the plastic sheeting is susceptible to damage and often must be removed purposely to view or access the emission points; the vacuum hoses that connect the emission points to the ventilation system must cross high traffic areas and areas accessed by sand delivery trucks, leading to hose damage that can adversely impact the efficacy of the control; and the presence of vacuum hoses and connections on top of the sand mover has resulted in more workers operating the equipment's ground level controls more frequently in a semi-enclosed environment, and this exposure has not been characterized (Document ID 4222, pp. 6-7).

API did not explain why the presence of vacuum hoses would cause workers to alter their work practices so that the workers have to operate controls for the sand movers on ground level (presumably as opposed to controls on top of the sand movers). API also did not explain why, when all sources of exposure are properly controlled, workers are overexposed at ground level more than when located on top of sand movers.

In contrast, KSW Environmental presented detailed photographs and illustrations of the ventilation system setup at a fracturing site in West Virginia (Document ID 1570, pp. 8-10, 15-19). OSHA's review of these photos and illustrations reveals none of the concerns expressed by API (Document ID 1570, pp. 8-10, 15-19). OSHA concludes that ventilation hoses can be attached to thief hatch openings such that they do not prevent workers from operating on top of the sand mover (Document ID 1570, pp. 8-10, 15-19). Additionally, OSHA believes that hoses can be placed such that they are not damaged by (nor do they interfere with) vehicular traffic (Document ID 1570, pp. 8-10, 15-19). API's concern about plastic sheeting can also be addressed by purchasing thicker or reinforced plastic that is more appropriate for the hydraulic fracturing environment. As this industry is a very technologically advanced sector, OSHA is confident that material design for partial enclosures and placement of vacuum hoses will improve and overcome these practical concerns.

API also questioned the availability of the KSW Environmental system. While noting that the system “has shown tremendous growth in the two years since it first presented it[s] services to [the] STEPS Respirable Silica Focus Group,” API stated that the system cannot currently service all of the hydraulic fracturing industry (Document ID 4222, Attachment 2, p. 8).

OSHA understands API’s comment regarding this particular manufacturer’s ability to service the hydraulic fracturing industry at this time to be a suggestion that the industry will need additional time to adopt this new technology. The Agency believes that, given time, the availability of this and other dust control systems will grow and present viable options for hydraulic fracturing companies. Consequently, the final rule provides an additional three years (five years total) for hydraulic fracturing operations to comply with the final rule’s PEL using engineering and work practice controls. As discussed elsewhere in this chapter, OSHA recognizes that most of this time will be needed for the industry to come into substantial compliance with the preceding PEL of 100 μg/m^3. However, once exposures are reduced to 100 μg/m^3, relatively minor additional steps will be needed to bring them to 50 μg/m^3 or below (e.g., Document ID 1570, p. 22).

After reviewing all of the information provided by the manufacturer and the industry and worker stakeholders and considering all of the arguments, OSHA has determined that this control, or a similar ventilation system, can substantially reduce exposures to respirable crystalline silica generated at thief hatches, hoppers, and t-belts. This conclusion is based on KSW Environmental PBZ sampling tests, which reported all 12 samples below 50 μg/m^3, and four customer reports of 76 samples below the previous PEL of 100 μg/m^3 (Document ID 1570, p. 14, 22; 4204, p. 35, Fn. 21; 4222, p. 7).

J&J Truck Bodies and Trailers Ventilation System

Another ventilation control documented in the record is a central dust collection manifold built into movers with filtration that controls dust from t-belt conveyors, trailer manways, and blenders (Document ID 4072, Attachment 36, p. 9; 1530, p. 3; 1537, p. 9). This system is similar to the KSW Environmental system described above and draws air from the sand mover to control dust released while sand trucks pneumatically fill the sand mover (Document ID 1530, pp. 3-5; 1537, p. 9). The manufacturer, J&J, specified that the system features a 45,000 cfm vacuum and filter system, dust collection manifold, and all necessary accessories (Document ID 1537, p. 9; 4072, Attachment 36, p. 9).

The manufacturer reports that 2011 test results on two prototypes suggest substantial reductions in airborne dust (Document ID 1530, p. 5). In these tests, the manufacturer reports that there was significantly less airborne dust during the loading of proppant onto the sand mover when the dust control system was used. This dust control system was used at 10 different hydraulic fracturing sites with reportedly good results (Document ID 1530, p. 5). No exposure data was submitted as part of this exhibit. Commercially available versions of these systems are described in the record (Document ID 4072, Attachment 36).

The manufacturer specifies that the cost of sand movers with integrated dust controls is comparable to other sanders available on the market. Additionally, the manufacturer specifies that the sand movers have the same functional capabilities with or without the control systems (Document ID 4072, Attachment 36, p. 10).

OSHA was not able to obtain additional information regarding exposure levels associated with this control. However, both commercially available systems (J&J and KSW Environmental) control generated airborne dust at the sand mover, t-belts, and hoppers using a 45,000 cfm ventilation capacity. These two systems control the same emission sources and have the same capacity and thus, OSHA expects the J&J system to be equally as effective as the KSW Environmental system in controlling dust from these sources.

DCS Quad Dust Collector

National Oilwell Varco (NOV) has developed a commercially available powered LEV system that can be installed as an add-on retrofit option for sand movers. The unit uses power from the sand mover and operates at a speed of 3,200 cfm (Document ID 1532; 1537, pp. 9-10). This system controls only the source(s) associated with the sand mover while the KSW and J&J Truck body systems uses 45,000 cfm to address other sources of exposure along the sand moving line to the blender hopper. NOV reports that the dust collection system minimizes dust during pneumatic filling of sand movers (Document ID 1537, pp. 9-10). No exposure data is available in the record regarding the effectiveness of this design, so OSHA cannot determine whether it would reduce exposure levels to at or below the PEL.

NIOSH Baghouse Technology

NIOSH has designed and tested a baghouse passive dust collection system that fits over individual thief hatches on sand movers and deposits collected sand back into the sand mover (Document ID 1537, p. 5; 1538, p. 2; 1546, p. 10).[156] NIOSH recommends that "baghouse material should be selected to control respirable particulates in the size range of 3-5 microns" (Document ID 1546, p. 10). NIOSH designed the bag-house to be self-cleaning, as the captured dust falls back onto the sand container as the bag-house collapses when positive air pressure is stopped after bins are full.

NIOSH reports that the design appears to be an effective point source control and will likely be commercially available in the future pending a patent (Document ID 1537, p. 5; 1538, p. 3).[157] NIOSH stated that the design has been evaluated for proof of concept and has also been evaluated in a field test with an industry partner (Document ID 3998, Attachment 1, pp. 3-4). NIOSH stated in its post-hearing submission to the record that it has made a presentation to the STEPS group regarding the development of the bag-house (Document ID 4233, p. 13).

[156] Baghouse dust collectors capture the particulate in an airstream by forcing the airflow through filter bags. A baghouse works by taking the inlet dustladendust-laden air and initially reducing the velocity to drop out larger particles, then filtering the remainder of the particles by passing the air through a fabric bag. Separation occurs by the particles colliding and attaching to the filter fabric and subsequently building upon themselves, creating a dust cake. Since the dust has been deposited on the outside of the bag, when the dust cake is removed from the bag or cleaned, it falls by gravity into the collection hopper located below the bag section. Collected dust is then removed from the collector through a hopper valve (Document ID 1540, p. 31). NIOSH has described the design considerations for baghouse dust collectors used in mining operations, a field that has dynamic working conditions and highly variable dust sources (much like hydraulic fracturing sites) (Document ID 1540, p. 31).

[157] NIOSH did not provide additional information regarding the exact timeline for commercial availability of this design (Document ID 3998, Attachment 1, p. 4)

API commended NIOSH for its research and development related to the baghouse technology, but questioned the availability and effectiveness of the NIOSH mini-baghouse (Document ID 4222, Attachment 2, p. 5). API commented that the NIOSH mini-baghouse does not support OSHA's conclusions of the technological feasibility of controlling access hatch emissions with LEV, pointing to an April 24, 2014, notice of license availability indicating that the NIOSH baghouse system remains a prototype that has not yet been fully tested and is not commercially available (Document ID 4222, Attachment 2, p. 5). Similarly, the Chamber and Dr. Knutson noted that there is no information on the effectiveness of the NIOSH baghouse technology or the time it will take to implement (Document ID 2264, pp. 29-30; 4224, Attachment 1, p. 10).

OSHA recognizes that this baghouse design is not yet commercially available and that the record does not include PBZ exposure data associated with this control. However, NIOSH has completed the essential steps of the design stage by considering the size distribution of particles (i.e., particles in the respirable dust range) captured by the baghouse and by performing proof-of-concept evaluations (Document ID 1537, p. 5; 1546, p. 10). Also, as NIOSH pointed out, the design should capture particles in the respirable range, ensuring effective control (Document ID 1546, p. 10). OSHA expects this design to capture these smallest particles in the respirable range, and believes that exposures from thief hatches can be almost completely eliminated with a properly-functioning, dust capturing device. Moreover, baghouse dust collection devices, such as the one designed by NIOSH for hydraulic fracturing, are already used in the mining industry to successfully control the high levels of silica dust generated due to dynamic working conditions (Document ID 1540, p. 31). These baghouses typically are able to contain almost all of the fugitive mine dust, including respirable dust, achieving air cleaning efficiencies of up to 99.97 percent (Document ID 1540, p. 31). Given these encouraging developments, OSHA expects that NIOSH and the hydraulic fracturing industry will continue working together to further develop and test this technology.

Dr. Knutson raised several issues associated with the NIOSH baghouse designed to collect fugitive dust from thief hatches (Document ID 2264, pp. 29-30). He argued that the baghouse had no cleaning mechanism to dislodge the dust from the contaminated side of the filter (i.e., the filter cake), and as a result the baghouse would need to be large. However, NIOSH designed the baghouse to be self-cleaning (Document ID 1537, p. 5; 1546, p. 10). Dr. Knutson argued that if new filter media is used, the efficiency of the baghouses would be low and exposures will be “similar to the current situation” until the media is “seasoned” (Document ID 2264, p. 30). OSHA recognizes that the bag filters become more efficient as dust is collected to form a cake on the inside of the bag, but this does not mean that new filter media will be ineffective given that the filter media selected is designed to capture particles in the low end of the respirable range. OSHA believes that, as NIOSH continues its testing, both new and seasoned media will be used, which will permit an assessment of the impact, if any, of using new filter media. Dr. Knutson also argued that covering thief hatches with the baghouses would increase pressure inside the sand movers and therefore increase emissions of silica dust through all other openings or cracks in the sand mover (Document ID 2264, p. 30). OSHA does not dispute that increased pressure within the sand mover could increase dust emissions through other openings, but concludes that such emissions can be addressed through work practices (e.g., ensuring that unused ports are capped and that equipment is diligently maintained).

