A 2008 report from Germany's Institute for Occupational Safety and Health of the German Social Accident Insurance (BGIA) [168] indicates that silica exposures are reduced by wet methods, but that "dust emissions are influenced substantially by the type and quantity of the water feed." The German report indicates that, compared with dry abrasive blasting, modest amounts of water result in some exposure reduction, but can still result in extremely high silica levels. As an extreme example, during laboratory tests using quartz-free blasting media moistened with 10 percent water to abrasively blast concrete,[169] airborne quartz concentrations were still up to 6,000 μg/m^3 (Document ID 0553, p. 145).

The BGIA report also indicates that increasing the water content to form a slurry improves dust control. One example involved replacing the conventional pneumatic blast unit with an ultra-high-pressure slurry blasting unit (29,000 psi) to work on a concrete silo. Under these conditions, investigators measured an average quartz concentration of 500 μg/m^3. They considered it possible that average results could be lower still, but concluded that use of such equipment was unlikely to reduce concentrations below 150 μg/m^3 (Document ID 0553, p. 145).

Increasing water application rates may reduce respirable dust concentration by a factor of 2 – 2.5 for workers performing wet abrasive blasting (Document ID 0230, p. 10). As mentioned previously, NIOSH evaluated a wet blasting operation in which workers blasted the exterior concrete surfaces of a parking garage (Document ID 0230). Their system used a mixture of 80 percent silica sand and 20 percent water. NIOSH reported that this method appeared to reduce the silica exposures associated with abrasive blasting, but the extent of the reduction was not determined, and operators' exposures remained as high as 407 μg/m^3 (Document ID 0230, p. 21). The same study is published as Mazzuckelli et al. (Document ID 0795). NIOSH concluded that the exposure readings obtained for this evaluation were lower than readings obtained for other abrasive blasting

[168] At the time of the report, Germany's Institute for Occupational Safety and Health of the German Social Accident Insurance was known as BGIA, but this organization is now called by the German acronym IFA.

[169] The pneumatic abrasive blasting unit operated at a pressure of 102 to 116 psi (Document ID 0553).

operations. The data in the record support NIOSH's conclusion, showing many dry blasting exposures in the thousands of μg/m^3.

Heitbrink (Document ID 0733, p. 22) conducted a field study of a wet abrasive blasting technique and obtained significantly reduced silica exposures compared with data reported in the literature for use of dry silica sand. The tested device was a water induction nozzle described as a venturi nozzle in which water is added to the abrasive-air mixture to reduce dust during blasting. Workers' exposures were monitored while blasting outdoors in open areas on concrete panels using silica sand abrasive from which the fines had been removed.[170] In 10 samples, the geometric mean silica exposure was 60 μg/m^3, and the range was 20 μg/m^3 to 130 μg/m^3. The author found that when compared to other published data, wet blasting using abrasive sand with the fines removed was effective in reducing silica exposures (Document ID 0733, p. 22).

CISC commented that using wet methods and creating a slurry may lead to environmental problems and may not be a viable solution in many circumstances (Document ID 2319, p. 36). PCI stated that wet method abrasive blasting is not feasible for its industry because it creates a slurry that obscures the surface and prevents the abrasive blasting operator from achieving consistent results (Document ID 2276, p. 9). PCI also commented that using wet method abrasive blasting is problematic under freezing conditions because the ice can create a slipping hazard, and noted that there can be a slipping hazard from the slurry even in warmer weather (Document ID 2276, pp. 9-10). PCI also commented on the potential for mold problems when using water, and stated that water is not always available on construction sites (Document ID 2276, pp. 9-10). Heitbrink determined that excessive water application rates were not a problem at the site, but noted that such water application rates could present a problem at other work sites[171] (Document ID 0733, p. 22). These data were also reported in a study by Old and Heitbrink (Document ID 0928, p. D58). OSHA concludes from the NIOSH studies and

[170] The abrasive media had been screened through a 100-mesh sieve so that particles passing through the sieve comprised less than 3 percent of the media (Document ID 0928, p. D56).