Dr. Knutson further suggested that additional silica exposures would occur as a result of installing and removing the baghouses from the thief hatches (Document ID 2264, p. 30). In its design, NIOSH describes that the baghouses include a transition flange that is fitted over the thief hatch opening, and this flange then connects the hatch opening to the baghouse (Document ID 1537, p. 5). OSHA understands that this transition flange can serve to reduce or eliminate emissions when the baghouse is disconnected from the thief hatch as the flange would seal the bag opening once it is disconnected. Changing baghouse filters in any application is a maintenance task that typically requires the use of respiratory protection. Accordingly, OSHA disagrees that an additional hazard will be created by installing or removing the baghouse.

Finally, Dr. Knutson stated that the media on the sample ports must be removed to obtain the samples (Document ID 2264, p. 30). OSHA expects that work practices allow workers to take sand samples at times other than during the pneumatic or mechanical filling of sand movers since to do otherwise would clearly result in a high-exposure event.

Based on the information presented here (i.e., collection of silica particles in the respirable range, initial field tests, and success of design in other industries), OSHA concludes that the bag-house technology, or a similar dust collection device, will foreseeably prove effective in reducing exposures of workers to RCS resulting from dust emissions from thief hatches. The Agency acknowledges that further testing is necessary to evaluate the impact on worker exposures from this technology and believes that providing additional time to phase in the final rule's engineering requirement, as discussed further below, is appropriate to allow the technology to be further developed.

Material Transfer Systems

The record contains information on a containment system developed by SandBox Logistics, LLC that replaces the pneumatic loading process with a containerized process, eliminating most of the dust emission points that currently exist (Document ID 3589, Tr. 4140-4141; 3554).

The SandBox process begins when sand is loaded into the sandbox storage unit at the sand mine. The storage unit has dimensions of eight feet by ten feet and weighs approximately 53,250 pounds when filled with fracturing sand (Document ID 3589, Tr. 4141). From this point, the sand is kept totally contained throughout the rest of the supply chain. The storage unit is put on a chassis designed specifically for it and then transferred to the worksite. At the worksite, the storage unit is put on a conveying system (also known as a cradle) where the sand is gravity fed onto a conveyor belt, which feeds the sand directly into the blender hopper (Documents ID 3554, pp. 9-11).

According to the manufacturer (SandBox Logistics), most of the silica dust producing steps in the process have been eliminated (Document ID 3589, Tr. 4140-4142). The company states that the delivery system eliminates the need for sand movers and pneumatic deliveries, which are the primary sources of dust emissions (Document ID 3554, pp. 14-15). Because of this, exposures from fill ports and transfer belts under the sand mover would be eliminated (Document ID 3554, p. 15). The company states that the belt design on the cradle generates fewer airborne particles, reducing exposures from the top end of the transfer (or t-) belt and material transfer that would occur between the sand mover and blender hopper (Document ID 3554, p. 15). The company also states that the SandBox process reduces silica dust, avoids demurrage charges for idled rail and truck, and reduces proppant degradation (Document ID 3554, p. 17).

SandBox Logistics submitted a summary of an initial industrial hygiene study that collected PBZ and area samples during the delivery of proppant to the well-head using the company's delivery system (Document ID 4020). The study collected PBZ samples for transfer-belt workers (number not specified) and found a geometric mean exposure of 87 μg/m^3 (Documents ID 4020, Attachment 1, p. 4), compared to 327 μg/m^3 for conveyor belt operators (transfer-belt operators) as reported by Esswein (Document ID 3828, p. 351) from the NIOSH surveys of fracking operations. This represents a 73-percent reduction in geometric mean exposure when compared to NIOSH's data, and the company reported a 65-percent reduction in the number of samples that exceeded 100 μg/m^3 (Document ID 4020, Attachment 1, p. 4).

API and the Chamber argued that exposures under the Sandbox Logistics technology remained above 50 μg/m^3, which is the final PEL (Document ID 4222, Attachment 2, pp. 8-9; 4224, pp. 9-10), and API argued that the exposures of the t-belt operators at the sandbox facility were 327 μg/m^3 (Document ID 4222, Attachment 2, p. 9). However, OSHA believes API misread the reported data: SandBox Logistics' submission stated that the exposure of 327 μg/m^3 represented baseline, uncontrolled conditions as reported by Esswein et al. (2013) (Document ID 4020, Attachment 1, p. 4, Fn). As stated above, the controlled exposure using the SandBox system was a mean exposure of 87 μg/m^3 (Documents ID 4020, Attachment 1, p. 4).

Although the sampling data from SandBox Logistics showed a geometric mean exposure above 50 μg/m^3, the data still demonstrate a significant decrease in exposures for t-belt workers operating the system. Additionally, SandBox Logistics reported that its engineers expect exposures can be further reduced with just a few minor modifications (Document ID 4020). Moreover, this method reduces the number of exposure sources by eliminating the need for sand movers, which should make it an important, effective, and viable part of an overall exposure control strategy.

Enclosures

Process enclosure can reduce emissions of dust from the major sources of emissions under positive pressure (e.g., fill ports and unused thief hatches on sand movers) and areas of turbulence (e.g., conveyors and sand drop points from the ends of conveyors) (Document ID 1541, pp. 5-6). There are several types of enclosures that can effectively reduce exposures on hydraulic fracturing sites.

Caps on Fill Ports

NIOSH reported based on its field studies that the fill ports on the sides of the sand movers can be a primary source of silica exposure for all fracturing sand workers in the area during the periods when the sand movers are refilled by the sand delivery truck drivers (Document ID 1541, pp. 5-6). Sand delivery trucks connect pneumatic sand transport hoses to the ports to add sand to the sand movers. The ports are designed for filling the sand mover and not as relief valves for dusty air (that is generated during pneumatic sand transport from the delivery truck) to escape the sand mover. When left uncapped during filling, dusty air vents out through any unused fill ports (particularly those on the opposite side of the sand mover) (Document ID 1541, p. 5).

One component of silica risk management at hydraulic fracturing sites involves preventing silica release from those fill ports that are not in use. During its field surveys, NIOSH found that ports on the sides of sand movers were often left open (Document ID 1538, p. 3). Fill ports are not intended for pressure relief and should be closed with manufacturer-provided or replacement end caps, as recommended by NIOSH in its field studies (Document ID 1541, p. 6; 1543, pp. 6-7; 1544, p. 7-8; 1546, p. 11). OSHA expects that tight closure with a cap will prevent silica emissions from this source because little or no dusty air would exit through these ports, and would thus greatly reduce emissions from fill ports. In a post-hearing submission by API, the STEPS network identified capping unused fill ports as one of several “quick fix” suggestions to reduce silica exposures among hydraulic fracturing workers. Fugitive emissions from fill ports contribute to higher exposures to workers at the site, especially fracturing sand workers who are the closest to the sand movers (Document ID 3828, p. 355). Thus, OSHA expects that controlling emissions from this source will contribute to reducing exposure of fracturing sand workers and others who are affected by the fugitive dust released from uncapped fill ports.

Partial Enclosures on Conveyors and Transfer Points

Exposure reduction can be achieved by partially enclosing conveyors, particularly conveyor drop points. For the mining industry, NIOSH advocates reducing drop points (Document ID 1540, p. 144), and for hydraulic fracturing sites, NIOSH recommended shrouding or skirting along the sides of the sand mover and at the end of the sand belt to limit dust released as material falls from the belt (Document ID 1541, p. 6; 1542, p. 5; 1543, p. 5; 1544, p. 6; 1545, p. 9; 1546, p. 10). The STEPS network also recommended as a “quick fix” minimizing sand fall distances during transfer operations as a way to reduce respirable crystalline silica emissions (Document ID 4024, Attachment 2). Noting NIOSH’s recommendation, Dr. Knutson acknowledged that shrouding and skirting could be beneficial (Document ID 2264, p. 26). Additionally, as presented in the discussion for LEV, one company (KSW Environmental) already provides LEV with temporary or permanent shrouding at the hopper (a transfer point) (Document ID 4204, p. 35, Fn. 21). According to ACGIH, ventilated conveyors require extra ventilation when the fall distance is three feet or greater (Document ID 3883, pp. 13-80, 13-83).

Dr. Knutson commented that there are several difficulties in using enclosures in hydraulic fracturing operations. He argued that (1) sand equipment is mobile and there are weight and size restrictions on the equipment, (2) sand transfer operations require visual inspection to ensure that sand is being conveyed correctly, (3) enclosures restrict access for maintenance, and (4) enclosures complicate spill cleaning, which could increase exposures (Document ID 2264, pp. 25-26). As pointed out by API (Document ID 2301, p. 52), Eric Esswein of NIOSH agreed that conveyors cannot be completely closed (Document ID 1538, p. 3). However, he also reported that companies would consider enclosing the conveyor under the sand movers and that walls along the sides of the conveyor could be made deeper to effectively enclose the conveyor (Document ID 1538,

p. 3). The NIOSH field study reports also suggested that the conveyor under the sand mover be replaced with a screw auger to contain dust (Document ID 1543, p. 6; 1544, p. 7; 1545, p. 9; 1546, p. 10).

OSHA finds that using partial enclosures with LEV on conveyor, transfer, and drop points would reduce exposures to all workers, especially fracturing sand workers, who operate in proximity to these sources.

Operator Booths

Providing climate-controlled booths for fracturing sand workers is another practical option for protecting workers who must work in particularly harsh environments. Some of the most highly exposed workers will benefit from operator enclosures (clean air booths) placed at or near the sand mover and conveyor belt operator work stations where workers can observe operations while breathing filtered air.

NIOSH analyzed the elements of effective control booths and cabs, reporting that the level of dust protection depends on the adequacy of the following factors: enclosure integrity (well-sealed); filtration (sufficiently efficient to keep out respirable particles); pressurization (positive pressure inside to keep dusty outside air from leaking in); work practices to keep doors and windows closed; climate control (so doors and windows can be kept closed); housekeeping in the enclosure (remove any dust that gets inside); and maintenance (including changing outside air filters as necessary) (Document ID 1540, pp. 196, 225, 231, 235).

A table summarizing NIOSH studies on personnel enclosures (cabs) associated with mining equipment (routinely used with massive quantities of dusty, silica-containing mineral materials) shows that cabs can reduce respirable dust exposures from 50 to 99.9 percent; efficiencies less than 90 percent were attributed to insufficient pressurization of the cab (Document ID 1540, p. 227).

API commented that the evidence on which OSHA relied to claim in the PEA that control booths can be 90-percent effective in reducing exposures is deficient because the evidence was taken from other industries with less dusty operations and does not account for the opening and closing of control booths nor the dust brought into the booth by the worker's "grossly contaminated" clothes (Document ID 2301, p. 59). Specifically, OSHA pointed to the NIOSH mining handbook, which describes the use and effectiveness of control booths in a variety of mining dust concentrations and conditions, and an inspection at a structural clay facility where a booth was used (Document ID 1720, p. A-41). OSHA disagrees that its evidence base was inappropriate in the manner described by API because OSHA's evaluation of the potential effectiveness of filtered booths at fracking sites did not assume that there would be no other controls or that conditions on the site would continue to be extremely dusty. In fact, OSHA stated in the PEA that its estimate of effectiveness for filtered booths assumed that side ports would be closed and LEV applied to thief hatches (Document ID 1720, p. A-40), thus reducing silica concentrations outside the booth and increasing its effectiveness.

Dr. Knutson was also critical of OSHA's calculation of the effect on exposures of using filtered booths, citing what he believed to be a faulty premise that workers are exposed to a constant concentration of silica over a shift, when in fact their exposures fluctuate depending on what tasks are being performed. He argued by way of example that if one accounts for task-specific changes in exposure throughout the shift, the actual reduction in exposure achieved is less than estimated by OSHA (Document ID 2264, pp. 30-31). OSHA did not make its estimate based on a premise that exposure is constant over the shift, but instead relied on full-shift TWA exposure measurements. Detailed task-specific exposure data was not available in the record. Use of TWA data did not affect how OSHA views the effectiveness of filtered booths in reducing exposure, nor its preliminary feasibility findings. In the hypothetical example given by Dr. Knutson, he assumed that the silica concentration in areas away from the booth was higher than in the vicinity of the booth, while OSHA's approach, based on 8-hour TWA exposure data, would assume concentrations are equal in different areas., Dr. Knutson's approach yielded an exposure estimate for a worker using a booth for part of a shift that was 23 percent higher (62 $\mu g/m^3$ vs. 47.8 $\mu g/m^3$) than would be the case assuming constant exposure throughout the shift, a difference that OSHA believes would not have materially changed its preliminary feasibility findings.

API contends that workers cannot spend an entire shift in a control booth (Document ID 2301, p. 58), and OSHA agrees that some work outside the booth may be needed. However, the amount of time outside the control booth can be minimized by integrating control panels into to the booth that would reduce the need to exit the control booth to monitor equipment performance. API's members believe that workers who may benefit from control booths would be required to spend much of their shift outside the booth, although API did not provide a rationale for this statement other than the workers' responsibility to monitor and control equipment. While control booths may be able to integrate control panels for equipment, such that workers can monitor and operate equipment from inside the booth, API has said that placing controls inside enclosed booths would be difficult and costly (Document ID 2301, p. 58). OSHA does not believe that it is infeasible to do so, however, as such control booths already exist in other high-silica industries such as mining (Document ID 1540, p. 225).

API further questioned the feasibility of these operator control booths, stating that its member companies report that dust control booths cannot feasibly be added to retrofit hydraulic fracturing equipment, particularly sand movers and conveyor belts (Document ID 2301, p. 60). Additionally, API contended that adding control booths could push many sand mover transporters over weight thresholds established by equipment transportation suppliers (thus increasing the cost of moving the equipment from one site to another) , and therefore, the booths must be capable of being removed, shipped separately, and reinstalled between each hydraulic fracturing site (Document ID 2301, p. 60).

API did not submit any specific evidence or explanation showing why booths cannot be added to retrofit hydraulic fracturing equipment or that portable control booths are not a feasible option to reduce exposures to dust. Regarding weight limitations, OSHA notes that bulldozers, cranes, and other very large heavy equipment fitted with enclosed cabs are frequently moved. If earthmoving and mining equipment with enclosed cabs can be transported over the road, then so can sand movers.

OSHA has determined that there are several types of operator enclosures that could be used to reduce exposures on hydraulic fracturing worksites. Environmental cabs on trucks and heavy equipment represent one form of mobile control booth. Portable control booths positioned on pallets or a truck bed are also an option. Worker enclosures, including operator control booths and heavy equipment cabs, are used successfully in operations in other industries that deal with large quantities of silica-containing materials. These include the Mining Industry (Document ID 1540, pp. 225-238), Concrete Products Industry (Section IV-4.3), Foundries (Section IV-4.8), Structural Clay Industry (Section IV-4.21), and Rock-Crushing Machines Operators and Tenders (Section IV-5.10). OSHA notes that the STEPS network also recommended using enclosed cabs or booths as a "quick fix" to reduce silica exposures (Document ID 4024, Attachment 2).

OSHA concludes that similar operator booths can be practical and effective controls for the hydraulic fracturing industry. Recognizing that the exposure-reduction potential of an operator enclosure or booth is related to both the efficiency of the booth in excluding dust and the amount of time the worker spends in the booth, OSHA expects that these booths will significantly reduce exposures to the more highly exposed fracturing sand workers controlling material transfer and delivery (e.g., sand mover operator, conveyor belt tender, blender tender).

<u>*Dust Suppressants*</u>

In this section, OSHA reviews the capabilities of dust suppressants to reduce exposures from dust created due to transfer of the proppant and from dust re-suspended in the air from general traffic at the worksite.

Dust Suppressants for Proppants

The record contains information about treating proppants with liquid dust suppressants to reduce respirable crystalline silica levels. The American Refining Group (ARG), a company specializing in refining, reported to the STEPS Respirable Silica Focus Group about a laboratory study that demonstrated the advantages of using a liquid dust suppressant in hydraulic fracturing operations (Document ID 4072, Attachment 35, pp. 9-10). API explained that the dust suppressant tested was a hydrofinished waxy oil that consists primarily of saturated hydrocarbons that works by binding smaller particles that may otherwise be released during moving, loading, dumping, and agitating the proppant

(Document ID 4222, Attachment 2, pp. 5-6). ARG stated that the EPA approved this material as an inert ingredient for pesticide use, and according to API HPV Testing Group data, the dust suppressant presents no acute or chronic toxic effects to humans (Document ID 4072, Attachment 35, p. 5). ARG concluded that the dust suppressants:

- offer a 99.8-percent reduction in respirable silica;
- reduce exposures during material transfer;
- add lubricity to treated sand thereby reducing friction and shearing; and
- reduce the need for larger exhaust rates on ventilation systems.

ARG also stated that it was looking for partners to perform field trials by measuring short and long-term performance (Document ID 4072, p. 11).

API commented that while the laboratory study indicated that the dust suppressant may be effective in reducing exposures, field tests have not yet been conducted (Document ID 4222, Attachment 2, pp. 5-6). Additionally, API expressed concern that adding this dust suppressant to the mixture may compromise the integrity of the operation, stating that directly wetting or chemically amending proppant material prior to introduction to the blender can cause serious binding issues and cause a fracture to fail (Document ID 4222, Attachment 2, pp. 5-6). API contended that without evidence that the suppressant will not impact fracture performance, it cannot be considered a feasible control (Document ID 4222, Attachment 2, pp. 5-6).

OSHA recognizes that this particular agent is still in development and must be field tested to evaluate its effectiveness on reducing worker exposures and its effect, if any, on proppant performance. Nevertheless, it appears to be a promising technology that could serve to reduce silica-containing dust emissions.

Another approach to suppressing dust is use of water misting, which has been suggested by NIOSH to be effective if misting nozzles are placed in the proper location and fine-spray, atomizing nozzles are used (Document ID 1546, p. 10). As a general principle, atomized water sprays will not exceed a 0.1-percent moisture application rate, though over large areas the application rate may be as high as 1.5 percent (Document ID 1540, p.

61). Mr. Esswein commented that one company working with NIOSH “had some success” with misters that knocked dust out of the air without wetting the sand (Document ID 1538, p. 3). Kenny Jordan of AESC testified that misting systems are among the dust controls currently in use (Document ID 3589, Tr. 4102).

In a road milling study, investigators Van Rooij and Klaasse reported results of using aerosolized water without additives to control dust (see Section IV-5.8 – Millers Using Portable or Mobile Machines for more details). The system consists of 24 spray nozzles (located at the picks drum, collection conveyor, and loading conveyor), which spray aerosolized water onto the milled asphalt material (Document ID 1217, p. 4). Aerosolized water alone provided a substantial benefit, reducing the mean exposure for drivers and tenders combined by 86 percent compared with baseline operations (Document ID 1217, pp. 8-10).

Dr. Knutson commented that there are sand agglomeration and equipment clogging issues with wetting the process material, such as when introducing water in sand movers and conveyor belts (Document ID 2264, pp. 23-24). Similarly, API commented that “OSHA, ERG, and NIOSH, all recognized that directly wetting or chemically amending proppant material prior to introduction to the blender can cause serious binding issues and cause a fracture to fail” (Document ID 2301, p. 56).

The goal of a water misting system is to limit the dispersal of respirable dust after it has been released, in contrast to other water-based dust control systems that apply water to source material to prevent generation of airborne respirable dust. In the PEA, OSHA cited NIOSH experience in the mining industry to distinguish using water to prevent dust from becoming liberated by directly spraying the material from using it to limit the dispersion of dust by spraying the dust cloud, causing particles to fall from the air (Document ID 1720, p. A-36). In his testimony, Dr. Knutson also made this distinction (Document ID 3576, Tr. 458). As cited above, one employer has had some success with using misting systems to limit the dispersion of airborne dust without wetting the sand (Document ID 1538, p. 3), and Mr. Jordan testified that misting systems are used at some facilities (Document ID 3589, Tr. 4102). Therefore, OSHA finds that misting systems designed to remove airborne dust have utility to reduce dust emissions without unduly wetting the source material.

Based on the evidence in the record, OSHA expects that dust suppressants such as the one developed by ARG or NIOSH's misting recommendation have the potential to reduce exposures from conveyors and transfer points. Although more research must be done to evaluate the efficacy of dust suppressants like ARG’s, water misting technology has been used at some sites and, with proper design, can be used to prevent dispersion of released dust without excessive wetting of the proppant.

Dust Suppressants for General Work Areas

Wet dust suppression methods have proven effective for controlling silica dust in general work areas in which exposures result from re-suspended dust (Document ID 0516; 1539; 1540; 4073, Attachment 8e). Spraying water or amended water (including additives to extend the functional benefit of the water spray), is widely used to control dust in outdoor storage yards in general industry and in demolition and excavation operations in construction (Document ID 0239; 0516; see Section IV-5.3 – Heavy Equipment Operators and Ground Crew Laborers). NIOSH has recommended that water trucks be used on hydraulic fracturing sites to control dust in general work areas (Document ID 1543, p. 6; 1544, p. 7; 1545, p. 10; 1546, p. 11).

NIOSH described several test results of watering haul roads with control efficiency ranging from 40 percent to 95 percent. The control efficiency for water can be highly variable as it is dependent upon frequency of water application, road material type, traffic, and weather conditions (Document ID 1540, p. 252). In a report on the characteristics of fugitive dust generated from unpaved mine haulage roads (Organiscak and Reed), the authors found that “road wetting was very effective in suppressing the respirable dust generated by the haulage trucks” (Document ID 4073, Attachment 8e, p. 15). The most common method of haul road dust control is surface wetting with plain water, but water amended by adding hygroscopic salts, surfactants, soil cements, bitumens, and films (polymers) to the road surface is also widely used (Document ID 1539, p. 69). Road material used for unpaved mine haulage roads are similar to other unpaved haulage roads and areas where there is vehicular traffic. Dr. Knutson stated that applying wet methods to roads and production areas has proven effective. Although he identified some difficulties associated with its use (mud creating slip and fall hazards, freezing problems, and potential runoff issues), he nevertheless stated that "wetting roads is feasible and will do some good" (Document ID 2264, p. 23). Dust controls such as wet methods can therefore be applied similarly to minimize exposures to haulage road fugitive dust.