[171] During Heitbrink's (2007) study, water was applied at rates ranging from 3.2 kilograms per minute (kg/min) to 8.6 kg/min (equal to 0.8 gallons/minute to 2.2 gallons/minute). The author noted that water puddles did occur at these water application rates.

the exposure profile that wet abrasive blasting is an effective method and feasible control for reducing airborne silica dust most of the time when using silica sand in abrasive blasting. However, the use of wet abrasive blasting may not be practicable in all situations involving abrasive blasting. In such cases, other engineering controls discussed in this section can be used to reduce silica dust exposures.

CISC noted that there have not been any studies demonstrating the most effective flow rate for wet blasting, and that different environments and conditions have not been analyzed to conclusively determine the effectiveness of wet methods (Document ID 2319, p. 36). The amount of water required for effective dust control during blasting depends on the device and the application, and on the relation between water flow rates and dust emissions has not been widely studied to date. In some cases, a volume of water is mixed directly with a volume of abrasive. For instance, Heitbrink provided an overview of wet blasting technology and described a wet abrasive blasting device that mixes water and abrasive in a pressurized tank, with a ratio of about 80 percent abrasive and 20 percent water (Document ID 0733, p. 4). In other devices, the water is supplied continuously at a given flow rate. The patent for a water induction nozzle tested by Heitbrink reported that visual dust was reduced as the water flow rate increased from 1 to 5 liters per minute (Document ID 0733, p. 2). Heitbrink pointed to the need for controlled laboratory testing to develop recommended water application rates for wet blasting. OSHA concludes that wet abrasive blasting is an effective method of controlling dust levels during abrasive blasting operations, despite questions about the optimal abrasive/water mix for dust control. Sample data from wet abrasive blasting in the NIOSH study (Document ID 0230) and an OSHA SEP inspection (Document ID 0497) show a marked decrease in dust levels when compared to uncontrolled, dry abrasive blasting. These data also demonstrate that wet method abrasive blasting equipment is available to companies for use at construction job sites and that it is, in fact, used by employers in some applications.

Although wet methods may not reduce exposures to at or below the new PEL of 50 $\mu g/m^3$ on a consistent basis, wet methods nonetheless can be used to reduce the amount of silica dust generated during abrasive blasting operations using silica sand or blasting on silica-containing surfaces. Table IV.5.1-B shows that average levels of silica dust are much higher during dry abrasive blasting. Wet methods are an important dust control where abrasive blasting operations are enclosed to prevent dust from entering the surrounding environment and exposing other workers at the construction site.

Enclosures and Local Exhaust Ventilation

Enclosures in which workers perform blasting keep silica contained, providing a measure of exposure control for other workers performing activities outside the enclosure. However, enclosures need to be properly ventilated to avoid concentrated levels of silica resulting in extremely high exposures to the person performing the abrasive blasting. For example, NIOSH found elevated short-term results of 820 $\mu g/m^3$, 1,730 $\mu g/m^3$, and 2,960 $\mu g/m^3$ (sample durations of 93, 96, and 93 minutes, respectively) for area samples collected inside an unventilated enclosure used to confine dust generated during the blasting process (Document ID 0910, p. 4). In order to control dust levels, the OSHA Ventilation Standard for abrasive blasting in construction (29 CFR 1926.57) already requires all blast-cleaning enclosures to be adequately ventilated, irrespective of whether silica or an alternative abrasive agent is used.

CISC commented that OSHA did not present any exposure monitoring results, studies, or data to show the extent to which enclosures or LEV systems reduce workers' silica exposures (Document ID 2319, p. 37). The record, however, contains support for OSHA's determination that enclosures and LEV reduce exposures. NIOSH researchers found that the high levels of dust produced by abrasive blasting in ventilated enclosures declined rapidly when blasting ceased, reducing overall exposures (Document ID 0212, p. 15). A World Health Organization document on airborne dust, submitted by the AFL-CIO, describes how enclosures are usually coupled with exhaust ventilation to remove contaminants from the workplace (Document ID 4072, Attachment 15, p. 97).

While the data in the record do not provide precise measurements of the extent to which silica exposures go down in ventilated enclosures, evidence in the record, coupled with basic ventilation principles, indicates that use of ventilated enclosures will result in reduced exposures among operators working within the enclosures. Basic ventilation engineering principles indicate that establishing air changes in an enclosed area by using LEV and filtration will likely result in lower dust levels in comparison to an unventilated enclosure.