In addition, there are additives that can enhance the effectiveness of water for dust suppression. A study by Addo and Sanders offers additional support for the application of dust suppressants to work areas and storage yards (Document ID 0516). The study examined three chemical dust suppressants (lignosulfate, calcium chloride, and magnesium chloride) applied to an unpaved roadway for four and a half months and found that, compared to an untreated roadway, the suppressants reduced fugitive dust emissions by 50 to 70 percent (Document ID 0516, p. 106).

Work Practices and Administrative Controls

Based on available evidence of worksite conditions, OSHA finds that work practices can help reduce exposures. Such work practices and administrative controls, which provide workers with standard operating procedures that help control or avoid sources of dust exposure, include covering fill ports during sand mover filling and hydraulic fracturing processes, requiring workers to stand back from dust emission points as much as possible, minimizing hot-loading unless adequate controls are in place to protect workers,[158] and limiting personnel in the areas where greatest exposure tends to occur.

Paragraph (e) of the final rule requires that employers establish regulated areas where employee exposures are or can reasonably be foreseen as exceeding the PEL. Such areas must be demarcated, and entry is allowed only to authorized persons whose work duties require them to be in the restricted area. The purpose of this requirement is to prevent

[158] This term refers to the act of filling a sand mover, which is also operating to release fracturing sand to the blender hopper (Document ID 3828, p. 354). OSHA recognizes that the practice of hot-loading reduces otherwise unproductive time spent refilling the sand mover.

unnecessary exposure of workers. OSHA expects that restricting areas to authorized personnel will reduce exposures of workers at hydraulic fracturing sites by limiting the number of personnel in the vicinity of the sand moving operation. The STEPS network also recommended as a "quick fix" that access to potential exposure zones by non-essential workers be limited (Document ID 4024, Attachment 2).

Another work practice control option involves adjusting equipment to minimize the height from which fracturing sand falls from conveyor belts during transfers to other conveyors or to the blender hopper. Reducing the drop distance minimizes the influence of competing air currents and reduces the amount of dust that becomes airborne as fracturing sand transfers between conveyors or from conveyor to blender hopper. ACGIH recommends that drop distances for general conveyor belts be less than 3 feet (Document ID 3883, p. 13-83). For the mining industry, NIOSH recommends that fall heights for materials be minimized whenever possible to reduce dust emissions at conveyor transfer points (Document ID 1540, p. 144). OSHA concludes that this principle applies to hydraulic fracturing operations as well.

Substitution

Substitution of proppant material is another option for reducing silica exposures at hydraulic fracturing sites. Hydraulic fracturing requires a granular media proppant—typically sand. To function as a proppant, the sand must stand up to considerable pressure in the well, and the physical properties of quartz make this type of sand particularly useful. However, alternate media are available and used for this purpose under certain circumstances (Document ID 1538, p. 3).[159] NIOSH observed a hydraulic fracturing crew using ceramic sand containing less than 1 percent silica (Document ID 1546, pp. 7-8).[160] OSHA concludes that substituting such a proppant for silica sand would reduce silica

[159] An example is the use of a ceramic proppant (Black Cat) that has higher compressibility than sand. It is used at sites where there is very high formation pressure, and this alternative proppant allows for successful fracture of the underground geological formations such that gas can be extracted (Document ID 1538, p. 3).

[160] NIOSH reported that the proppant's material safety data sheet listed less than 1 percent quartz in the product. NIOSH analysis confirmed that the percentage was slightly lower than 1 percent (Document ID 1546).

exposure levels substantially (depending on the amount of silica in the alternative proppant) compared to using pure silica sand, but the Agency recognizes that use of low-silica-containing substitutes is a solution for specific circumstances and that future development may be necessary to increase the availability of substitute materials and broaden their application.

Low-silica alternate media can also be used in combination with (high-quartz) natural sand media. NIOSH obtained PBZ samples at a hydraulic fracturing site that used a mixture of natural sand and ceramic proppant (58 percent of the total proppant used that day was the low-silica ceramic proppant, while the remaining 42 percent was silica sand) (Document ID 1546, pp. 7-8). PBZ samples confirmed that the silica content of the samples was lower (3 to 25 percent silica) than at sites using only high-silica sands (typically between 50 and 100 percent silica) (Document ID 1546, p. 4). Although reducing the silica content of the proppant does reduce the silica in the airborne dust, worker exposures can still be significant; at this NIOSH site, nine of the 11 PBZ samples exceeded 50 $\mu g/m^3$, although none exceeded 100 $\mu g/m^3$ (Document ID 1546, p. 4).

OSHA acknowledges that these substitute materials are more costly than natural sands (Document ID 1712, p. 6-16). Due to their cost, alternate proppants tend to be reserved for special circumstances (particularly high-pressure wells) where the special characteristics (increased durability, uniformity, or roundness) are needed to help extend well life (Document ID 1538, p. 3).

Combination of Controls

Based on the best available evidence, OSHA concludes that the most effective control strategy is one that addresses all of the sources of exposure simultaneously. Such a strategy would ensure that all workers benefit from reductions in exposure. Table IV.4.22-C shows the primary and secondary exposure sources for each job category. This classification, presented in the PEA, is based on NIOSH information from six site visits (Document ID 1541; 1542; 1543; 1544; 1545; 1546; 1720, p. A-21).

Table IV.4.22-C Sources of Worker Exposure to RCS			
Source	**Hydraulic Fracturing Worker (Central Zone)**	**Ancillary Support Workers (Nearby)**	**Remote/Intermittent Support Workers**
Thief hatches –sand mover top	**	*	*
Conveyor belt under sand movers	**	*	*
Blender hopper	**	*	*
Conveyor belt operation	**	*	*
Transfer point from sand belts on sand movers	**	*	*
Sand Fill Ports	**	*	*
Sand sieve (QC laboratory only)	NA	NA	**
Dust in vehicle cabs	NA	**	*
Dust raised by traffic	*	**	*
Number of Primary Sources	6	2	1
** = Exposure is directly associated with the workers' activities and equipment. * = Exposure is primarily as bystander; silica dust originates with other workers' activities. Sources: Document ID 1541, 1542, 1543, 1544, 1545, and 1546.			

Sources of dust emissions are located in close proximity to each other and to the workers potentially exposed, and therefore the relative contribution of each source can only be assessed qualitatively. Esswein et al. reported significant visible emissions observations from each of the major sources identified in Table IV.4.22-C, and the most highly exposed workers were those closest to the sand moving operation (Document ID 3828, p. 354). They also reported that PBZ exposures can exceed 100 μg/m^3 even when workers are not in close proximity to the primary sources of dust generation (Document ID 3828, p. 354). Accordingly, meeting the final rule's PEL requires that all sources of dust be addressed.

According to Esswein et al., "controls to limit silica-containing dust generation during hydraulic fracturing are only now emerging due to the relatively recent understanding of the hazard and magnitude of the risk" (Document ID 3828, p. 355). Local exhaust ventilation (LEV) is the primary dust control strategy that has been and continues to be developed to reduce silica exposures of hydraulic fracturing workers. As discussed above, among the more promising are LEV systems that contain and collect airborne dust along the sand moving line. These include points at the thief hatches, conveyor under the sand mover and to the blender hopper, transfer points from sand belts on sand movers, and at the blender hopper. Two of these systems, from KSW Environmental Document ID 1570; 4204, Attachment 1, p. 35, Fn. 21) and J&J Bodies (Document ID 1530; 4072, Attachment 36) are designed to control each of these sources by venting thief hatches and partially enclosing and venting the conveyor and hopper. Summary data provided by KSW Environmental show promising results, reporting that all 12 exposure measurements were below 50 μ/m^3 and that four customer surveys reported 76 PBZ samples all below 100 μg/m^3. These exposure results represent a significant improvement in comparison to the 42 percent of fracturing sand workers currently exposed above 250 μg/m^3 (Table IV.4.22-B). Exposure data for the J&J system were not available, although prototypes have been tested at 10 fracturing jobs with “excellent results” reported (Document ID 1530, p. 5).

Two other systems provide dust capture on the sand mover. National Oilwell Varco (NOV) developed a dust collection system for retrofit on the sand mover that collects dust during the filling operation (Document ID 1532; 1537, p. 9). NIOSH has designed a baghouse to collect dust from thief hatches that will use filter material designed to collect respirable particulate. Both of these systems are self-cleaning and the NOV system is available now. The baghouse designed by NIOSH continues to undergo testing and will likely be commercially available in the future (Document ID 1538, pp. 2-3). OSHA notes that bag houses are commonly used to control crystalline silica and other dusts in many industry sectors and are not a novel approach. Although it is expected that the baghouse will capture nearly all of the dust emitted from thief hatches, no data are yet available that describe the impact of using the device on workers’ exposures. Even with the LEV systems described above, dust can be released from unused sand fill ports when the sand mover is being filled. These emissions can be prevented very simply by ensuring that unused ports are capped (Document ID 1541, p. 6; 3828, p. 355).

Another previously discussed system designed to address dust release from the sand mover is that from Sandbox Logistics, LLC. This system replaces the pneumatic loading process with a containerized process, eliminating most of the dust emission points that currently exist from the sand mover (Document ID 3554; 3589, Tr. 4140-4143). Because of this, exposures from fill ports and transfer belts under the sand mover would be eliminated (Document ID 3554, p. 15). SandBox Logistics submitted a summary of an initial industrial hygiene study that collected PBZ and area samples during the delivery of proppant to the well-head using the company's delivery system and found a geometric mean exposure of 87 μg/m^3 for t-belt operators (Documents ID 4020, Attachment 1, p. 4).

For those LEV systems that address dust emissions from the sand mover alone, partial enclosure and ventilation of conveyors and blender hoppers will still be needed to control those dust sources. Use of water misting systems can provide additional dust control and has been suggested by NIOSH to be effective if misting nozzles are placed in the proper location and fine-spray, atomizing nozzles are used (Document ID 1538, p. 3; 1546, p. 10). Water misting has been used at some hydraulic fracturing sites (Document ID 1538, p. 3; 3589, Tr. 4102). While exposure data describing the effectiveness of such systems at hydraulic fracturing sites are not available, an aerosolized water system used on road milling equipment reduced the mean exposure for drivers and tenders combined by 86 percent compared with baseline operations (Document ID 1217, pp. 8-10).

Traffic on hydraulic fracturing worksites is a primary source of exposure for ancillary/remote workers and a secondary source for fracturing sand workers (see Table IV.4.22-C). Evidence in the record demonstrates the capability of dust suppressants to reduce silica exposures due to re-suspension of dust from traffic (Document ID 0516, p. 106; 1539; 1540; 4073, Attachment 8e). This evidence shows that exposures at or below the PEL of 50 μg/m^3 have been achieved and that reductions in dust emissions range from 40 to 95 percent (Document ID 0516; 1540). Using the low end of the range, OSHA estimates that a 50-percent reduction in dust emissions from road dust raised by vehicle traffic is achievable.

Once all of the sources of exposure have been controlled by the methods described above, sealed and ventilated control booths would offer additional protection for fracturing sand workers that operate machinery in the sand moving area. As previously stated in this Additional Controls section, control booths can reduce exposure concentrations by up to 99 percent. OSHA expects a 90-percent efficiency to be achievable, as demonstrated by Cecala et al. (Document ID 1563, p. 1). Assuming that operators can spend about half their time in the booth, exposures can be reduced by almost half.

Further reductions in exposure can be achieved by using work practices such as reducing drop heights at transfer points and at the hopper, and establishing regulated areas where exposures may exceed the PEL (as is required by the final rule).

4.22.4 Feasibility Finding

Based on the exposure profile in Table IV.4.22-B and other information in the record, OSHA has determined that some engineering controls are already commercially available for the hydraulic fracturing industry, and other controls that have demonstrated promise are currently being developed. OSHA recognizes, however, that engineering controls have not been widely implemented at hydraulic fracturing sites, and no individual PBZ results associated with controls have been submitted to the record.

The available information indicates that controls for dust emissions occurring from the sand mover, conveyor, and blender hopper have been effective in reducing exposures. KSW Environmental reported that a commercially-available control technology reduced exposures in one test with all 12 samples below the NIOSH recommended exposure limit (REL) of 50 μg/m^3 (Document ID 4204, p. 35, Fn. 21). KSW Environmental also stated that four additional customer tests resulted in 76 PBZ samples, all below 100 μg/m^3 (Document ID 4204, p. 35, Fn. 21). Another manufacturer of a similar ventilation system (J&J Bodies) reported that there was significantly less airborne dust during the loading of proppant onto the sand mover when its dust control system was used. This dust control system was used at 10 different hydraulic fracturing sites with reportedly good results (Document ID 1530, p. 5).

These findings indicate that, with good control of the major dust emission sources at the sand mover and along the conveyor to the blender hopper, exposures can be reduced to at least 100 μg/m^3. Use of other dust controls, including controlling road dust (reducing dust emissions by 40 to 95 percent), applying water misting systems to knock down dust released from partially-enclosed conveyors and blender hoppers (reducing dust emissions by more than half), providing filtered booths for sand operators (reducing exposure to respirable dust by about half), reducing drop height at transfer points and hoppers, and establishing regulated areas, will further reduce exposures to 50 μg/m^3 or below. Additional opportunities for exposure reduction include use of substitute proppant, where appropriate, and development and testing of dust suppression agents for proppant, such as that developed by ARG (Document ID 4072, Attachment 35, pp. 9-10). OSHA anticipates that once employers come into compliance with the preceding PEL, the additional controls to be used in conjunction with those methodologies to achieve compliance with the PEL of 50 μg/m^3 will be more conventional and readily available.

Therefore, OSHA finds that the PEL of 50 μg/m^3 can be achieved for most operations in the hydraulic fracturing industry most of the time. As shown in Table IV.4.22-B, this level has already been achieved for almost one-third of all sampled workers (and nearly 1 in 5 sand fracturing workers, the highest exposed job category). OSHA expects that the growing availability of the controls needed to achieve the preceding PEL, along with further development of emerging technologies and better use and maintenance of existing controls will reduce exposures to at or below the PEL for the remaining operations.

API, MSC, and Halliburton questioned whether the analysis of engineering controls presented in the PEA was sufficient to demonstrate the technological feasibility of reducing exposures to RCS at hydraulic fracturing sites to levels at or below 50 μg/m^3, in part because the analysis did not include industry-specific studies on the effectiveness of dust controls but largely relied instead on research from other industries (Document ID 2301, Attachment 1, pp. 29, 60-61; 2302, p. 4-7; 2311, p. 2-3). These stakeholders argued that OSHA needed to do significantly more data collection and analysis to show that the PEL of 50 μg/m^3 is feasible for hydraulic fracturing operations.

OSHA sought additional information on current exposures and dust control practices. Throughout the NPRM and hearings, OSHA, as well as other stakeholders, requested additional information on exposures and engineering controls (Document ID 3589, Tr. 4068-4070, 4074-4078, 4123-4124; 3576, Tr. 500, 534). Submissions to the record indicate that significant efforts are currently being made to develop more effective dust controls specifically designed for hydraulic fracturing (Document ID 1530; 1532; 1537;

1538; 1570; 4072, Attachments 34, 35, 36; 4204, p. 35, Fn. 21). However, industry representatives provided no additional sampling data to evaluate the effectiveness of current efforts to control exposures. Thus, NIOSH and OSHA provided the only detailed air sampling information for this industry, and summary data were provided by a few rulemaking participants (Document ID 4204, Attachment 1, p. 35, Fn. 21; 4020, Attachment 1, p. 4).

When evaluating technological feasibility, OSHA can consider engineering controls that are under development. Under section 6(b)(5) of the OSH Act, 29 U.S.C 655(b), OSHA is not bound to the technological status quo and can impose a standard where only the most technologically advanced companies can achieve the PEL even if it is only some of the operations some of the time. *Lead I* (*United Steelworkers v. Marshall*, 647 F.2d 1189 (D.C. Cir. 1980)); *American Iron and Steel Institute v. OSHA*, 577 F.2d 825 (3rd Cir. 1978). Relying on these precedents, the D.C. Circuit reaffirmed that MSHA and OSHA standards may be "technology-forcing" in *Kennecott Greens Creek Min. Co. v. MSHA*, 476 F.3d 946, 957, 960 (D.C. Cir. 2007), and that "the agency is 'not obliged to provide detailed solutions to every engineering problem,' but only to 'identify the major steps for improvement and give plausible reasons for its belief that the industry will be able to solve those problems in the time remaining.'" *Id.* (finding that MSHA provided "more than enough evidence," including "identif[ying] several types of control technologies that are effective at reducing . . . exposure," to conclude that the industry could comply with the two-year implementation date of a technology-forcing standard) (citing *Nat'l Petrochemical & Refiners Ass'n v. EPA*, 287 F.3d 1130, 1136 (D.C. Cir. 2002)).

Above, OSHA has described technologies that have been developed and tested, and that have demonstrated that the PEL is obtainable. These technologies have been developed to reduce exposures to the preceding PEL, but some of them appear also to have the capability to reduce some exposures to the PEL of 50 $\mu g/m^3$. KSW Environmental has provided data that indicate exposures can be achieved at or below the PEL (Document ID 1570, p. 22; 4204, Attachment 1, p. 35, Fn 21; 4222, Attachment 2, p. 6), and NIOSH has presented concepts of "mini-bag houses" that can be retrofitted on existing equipment (Document ID 1537, p. 5; 1546, p. 10). SandBox Logistics, LLC, has developed a shipping container for bulk transport of sand specifically designed for hydraulic fracturing operations that eliminates the need for sand movers, a major source of exposure to silica at fracturing sites (Document ID 3589, Tr. 4148). OSHA views these and other advanced controls discussed above as on the “horizon,” but not currently widely available for operational use (*Am. Fed'n of Labor & Cong. of Indus. Organizations v. Brennan*, 530 F.2d 109, 121 (3d Cir. 1975). Once they are deployed, as noted above, more conventional adjustments and additional controls can be used with them to lower exposures to the new PEL or below.

Evidence in the record shows that widespread recognition of silica exposure hazards on hydraulic fracturing sites and industry’s efforts to address them through the STEPS network accelerated after 2010, when NIOSH first publicized the severity of hazardous silica exposures as part of its Field Effort to Assess Chemical Exposures in Gas and Oil Workers (Document ID 1541). Recognition of silica exposures in the industry well above the preceding PEL of 100 $\mu g/m^3$ prompted the development of engineering controls to reduce exposures to RCS. While some companies in the hydraulic fracturing industry are able to obtain and implement controls to comply with the preceding PEL (*See, e.g.*, Document ID 4204, Attachment 1, p. 35, Fn. 21), the technology is not currently widely available. Given the progress that has been made since 2010, OSHA concluded that these technologies will become more widely available and enable the industry to comply with the final PEL within five years. As noted by Kenny Jordan, the Executive Director of the Association of Energy Service Companies (AESC), his organization’s participation on the National Occupational Research Agenda (NORA) NIOSH Oil and Gas Extraction Council enabled members to be “at the forefront of building awareness of the silica at the well site issue, particularly among those working in fracking operations” (Document ID 3589, Tr. 4059). In the five years since that time, the substantial progress in controlling silica exposures at fracking sites described above has occurred.

In June 2012, the STEPS network, in which AESC and many other industry, educational and regulatory entities participate, launched a respirable silica focus group to spread awareness, better characterize on-site silica exposures, and facilitate and evaluate the development of engineering controls (Document ID 3589, Tr. 4059; 1537). This enabled several manufacturers of engineering controls, such as KSW Environmental (formerly Frac Sand Dust Control and Dupre) who had developed a working model in 2009 (Document ID 1520), to collaborate and share information on various engineering controls. As a consequence, the silica control field has grown significantly during this period, including the development, testing and, in some cases, deployment of new technologies, including those from KSW Environmental, J and J Truck Bodies, SandBox Logistics, and NIOSH's baghouse. For example, John Oren, the co-inventor of the SandBox Logistics technology, said it had taken his company only three years to develop the product and make it commercially available (Document ID 3589, Tr. 4148). OSHA concludes that an additional five years will be more than enough time for these and other firms to complete development and increase manufacturing and sales capacity, and, simultaneously, for hydraulic fracturing employers to test, adopt and adapt these emerging technologies to their workplaces. Indeed, in light of the progress that has already been made, it may be more accurate to call the standard "market-accelerating" than "technology-forcing."

During the rulemaking, API touted the efforts of this industry to develop technology to protect workers against the hazards of silica (Document ID 4222, Attachment 2, p. 9). OSHA agrees with API that these efforts have been noteworthy and that more time is warranted to allow for continued development, commercialization, and implementation of these innovative technologies. OSHA is confident that with the innovation displayed by this industry to date, the hydraulic fracturing industry can further reduce worker exposures to the PEL if sufficient time is provided. Therefore, OSHA is providing an extra 3 years from the effective date of the standard – for a total of 5 years – to implement engineering controls for the hydraulic fracturing industry. OSHA concludes that this is ample time for this highly technical and innovative industry to come into compliance with the final PEL. This is consistent with, but longer than, the time frame OSHA granted for implementation for engineering controls for hexavalent chromium, where OSHA provided four years to allow sufficient time for some industries to coordinate efforts with other regulatory compliance obligations as well as gain experience with new technology and learn more effective ways to control exposures (71

FR 10100, 10372, Feb. 28, 2006). Thus, with the extra time provided for this industry to come into compliance, OSHA finds that the final PEL of 50 μg/m^3 is feasible for the Hydraulic Fracturing industry.

In the two years leading up to the effective date, the hydraulic fracturing industry will continue to be subject to the preceding PEL in 29 CFR 1910.1000 (Table Z). In order to meet the preceding PEL of 100 μg/m^3 during this interim period, such compliance will include adoption of the new engineering controls discussed above as they become widely available for field use.[161] As a result, OSHA expects many exposures in hydraulic fracturing to be at or near the 50 μg/m^3 level ahead of the five-year compliance date due to the expected efficacy of this new technology.