LEV can also be used on the blasting equipment itself to capture dust generated during the blasting operation. Although not associated with the construction industry, the National Automobile Dealers Association testified on the subject of LEV-equipped blasting equipment, noting that it is not uncommon for autobody shops to use ventilated spot blasters for dust controls purposes, and that the use of ventilated blasters and ventilated sanders helps minimize exposure (Document ID 3587, Tr. 3722). Flynn et al. found that controls, such as vacuum blasting using a ventilated shroud around the nozzle to collect dust, can reduce exposures when used properly; the authors concede, however, that there is a lack of exposure data that would allow for definitive conclusions on the effectiveness of controls for abrasive blasting (Document ID 1717, pp. 685-86).

Portable blast-cleaning equipment and temporary containment structures must have sufficient exhaust ventilation to: 1) prevent a build-up of dust-laden air and reduce the concentrations of hazardous air contaminants; 2) prevent any leakage of dust to the outside; and 3) provide prompt clearance of dust-laden air from the enclosure when blasting ceases. Exhaust ventilation systems must be constructed, installed, inspected, and maintained according to 29 CFR 1926.57, the OSHA Ventilation Standard for construction. The exhaust air from blast-cleaning equipment must be discharged to the outside through an appropriate dust collector to protect the workplace, the environment, and the surrounding community from hazardous air contaminants. The dust collector should be set up so that the accumulated dust can be emptied and removed without contaminating work areas.

Thus, while LEV alone is not expected to control workers’ silica exposures to at or below the final rule’s PEL, OSHA nonetheless finds that LEV installed in accordance with 29 CFR 1926.57 is useful in reducing dust in enclosures.

Use of Dust Suppressant Additives

Dust suppressant additives provide a limited amount of dust control during blasting with silica sand. For instance, during a study evaluating several types of abrasive media, silica sand abrasive was used to blast the side of a coal barge (Document ID 0774, p. 3). Silica exposures ranged from 9,910 $\mu g/m^3$ to 50,522 $\mu g/m^3$, with a geometric mean of 27,959 $\mu g/m^3$. When a dust suppressant was used with the silica sand abrasive, silica levels in four readings had a geometric mean of 19,040 $\mu g/m^3$ (ranging from 9,180 $\mu g/m^3$ to 28,200 $\mu g/m^3$), about 68 percent of the mean for untreated silica sand (Document ID 0773, p. 45). Although these levels are still excessive, dust suppressant methods used in combination with other measures, such as ventilation and work practices, can help to reduce silica exposures when silica sand must be used as the blasting agent. Effective dust suppressant additives will also help reduce silica exposures when workers (e.g., abrasive blasters' helpers) handle abrasives before and after the actual abrasive blasting. OSHA did not receive comments or exposure information on dust suppressant additives, and continues to believe that they (in combination with other control measures) are useful in reducing workers' exposures to silica.

Housekeeping

Dry sweeping of spent abrasive blasting media and debris can be a sizeable source of silica exposure for workers. For example, a NIOSH study of abrasive blasting in a shipyard found exposure levels of 85 $\mu g/m^3$, 160 $\mu g/m^3$, and 280 $\mu g/m^3$ for workers who spent the entire sampling period dry sweeping material from surfaces, using a hand broom or a whiskbroom (Document ID 0852, p. 3). CISC noted that this study was not related to abrasive blasting in construction and involved workers who spent the entire sampling period with their faces close to the dust source (Document 2319, p. 37).

Although the study is not specific to the construction industry, it demonstrates that dry sweeping material will create higher airborne dust levels than other cleaning methods (such as vacuums, shovels, and scrapers). Using vacuums, shovels, and scrapers to clean surfaces introduces less dust into the air than dry sweeping – regardless of industry. Riala (1988) completed a study of Finnish construction site workers that compared silica exposures among workers dry sweeping with exposures among workers using alternate cleaning methods (Document ID 1163). When compared with dry sweeping, exposures were approximately three times lower when the workers used squeegees to scrape surfaces and approximately five times lower when workers used vacuums (Document ID 1163, p. 3). Additionally, when wet abrasive blasting is implemented as a control, moisture in the abrasive media will continue to suppress dust as long as workers dispose of or recover the abrasive before it dries.