[161] Compliance with Table Z requires implementing all feasible engineering and administrative controls to achieve the PEL before using protective equipment such as respirators. 29 CFR 1910.1000(e). OSHA acknowledges that the technologies to meet the PEL in Table Z are not currently widely available in the quantities needed for the entire industry to achieve compliance. Accordingly, as employers work toward implementing controls during the interim period, supplemental respiratory protection may be necessary to comply with the PEL of 100 μg/m^3. Likewise, during the additional three-year phase-in period, OSHA anticipates that many employers may need to use supplemental respiratory protection to comply with the PEL of 50 μg/m^3.

5. TECHNOLOGICAL FEASIBILITY FOR THE CONSTRUCTION INDUSTRY

5.1 ABRASIVE BLASTERS

5.1.1 Description

This section addresses abrasive blasting operations that occur in the construction industry. Abrasive blasting is commonly used in the construction industry to remove surface coatings, create architectural surface finishes, or clean the surfaces of structures and equipment (such as oil tanks, water tanks, gasoline tanks, bridges, and steel beams). Workers in this industry perform abrasive blasting as part of their jobs or assist in abrasive blasting operations by maintaining the abrasive blasting machine and components or by helping to maneuver the hoses. OSHA has identified abrasive blasting as a significant source of crystalline silica exposure when conducted at construction sites (Document ID 1720, p. IV-385).

OSHA has identified two job categories associated with abrasive blasting in the construction industry: abrasive blasting operator and abrasive blaster's helper. Table IV.5.1-A summarizes the major activities and primary sources of silica exposure for these abrasive blasting job categories in the construction industry.

Table IV.5.1-A Job Categories, Major Activities, and Sources of Exposure of Abrasive Blasters

Job Category*	Major Activities and Sources of Exposure
Abrasive Blasting Operator	Uses abrasive blasting equipment to clean a variety of surfaces. • Dust generated from the use of silica-containing abrasive blast media. • Dust generated from abrasive blasting on concrete substrates. • Dust raised by sweeping or shoveling spent abrasive material (housekeeping).
Abrasive Blaster's Helper (Pot Tender)	Tends blasting equipment. • Dust raised by filling abrasive blasting reservoir (e.g., emptying bags of silica-containing abrasive media). • Dust generated by abrasive blasting operations carried out by the Abrasive Blasting Operator. • Dust raised by sweeping or shoveling spent abrasive material (housekeeping).
*Job categories are intended to represent job functions; actual job titles may differ and responsibilities may be allocated differently, depending on the construction site.	

5.1) Abrasive Blasters

Source: Document ID 1720, p. IV-373.

Abrasive blasting workers are employed in a diverse range of manufacturing and service industries in general industry. Their work occurs mainly in the following application groups and is addressed in those sections of this technological feasibility analysis: IV-4.3 Concrete Products, IV-4.4 Cut Stone, IV-4.6 Dental Laboratories, IV-4.8 Foundries, IV-4.10 Jewelry, and IV-4.20 Shipyards (Maritime Industry).

Generally, abrasive blasting related to construction differs from industrial abrasive blasting in that construction workers perform these activities at temporary worksites using portable abrasive blasting equipment without the use of a fixed-position abrasive blasting room, booth, or cabinet fitted with dedicated exhaust ventilation. Abrasive blasting operations similar to those found on construction sites can occur on the premises of some manufacturing and nonmanufacturing general industry establishments, where the abrasive blasting operation is not a normal part of the establishments' main business (e.g., food manufacturing, retail stores). The baseline conditions, exposure profile, and additional controls presented here apply to this type of abrasive blasting work, regardless of whether the abrasive blasting is for the purpose of construction or maintenance.

OSHA has existing requirements for abrasive blasting under the Ventilation Standard for construction (29 CFR 1926.57). In certain situations, that standard requires abrasive blasting operators to wear abrasive blasting respirators approved by NIOSH for protection from dusts produced during abrasive blasting operations (29 CFR 1926.57(f)(5)(i) through (iii)). That standard also includes specifications for blast-cleaning enclosures (29 CFR 1926.57(f)(3)), exhaust ventilation systems (29 CFR 1926.57(f)(4)), air supply and air compressors (29 CFR 1926.57(f)(6)), and operational procedures (29 CFR 1926.57(f)(7)). OSHA also has similar requirements for abrasive blasting under the general industry Ventilation Standard (29 CFR 1910.94).

Construction workers who perform abrasive blasting at least occasionally are associated with numerous construction industry North American Industry Classification System (NAICS) codes, including: 236210, Industrial Building Construction; 236220, Commercial and Institutional Building Construction; 237110, Water and Sewer Line and

Related Structures Construction; 237120, Oil and Gas Pipeline and Related Structures Construction; 237130, Power and Communication Line and Related Structures Construction; 237310, Highway, Street, and Bridge Construction; 237320, Paint and Wall Covering Contractors; 237990, Other Heavy and Civil Engineering Construction; 238190, Other Foundation, Structure, and Building Exterior Contractors; and 238990, All Other Specialty Trade Contractors. This section presents information from these segments of the construction industry and is representative of most abrasive blasting operations and conditions in construction.

5.1.2 Exposure Profile and Baseline Conditions

The following paragraphs describe baseline conditions for the job categories of abrasive blasting operator and abrasive blaster's helper, based on OSHA Special Emphasis Program (SEP) inspection reports, NIOSH reports, New York Department of Transportation reports, and published articles. These reports present information on abrasive blasting (identified by construction industrial classification codes) performed for construction purposes at building sites, steel and concrete tanks (inside and outside), swimming pools, highways/bridges, and an oilfield construction site. Together, these sources provide the best available information on workers performing miscellaneous abrasive blasting operations in construction.

For the exposure profile, OSHA reviewed exposure data that was originally contained in the PEA (Document ID 1720, p. IV-375). OSHA derived that data from OSHA SEP reports, NIOSH studies (mainly from 1999 to 2009), New York Department of Transportation memoranda (Document ID 0925; 1255), and published articles. OSHA supplemented these data with more recent data from 12 samples identified in OSHA's Information System (OIS) (Document ID 3958). The exposure profile summarizes the results of 71 silica samples for abrasive blasting workers at 27 commercial, storage tank, and highway construction sites, including bridge locations.[162]

Table IV.5.1-B presents the exposure profile and summarizes the silica exposure data available to OSHA for the job categories of abrasive blasting operator and abrasive blaster's helper.

Baseline Conditions for Abrasive Blasting Operators

Based on descriptions of abrasive blasting operators' activities and equipment in the sources mentioned above, OSHA concludes that baseline conditions for this group of workers include the use of a portable abrasive blasting machine in the following three scenarios:

- using dry silica-containing abrasive blast media;
- using alternative media on silica-containing surfaces; and
- using wet methods with silica sand abrasive media.

These baseline conditions are represented in Table IV.5.1-B by the data summarized for workers performing "dry blasting, uncontrolled" and "wet methods used."

OSHA's existing Ventilation Standard for construction (29 CFR 1926.57) requires abrasive blasting operators to wear abrasive blasting respirators approved by NIOSH, in certain circumstances, for protection from dusts produced during abrasive blasting operations.

The exposure profile in Table IV.5.1-B includes 55 samples of respirable crystalline silica for abrasive blasting operators. Of the 55 results, 38 samples (69 percent) were obtained while workers performed dry abrasive blasting, with 8-hour time-weighted

[162] As noted in Section IV.2 – Methodology, all sample results included in the exposure profile are 8-hour time-weighted averages (8-hour TWAs) calculated assuming zero silica exposure during any unsampled portion of the shift. Unless explicitly stated otherwise, all sample results discussed in the additional controls section are also 8-hour TWAs calculated in the same manner. Assumptions made in calculating 8-hour TWAs are discussed in Section IV.2 – Methodology.

average (TWA) exposure levels ranging from below the limit of detection (LOD)[163] to 29,040 micrograms per cubic meter (μg/m^3). The median silica exposure for this job category is 251 μg/m^3, and the mean exposure is 3,160 μg/m^3. The remaining 17 silica sample results (31 percent of total samples) were from operators using wet blasting methods. Those results show 8-hour TWA silica exposures ranging from 36 μg/m^3 to 407 μg/m^3, with a median exposure of 125 μg/m^3 and a mean exposure of 161 μg/m^3.

Among operators, the highest silica exposure levels are found when workers are performing dry blasting using silica sand abrasive in unventilated enclosed spaces. For instance, a silica exposure of 29,040 μg/m^3 was obtained by OSHA for a worker blasting inside a city water tower (Document ID 0547, p. 324).[164] A NIOSH Health Hazard Evaluation also found high readings associated with dry blasting in a tank that was only naturally ventilated (Document ID 0885, p. 17). Workers conducting abrasive blasting operations using a silica sand abrasive[165] inside a steel plate water tank were exposed to silica at levels ranging from 15,000 to 27,000 μg/m^3 (Document ID 0885, p. 29). An OSHA inspection of a painting contractor in 2013 found respirable dust exposures of 32,000 μg/m^3 (12,983 μg/m^3 respirable silica) and 25,000 μg/m^3 (8,749 μg/m^3 respirable silica) during sampling of abrasive blasting operators, although the inspection

[163] Results reported as “none detected” are assigned a value equal to the LOD. The LOD is determined individually for each sample based on the volume of air sampled and the method used to analyze the sample; therefore, the limit of detection varies between samples. See Section IV.2 – Methodology for additional information on LODs.

[164] The prior silica PEL limited exposure to silica-containing respirable dust, and the limit on exposure to respirable dust decreased with increasing silica content. For this sample, OSHA reported the silica PEL as 0.31 mg/m^3 and a respirable dust level of 96.17 mg/m^3. Based on the respirable dust level, the silica PEL of 0.31 mg/m^3 corresponds to a silica content of 30.2 percent. To express the PBZ result in terms of the gravimetric measurement of silica, OSHA multiplied the silica concentration by the respirable dust value, and determined that the silica exposure was 29,040 μg/m^3.

[165] In this study, NIOSH collected half-shift (240 minute) samples to reduce the chance of filter overloading. According to NIOSH, workers typically spend the same proportion of their shifts performing abrasive blasting as they spend performing abrasive blasting during the 4-hour sampling period, so silica concentrations measured during the sampling period are also representative of the workers’ 8-hour exposures. NIOSH stated: “[A]t this operation, half-shift sample concentrations are reasonable approximations of full-shift concentrations (2 hours of sandblasting per 4-hour half-shift is similar to 4 hours of sandblasting per 8-hour full-shift). Therefore, half-shift, 4-hour time-weighted average (TWA) exposures are believed to be reasonable approximations of full-shift, 8-hour TWA exposures” (Document ID 0885, p. 14).

information does not state whether the abrasive blasting was performed in an enclosed area (Document ID 3958, Rows 591, 593).

The lowest exposures for dry blasting operators occurred when workers were using a non-silica containing abrasive blasting media. However, significant silica exposures can still occur during the use of non-silica abrasives, mainly when the work surface contains silica. NIOSH obtained a 90-minute short-term reading of 440 μg/m^3 (83 μg/m^3 as an 8-hour TWA) for a worker using abrasive containing less than 1-percent quartz to remove paint from the steel understructure of a bridge. The worker blasted inside a temporary enclosure; silica was believed to come from concrete adjacent to the steel being cleaned (Document ID 0910, p. 4).