Respiratory Protection

OSHA's Ventilation Standard for construction, at 29 CFR 1926.57(f)(5)(ii)(A-C), requires that employers provide abrasive blasting respirators for abrasive blasting operators to wear when they are working inside of blast-cleaning rooms, or when the nozzle and blast are not physically separated from the operator in an exhaust-ventilated enclosure and either the operator is using silica sand in manual blasting operations or the concentrations of toxic dust dispersed by the abrasive blasting might exceed the limits set in 29 CFR 1926.55 or other pertinent OSHA standards.[172]

Employers must also adhere to OSHA's Respiratory Protection standard (29 CFR 1910.134) when respiratory protection is required. Much of the testimony and comments on the subject of abrasive blasting in construction acknowledged that respiratory protection is necessary for abrasive blasting workers. In its post-hearing brief, the Laborers' Health and Safety Fund of North America acknowledged that abrasive blasting operations can be difficult to control and would require the use of respirators (Document ID 4207, p. 2).

Julie Tremblay of 3M's Personal Safety Division questioned the respirator requirements under the OSHA Ventilation Standard, stating that the standard specifies the type of respirator that is required based on the work being done rather than on the exposure level. OSHA's Ventilation Standard for construction requires that employers use only respirators approved by NIOSH under 42 CFR Part 84 to protect employees from dusts

[172] Similar requirements apply to general industry under the Ventilation Standard at 29 CFR 1910.94.

produced during abrasive-blasting operations. Ms. Tremblay noted that the specified respirator is available with two different levels of performance: assigned protection factors (APF) of either 25 or 1000 (Document ID 2313, p. 3). 3M requested that OSHA mandate the use of a respirator with an APF of 1000 or higher for abrasive blasting operators.

OSHA's Respiratory Protection Standard, at 29 CFR 1910.134(d), requires employers to evaluate respiratory hazards in the workplace, identify relevant workplace and user factors, and base respirator selection on these factors. This would dictate selecting the appropriate abrasive blasting respirator and the level of performance that would protect the abrasive blasting operator from the expected level of exposure. During dry blasting with silica sand inside unventilated enclosures or spaces (in an apparent violation of OSHA's Ventilation Standard), workers were exposed to extremely high levels of silica, as high as 29,040 μg/m^3 (or 580 times the new PEL) (Document ID 0547). In this case, under the new PEL, a supplied-air respirator with an APF of 1,000 would be necessary to protect a worker in these conditions. However, OSHA does not anticipate that a supplied-air respirator with an APF of 1,000 would be necessary in all circumstances.

To be effective, respirators must be selected, used, and maintained properly. And workers must be vigilant in following work practices to prevent contamination of their respirators. For example, one NIOSH study found silica readings of 85 μg/m^3 and 87 μg/m^3 in sampling conducted inside airline respirators (Document ID 0880, p. 10). The source of exposure was undetermined, but was assumed to be due to contamination of the airlines. These results highlight the importance of properly maintaining and cleaning respiratory protective equipment.

Moreover, respirators protect only the workers wearing them. Depending on their proximity to the blasting operation, abrasive blasters' helpers and adjacent construction site workers might have significant exposures and thus require respiratory protection. For example, OSHA obtained a respirable silica exposure of 1,466 μg/m^3 for a helper at a site that used silica sand to remove paint from inside a city water tower (Document ID 0547, p. 325). Because the exposure was 16.7 times the calculated PEL for silica, the particulate-filtering face piece with an APF of 10 worn by the worker was not sufficiently protective.

Despite the disadvantages of respirator use, OSHA concludes that, given the extremely high levels of silica that can be generated by abrasive blasting, respirators will usually be necessary to control the silica exposures of abrasive blasting workers. It is likely that respirators will be required even when individual controls or combinations of them (for example LEV and alternative blasting media) are in place.

Additional Controls for Abrasive Blasters' Helpers

Controls are essential not only to protect the abrasive blasting operator, but also the abrasive blaster's helper and any workers near the blasting operation. The exposure levels associated with abrasive blasters' helpers are routinely lower than abrasive blasting operator exposures, but, as shown in Table IV.5.1-B, half of the silica samples on helpers still exceed the new PEL of 50 μg/m^3. Control measures that reduce operator exposures will also reduce the silica concentrations to which helpers are exposed. Furthermore, some of the controls described as additional controls for abrasive blasting operators will directly affect specific job tasks performed by helpers. The use of wet media during blasting can reduce exposures to helpers during clean up if the helper sweeps or shovels spent media while the media is still wet. Likewise, the use of alternative abrasive blast media in place of silica sand will eliminate or reduce the helpers' silica exposures. Although not evaluated due to a lack of available information, OSHA expects that dust suppressants added to the media before abrasive blasting will also help reduce the silica exposure levels of helpers when they perform housekeeping activities and when they empty bags of abrasive media into the grit pot.