Similarly, a result of 73 μg/m^3 was collected for an operator who used a non-silica abrasive to blast a swimming pool (Document ID 0505, p. 11). The specific source of the silica was not indicated; however, OSHA notes that swimming pools are typically lined with painted concrete and tile, both of which contain silica. Although these results are markedly lower than results for workers performing abrasive blasting using silica sand, it nonetheless indicates the potential for exposure from abrasive blasting on materials that contain silica, even when the worker uses a non-silica-containing blasting media. While these non-silica abrasive media can reduce silica exposure levels, they do not necessarily eliminate silica exposure under all conditions.

NIOSH evaluated a wet blasting operation in which abrasive blasting operators blasted the exterior concrete surfaces of a parking garage with a wet blasting system that projected a mixture of water and silica sand (Document ID 0230, p. 3). Sixteen silica exposure results, ranging from 36 μg/m^3 to 407 μg/m^3, were obtained during these abrasive blasting operations (Document ID 0230, p. 21). A separate OSHA SEP inspection of a wet abrasive blasting operation at a bridge painting site found a silica exposure level of 45 μg/m^3 for the abrasive blasting operator (Document ID 0497, p. 20). These data, when compared to the data obtained for dry abrasive blasting using silica sand, suggest that wet abrasive blasting is useful in preventing very high levels of silica dust levels during abrasive blasting operations, but that exposures to silica will still frequently exceed the revised PEL.

Baseline Conditions for Abrasive Blasters' Helpers

Baseline conditions for abrasive blasters' helpers are similar to those for abrasive blasting operators, with the key exception being the helper's greater distance from the actual abrasive blasting. Also, abrasive blasters' helpers typically use particulate-filtering half face piece respirators instead of the supplied-air abrasive blasting respirators used by the operator.

The baseline conditions for abrasive blasters' helpers are represented in Table IV.5.1-B by the data summarized for workers "assisting with dry blasting, uncontrolled" and "assisting with wet methods used." The exposure profile in Table IV.5.1-B includes 16 samples of respirable crystalline silica for abrasive blasters' helpers. Eight of these samples are associated with dry abrasive blasting, with a median silica exposure of 35 μg/m^3, a mean exposure of 811 μg/m^3, and exposures ranging from 10 μg/m^3 to 4,700 μg/m^3. The remaining eight samples, all from one concrete parking garage construction site described in a NIOSH study, represent exposures among abrasive blasters' helpers during the use of wet abrasive blasting using silica sand on a concrete surface (Document ID 0230, p. 3). Table IV.5.1-B shows that the median silica exposure for these samples was 68 μg/m^3, with a mean exposure of 60 μg/m^3 and exposures ranging from the limit of detection (12 μg/m^3) to 104 μg/m^3. As with abrasive blasting operators, exposure data on abrasive blasters' helpers indicate that wet abrasive blasting methods can prevent extremely high silica exposures among helpers.

Silica exposures for abrasive blasters' helpers can vary widely depending on the activities required of the helper (e.g., refilling media reservoirs, maintaining air compressors, maneuvering hoses), the helper's proximity to the location where abrasive blasting is performed, and the amount of time spent near the abrasive blasting (Document ID 1720, p. IV-377). As with abrasive blasting operators, some of the highest exposure levels for abrasive blasters' helpers were associated with dry blasting using silica sand in unventilated enclosed spaces. For instance, NIOSH reported a silica exposure of 4,700 μg/m^3 as an 8-hour TWA (actual exposure of 27,000 μg/m^3 over 84 minutes of sampling) for a helper involved in dry sandblasting operations on the interior of a 750,000-gallon steel-plate water tank (Document ID 0885, p. 15). The helper shoveled sand from an elevated ledge to the bottom of the inside of the tank. OSHA also obtained an exposure reading of 1,466 μg/m^3 for a helper involved in a sandblasting operation inside a city water tower, a job that lasted 8 hours (Document ID 0547, p. 325).[166] Additionally, NIOSH measured a 72-minute short-term silica reading of 1,470 μg/m^3 (221 μg/m^3 as an 8-hour TWA) for a helper involved in an operation that was removing paint from the steel understructure of a bridge using coal slag abrasive media. The abrasive blaster's helper spent the majority of the sampling period in the temporary enclosure, where silica concentrations were quite high (Document ID 0910, p. 4).

[166] As noted earlier, the prior silica PEL limited exposure to silica-containing respirable dust. For this sample, OSHA reported the silica PEL as 0.59 mg/m^3 and a respirable dust level of 9.84 mg/m^3. A silica PEL of 0.59 mg/m^3 corresponds to a silica content of 19 percent. To express the PBZ result in terms of respirable crystalline silica in μg/m^3, OSHA multiplied 9.84 mg/m^3 by 19 percent (the silica concentration of the respirable dust) and determined that the silica exposure was 1,866 μg/m^3.

Table IV.5.1-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Construction Workers: Abrasive Blasters (NAICS 236210, 236220, 237110, 237120, 237130, 237310, 237320, 237990, 238190, 238990)

	Exposure Summary			**Exposure Range**		**Exposure Profile**				
Job Category	**N**	**Mean ($\mu g/m^3$)**	**Median ($\mu g/m^3$)**	**Min ($\mu g/m^3$)**	**Max ($\mu g/m^3$)**	**<25 ($\mu g/m^3$)**	**≥25 and ≤50 ($\mu g/m^3$)**	**>50 and ≤100 ($\mu g/m^3$)**	**>100 and ≤250 ($\mu g/m^3$)**	**>250 ($\mu g/m^3$)**
Abrasive Blasting Operator (Dry blasting, uncontrolled)	38	3,160	251	12	29,040	10 (26.3%)	1 (2.6%)	4 (10.5%)	4 (10.5%)	19 (50%)
Abrasive Blasting Operator (wet methods)	17	161	125	36	407	0 (0%)	3 (17.6%)	3 (17.6%)	7 (41.2%)	4 (23.5%)
Abrasive Blasting Operator Subtotal	55	2,233	189	12	29,040	10 (18.2%)	4 (7.3%)	7 (12.7%)	11 (20%)	23 (41.8%)

5.1.3 Additional Controls

The exposure profile in Table IV.5.1-B shows that approximately 68 percent (49 out of 71 samples) of abrasive blasting operators and helpers have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Some abrasive blasting workers are potentially exposed to levels of silica hundreds of times higher than the PEL.

Additional Controls for Abrasive Blasting Operators

Traditional practice in industrial hygiene uses a hierarchy of controls to determine how to protect workers from hazardous exposures. At the top of the hierarchy is elimination, followed in order by substitution, engineering controls, administrative controls, and personal protective equipment. Respiratory protection falls into the bottom level of the hierarchy.

Exposure control options for abrasive blasting operators include:

- Substituting alternative abrasive blasting media for silica sand;
- Blasting with wet methods or other processes that reduce or eliminate dust generation;
- Local exhaust ventilation (LEV) of temporary containments or enclosed areas (with proper filtration to protect adjacent workers);
- Dust suppressant additives;
- Housekeeping; and
- Respiratory protection.

Given the high levels of hazardous dust generated during abrasive blasting, OSHA finds that respiratory protection will continue to be necessary, in many circumstances, to reduce silica exposures to acceptable levels, even with other controls in place. All pertinent comments and testimony supported the need for respiratory protection for workers performing abrasive blasting operations. In its written comments, the Construction Industry Safety Coalition (CISC) questioned OSHA's position requiring employers to implement technologically feasible engineering and work practice controls before placing employees in respirators (Document ID 2319, p. 37). However, 3M agreed with OSHA that effective engineering and work practice controls should be the primary means of reducing employee exposures to respirable crystalline silica (Document ID 2313, p. 6). Based on information submitted to the docket and summarized in this section, the Agency maintains its position that adherence to the hierarchy of controls is essential to help reduce the extremely high silica exposures experienced by abrasive blasting workers and adjacent workers at construction sites.

Use of Alternative Abrasive Media

To eliminate or reduce the hazards posed by using silica sand as the abrasive media, employers can select alternative blasting media that does not contain crystalline silica. Silica sand, which became popular as an abrasive blasting material because of its effectiveness and its low cost, can contain as much as 96 percent crystalline silica. However, in recent years the amount of silica sand used or sold for abrasive blasting has been declining, and, in many applications, other types of abrasive blasting media have replaced sand (Document ID 1720, p. IV-383). During OSHA's public hearings, Paul Mellon of Novetas Solutions testified that the annual tonnage of silica sand used for abrasive blasting operations decreased 67 percent from 1996 to 2007, primarily due to the use of alternative blasting media and high-pressure water-jet blasting techniques (Document ID 3545, p. 4).

Many types of alternative abrasive blasting media are available for use as a substitute for silica sand. Alternative abrasive media containing less than 1 percent silica include garnet, staurolite, aluminum oxide, and slags of copper, coal, or nickel (Document ID 3747, p. 14). In its written comments, the International Safety Equipment Association (ISEA) describes one blasting media alternative, steel shot, as an effective and economical substitute for silica sand (Document ID 2212, p. 4). ISEA also identified 23 states that have demonstrated the feasibility of using alternative abrasive blasting media in response to bans or restrictions on the use of silica sand for abrasive blasting (Document ID 2212, p. 3). Sarah Coyne, the Health and Safety Director of the International Union of Painters and Allied Trades, described coal slag (Black Beauty) as the most preferred alternative to sand; coal slag has a 0.01 percent silica content and results in low dust output. Ms. Coyne said that she isn't aware of any of the union's signatory contractors using silica sand for abrasive blasting, "and the reason for that is because it kills their workers" (Document ID 3581, Tr. 1644**)**.

A NIOSH-sponsored study evaluating several types of abrasive media found that the silica exposures of abrasive blasting operators can be reduced with the use of certain media (Document ID 0772; 0773; 0774). Phase I of the study involved collecting exposure monitoring data during test trials in which the abrasive blasting operator used different media to blast a steel surface inside a ventilated enclosure (Document ID 0772, pp. 5-20). Exposures ranging from 2,930 μg/m^3 to 22,030 μg/m^3 were obtained during trial runs in which silica sand media was used (Document ID 0774, Table 10, p. 19).[167] No respirable quartz was detected in samples collected during trial runs in which the operator used crushed glass, coal slag, nickel slag, olivine, specular hematite, copper slag, or steel grit (Document ID 0772, p. 82). The study also showed that blasting operations using some media with low silica content and non-siliceous substrates can still result in elevated airborne concentrations of silica (Document ID 0774, Table 10, p. 19). Exposure readings ranging from 240 μg/m^3 to 6,830 μg/m^3 were obtained during trial runs with garnet along with a sample result of 740 μg/m^3 during copper slag use (Document ID 0774, Table 10, p. 19). The study also indicated that the potential presence of other toxic substances requires that alternative blast media be selected carefully (Document ID 0772, p. 4).

In another study, the use of blasting media containing less than 1-percent quartz resulted in an area respirable quartz level of 1,580 μg/m^3 (369-minute sample duration) inside a ventilated containment structure erected around two steel tanks (Document ID 0212, p. 13). NIOSH concluded that the high levels of dust produced by the abrasive blasting overwhelmed the LEV (Document ID 0212, p. 15). A 2012 report from Alberta Human Services on worker exposure in the Alberta construction industry found that the use of vitreous smelter slag (0.28 percent quartz silica) and nickel slag (0.30 percent quartz

[167] The referenced report table cannot be viewed in the record, but it is publicly available from NIOSH's website at http://www.cdc.gov/niosh/topics/silica/pdfs/ab_p3tab.pdf.

silica) in abrasive blasting resulted in a maximum silica concentration of 270 µg/m^3 (Document ID 3747, p. 11).

In a study of exposures among painters using three alternative blasting abrasives during a New Jersey highway footbridge repainting project, Meeker et al. reported that steel grit, specular hematite, and coal slag all resulted in elevated silica exposures, ranging from 420 µg/m^3 to 90,100 µg/m^3, likely due to the very high silica content in the paint (Document ID 3855, p. 82). High variability in silica exposures during the two- to three-hour task-based sampling periods, however, made it difficult for researchers to detect statistical differences in exposures associated with the different abrasives. Sources of the high level of variability are unknown; however, they could be related to harsh environmental conditions during abrasive blasting as well as the small sample size. This study also found that workers could be exposed to other hazardous substances (such as beryllium, cadmium, chromium, manganese, and nickel) during the use of the alternative blasting abrasives (Document ID 3855, p. 83).

OSHA received a number of comments pertaining to the health hazards associated with using alternative abrasive media. The Precast/Prestressed Concrete Institute (PCI) cautioned that coal and copper slags, commonly used as a substitute for silica sand in abrasive blasting, contain hazardous substances (such as beryllium) that cause adverse health effects in workers (Document ID 2276, p. 9). The Meeker study, described above, found elevated levels of arsenic, beryllium, and other toxic metals among painters using the three alternative blasting abrasives (Document ID 3855, p. 82).

Additional literature suggests there may be more benign abrasive media substitutes. For example, based on a review of engineering control technology for abrasive blasting, Flynn and Susi report that dolomite (i.e., calcium magnesium carbonate) might be a good, nontoxic alternative to silica-containing abrasive blasting media (Document ID 1717, p. 682). The authors also commented on the apparent potential for good results with crushed glass (Document ID 1717, p. 682). However, OSHA received comments on some of the limitations of using alternative blasting media: for example, PCI commented on performance limitations and/or high costs associated with many types of alternative blasting media (Document ID 2276, p. 9).

OSHA received numerous comments calling for a ban on the use of silica sand in abrasive blasting. The Building and Construction Trades Department, AFL-CIO (BCTD) urged OSHA to prohibit abrasive blasting with silica sand, and identified Great Britain, Germany, Sweden, and Denmark as countries that currently ban the use of silica sand in abrasive blasting (Document ID 2371, Attachment 1, p. 31). Sally Greenberg of the National Consumers League testified that the U.S. Navy, Air Force, Coast Guard, and 23 state departments of transportation prohibit the use of silica sand in abrasive blasting (Document ID 3588, Tr. 3752). One commenter suggested a partial ban on silica sand abrasive blasting in areas such as confined spaces and shipyards where it is difficult to protect adjacent workers (Document ID 2163, Attachment 1, p. 18). Dr. Paul Schulte of NIOSH testified that NIOSH has called for a ban of silica sand in abrasive blasting since 1974 (Document ID 3579, Tr. 141-142). Diane Brown of the American Federation of State, County and Municipal Employees (AFSCME) reported that local unions in Maryland no longer use silica-based abrasive media and have switched to other materials, such as aluminum shot (Document ID 2106, p. 2). Additionally, the design standard developed by the American National Standards Institute (ANSI) on exhaust systems for abrasive blasting operations at fixed location enclosures prohibits the use of silica sand as an abrasive blasting agent in such operations (Document ID 0528, p. 1).

Other commenters argued against banning silica sand in abrasive blasting. James Toscas of PCI commented that the use of certain alternative abrasives, like steel grit, may cause particle embedment or discoloration on their architectural cladding products (Document ID 2276, p. 9). Mr. Toscas further described how other alternatives, like staurolite, olivine, baking soda, nut shells, glass beads, and dry ice, are not hard enough to provide the desired finish on their products, and stated that other alternatives, like aluminum oxide and stainless steel grit, were cost prohibitive (Document ID 2276, p. 9). The American College of Occupational and Environmental Medicine (ACOEM) supported the use of alternative abrasive media, but cautioned that substitutes must demonstrate safety in short- and long-term inhalation toxicology studies (Document ID 2080, p. 4).

CISC joined other commenters in warning about the other possible hazards associated with substitutes for silica sand (Document ID 2319, p. 37).

Many of the silica sand substitutes used in abrasive blasting can create hazardous levels of dust containing other hazardous substances. In a laboratory study of alternative materials for abrasive blasting which was funded by NIOSH, researchers focused on eleven health-related agents, including arsenic, beryllium, cadmium, chromium, and lead. In summary, nine of the eleven alternate abrasives had substantially higher levels of some other health-related agents, as compared to silica sand (Document ID 0772, pp. 1-3, 144). Other studies conducted by NIOSH on the toxicity of silica sand substitutes for abrasive blasting found that many alternatives, including coal slag, garnet, copper and nickel slags, olivine, and crushed glass, produced lung damage and inflammatory reactions in rodent lungs similar to the effects of silica sand, indicating that the use of such materials might not be effective in reducing lung disease risks to workers (Document ID 3857, pp. 139-142; 3859, pp. 1121-1122). While other alternatives, such as steel shot, dolomite, and walnut shells, are considered lower hazard materials, abrasive blasting on silica-containing surfaces and other hazardous surface materials (e.g., lead paint) can also produce high levels of airborne toxic dust. Although OSHA finds that substituting non-silica abrasive media for silica sand does reduce silica exposures, the limitations on selecting effective substitutes may leave silica sand as the only feasible choice in some applications. Wet abrasive blasting (discussed below) can be an effective control when silica sand cannot be replaced with a non-silica abrasive alternative. Regardless of the abrasive blast media used, abrasive blasting operations create high levels of potentially hazardous dust and workers will still need respiratory protection.

OSHA has considered the comments associated with the complex issues related to banning silica sand for use in abrasive blasting. Based on the information available, the Agency concludes that a ban on the use of silica sand is not warranted at this time. OSHA bases this decision on a number of factors already discussed in this section, including the potential hazards, and concerns about the effectiveness, of certain abrasive alternatives.

Under the existing OSHA Ventilation Standard (29 CFR 1926.57), abrasive blasting operators in construction must use abrasive blasting respirators, in certain circumstances, for protection from the high level of hazardous dust generated by this operation. The Ventilation Standard also contains requirements applicable to engineering controls used to control and reduce levels of hazardous dusts.

Wet Blasting and Other Alternative Methods to Dry Abrasive Blasting

Alternative techniques to dry abrasive blasting can be used to reduce the silica exposure levels of abrasive blasting workers and adjacent workers, although the effectiveness of these methods in reducing silica exposures has not been extensively documented. These techniques, summarized below in Table IV.5.1-C, include wet abrasive blasting, centrifugal wheel blasting, vacuum blasting, and blasting with dry ice pellets. Hydroblasting is a surface cleaning technique that does not use abrasive blast media and instead uses a high pressure water jet (along with additives). Other cleaning techniques that do not use abrasive blasting and are suitable for smaller jobs include thermal, chemical, and mechanical stripping methods (Document ID 1720, p. IV-339). Other removal techniques that could reduce or eliminate silica dust levels during surface preparation include blast cleaning with baking soda (sodium bicarbonate), reusable sponge abrasives, or plastic media blasting (PMB); cryogenic stripping (immersing small parts into liquid nitrogen, followed by gentle abrasion or PMB); and laser paint stripping (generates no waste and uses a pulsed carbon dioxide laser as the stripping agent) (Document ID 1720, p. IV-378).

Wet methods can be used to reduce the amount of dust generated during surface preparation. All wet blasting techniques produce substantially lower dust emissions compared with dry abrasive blasting. For example, after reviewing other published and unpublished work, Lahiri et al. estimated that silica exposure associated with sandblasting can be eliminated by using hydroblasting (which involves no abrasive media), even when the surface being hydroblasted contains silica (e.g., concrete) (Document ID 0776, p. 505). OSHA recognizes that although this method effectively cleans many surfaces with minimal silica release, it cannot replace abrasive media blasting under all circumstances. PCI explained that the industry needs to use abrasive blasting abrasives that are aggressive enough to provide the desired concrete finishes (Document ID 2276, p. 9); this may eliminate hydroblasting as a feasible method for some job specifications.

Table IV.5.1-C
Examples of Alternatives to Dry Abrasive Blasting

Name	Description/Comments
Wet Abrasive Blasting	Can be used in most instances where dry abrasive blasting is used. Includes: 1) compressed air blasting with the addition of water into the blast stream before the abrasive leaves the nozzle, and 2) water jetting with the addition of abrasive into the water stream at the nozzle. Additives and rust inhibitors may be used.
Hydroblasting	High Pressure Water Jetting: Uses pressure pump, large volume of water, and specialized lance and nozzle. Pressures range from 3,000 to 25,000 pounds per square inch (psi). Can remove loose paint and rust; will not efficiently remove tight paint, tight rust, or mill scale. Can be used in most instances where abrasive blasting is used. Primary application is for an older surface rusted in a saline environment (rather than for new steel). Rust inhibitors could be required to prevent flash rusting. Ultra High Pressure Water Jetting: Similar to high pressure water blasting. Uses pressurized water from 25,000 to 50,000 psi. Removes tight paint and rust, but not mill scale.
Centrifugal Wheel Blasting	Uses a rotating wheel assembly inside an enclosure equipped with a dust collector. Abrasive is propelled outward from the rotating wheel and removes rust, paint, and mill scale. Abrasives are recycled and include steel shot, steel grit, cut wire, and chilled iron grit. The operator has no contact with airborne dust or high velocity particles.
Vacuum Blasting	Uses standard blast nozzle inside a shroud (head) that forms a tight seal with the work surface. Vacuum is applied inside shroud during blasting to remove dust and debris. Abrasives are recycled and include aluminum oxide, garnet, steel shot, steel grit, and chilled iron grit. When used properly, cleans effectively with minimal dust.
Dry Ice Pellets	Dry ice blast cleaning with solid carbon dioxide. Waste is minimized and includes paint chips and rust. Storage and handling costs can be significant.
Thermal Stripping	Uses a flame or stream of superheated air to soften paint, allowing for easy removal. Generates one waste stream (i.e., waste paint). Effective for small parts; not suitable for heat-sensitive surfaces. Very labor intensive.
Chemical Stripping	Uses hazardous chemical strippers, such as methylene chloride-based or caustic solutions. Effective for small fiberglass, aluminum, and delicate steel parts. Requires adequate ventilation and other safety measures. Generates multiple waste streams (i.e., contaminated rinse water and waste strippers).
Mechanical Stripping	Involves chipping, grinding, sanding, or scraping the coating off small parts or surfaces through the use of needle guns, chipping hammers, sanders, and grinders. Generates paint waste and airborne dust. Some power tools are equipped with dust collection systems.