Abrasive blasters' helpers also rely on respiratory protection during abrasive blasting operations, but they are not required to use the abrasive blasting respirators specified for operators under OSHA's Ventilation Standard for construction. The Ventilation Standard permits the use of properly fitted particulate-filter respirators for short, intermittent, or occasional dust exposures, such as cleanup, dumping of dust collectors, and other activities when it is not feasible to control the dust by enclosure, exhaust ventilation, or other means (29 CFR 1926.57(f)(5)(iii)). These types of activities are usually carried out by abrasive blasters' helpers. Testimony from Sarah Coyne with the International Union of Painters and Allied Trades discussed the role of the abrasive blasters' helpers and noted that helpers often do not receive adequate respiratory protection and personal protective equipment (PPE) even though conditions at the worksite could result in considerable amounts of dust (Document ID 3581, Tr. 1616-17). Based on the available exposure data summarized in Table IV.5.1-B, OSHA anticipates that abrasive blasters' helpers would generally need to be equipped with properly fitted, half-face respirators with an APF of 10, and in some situations, would require a higher level of respiratory protection.

5.1.4 Feasibility Findings

Based on the available information, including submitted comments, testimony, and exposure data, OSHA concludes that for most abrasive blasting operators, and approximately half of abrasive blasting helpers, employers will not reliably achieve the new PEL of 50 $\mu g/m^3$, even with the use of engineering controls. Thus, OSHA cannot find that the new PEL is technologically feasible for these workers.

In the final rule, OSHA is requiring employers to implement feasible engineering and work practice controls, such as housekeeping, to reduce levels of silica to the extent feasible. Employers must already comply with 29 CFR 1926.57(f), which provides specifications for blast-cleaning enclosures, exhaust ventilation systems, air supply and air compressors, and operational procedures. The Ventilation Standard, which will continue to apply concurrently with this standard, requires abrasive blasting operators, in certain circumstances, to wear abrasive blasting respirators approved by NIOSH under 42 CFR Part 84 (29 CFR 1926.57(f)(5)(ii)). In some cases the Ventilation Standard permits dust-filter respirators to be used for short, intermittent or occasional dust exposures. The Ventilation Standard also requires operators to be equipped with other PPE (such as heavy canvas or leather gloves and aprons, protective footwear, and eye and face protection). In addition, all requirements of OSHA's Respiratory Protection Standard (29 CFR 1910.134) apply when respirators are use in the workplace.

5.1) Abrasive Blasters

OSHA did not include abrasive blasting in Table 1 of the final rule because employers have a variety of options for controlling exposures to respirable crystalline silica during blasting operations. These include: (1) use of abrasive media other than silica sand to reduce crystalline silica dust emissions; (2) use of wet blasting techniques; (3) use of dust suppressors; (4) use of LEV systems; and (5) use of hydroblasting technologies that avoid having to use abrasive media. Employers can choose among these dust control strategies to select control methods that best fit the needs of each job. OSHA believes that, for these operations, the employer is in the best position to decide, based on the specific circumstances of the job, what approach, or combination of approaches, will most effectively meet the requirements of the project while protecting workers engaged in blasting operations. The employer is required to implement feasible engineering controls to reduce silica dust to the PEL. If the employer cannot meet the PEL, it must supplement the controls with appropriate respiratory protection, as needed.

Feasibility Finding for Abrasive Blasting Operators

Based on the available information, OSHA concludes that the silica exposure levels of most abrasive blasting operators cannot be reduced to levels at or below the new PEL of 50 μg/m^3, even with the use of feasible engineering controls. OSHA notes that the best available information indicates that the use of engineering controls (such as wet abrasive blasting, substituting alternative non-silica abrasive blasting media, and local exhaust ventilation) can be used to reduce the extremely high silica dust levels generated by abrasive blasting operations. OSHA also concludes that appropriate respiratory protection will be required to protect employees from harmful silica exposure. All testimony and comments received by OSHA were in agreement with OSHA's preliminary finding that most abrasive blasting operators' silica exposures will be above 50 μg/m^3 even with the use of engineering controls. Therefore, there is nothing in the record supporting a change to this finding.

This conclusion is based, in part, on the median 8-hour TWA reading of 125 μg/m^3 for workers who used wet abrasive blasting. As indicated in Table IV.5.1-B, over 80 percent of workers had exposure levels that exceeded the final PEL of 50 μg/m^3 when employing wet abrasive blasting methods. Thus, the use of appropriate respiratory protection, especially within enclosures, where exposures are highest, will still be needed to protect workers from hazardous levels of contaminants that may be generated during abrasive blasting (from the abrasive, the substrate, or both). To ensure protection for abrasive blasting operators, employers conducting abrasive blasting operations must follow the requirements under both the Ventilation Standard and the Respiratory Protection Standard.

Feasibility Finding for Abrasive Blasters' Helpers

Based on the available information, including the exposure profile in Table IV.5.1-B, OSHA concludes that half of all abrasive blasters' helpers currently experience exposures that exceed the new PEL of 50 μg/m^3. Even when wet abrasive blasting is performed, more than half (62 percent) of the abrasive blasters' helpers were exposed above 50 μg/m^3. OSHA notes that the available information indicates that the use of engineering controls (such as wet abrasive blasting, substituting alternative non-silica abrasive blasting media, and local exhaust ventilation) will greatly reduce the extremely high silica dust levels generated by abrasive blasting operations using silica sand. OSHA anticipates that abrasive blasters' helpers will remain at risk of exposures above 50 μg/m^3, and these workers will require appropriate respiratory protection whenever they work in the vicinity of the abrasive blasting activity. To ensure protection for abrasive blasters' helpers, employers conducting abrasive blasting operations must follow the requirements under both the Ventilation Standard and the Respiratory Protection Standard.

5.2 DRYWALL FINISHERS

5.2.1 Description

After segments of drywall have been installed, drywall workers use a joint compound paste to seal the joints between segments and to cover divots from nails. Once the joint compound is dried, workers sand the surface by hand to create a smooth finish. The drywall installer might perform the finishing, or a specialized trade worker might perform this work. Sanding dried joint compound containing silica is believed to be the primary source of silica exposure in this job category. Mr. Zimbelman, a homebuilder representing the National Association of Homebuilders (NAHB), testified that during drywall sanding tasks, the workers performing the sanding are typically the only crew present on a home construction site (Document ID 3587, Tr. 3549-3550). Industries that engage in drywall work are classified in the North American Industry Classification System (NAICS) code, 238310 (Drywall and Insulation Contractors).

Silica-free joint compounds have become widely available in recent years; however, some joint compound products may continue to contain silica. NIOSH tested bulk samples of a commercially available joint compound and found up to 6 percent quartz, although silica was not listed on the material safety data sheet for the product (Document ID 0213, p. 5). In another study, NIOSH determined that three of six drywall compounds purchased at a retail store contain trace amounts of silica (Document ID 1335, p. iii). Epling et al. (1999) identified four personal air samples taken during the application and sanding of drywall joint compound that contained between 1.1 and 3.7 percent respirable crystalline silica (Document ID 0662, p. 11). Table IV.5.2-A summarizes the major activities and sources of exposure for drywall sanders.

Table IV.5.2-A
Job Category, Major Activities, and Sources of Exposures of Drywall Finishers

Job Category	Major Activities and Sources of Exposure
Drywall Finisher	Applying joint compound to sections of drywall and sanding dried joint compound to create a smooth finish. • Dust generated while sanding dried, silica-containing joint compound.

5.2.2 Exposure Profile and Baseline Conditions

Fifteen sample results obtained by NIOSH form the basis of this exposure profile (Table IV.5.2-B) (Document ID 1335). NIOSH, in collaboration with the Center to Protect Workers' Rights, obtained these results from 10 drywall finishers working at two work sites: an office renovation job and a project renovating a low-income public housing apartment complex (Document ID 1335, p. 2). Workers in this study applied typical joint compounds -- silica-free joint compounds or compounds with very low silica content -- and performed sanding by hand or with a pole sander. Drywall finishing jobs monitored by NIOSH lasted from 1.5 hours to more than 12 hours per shift (Document ID 1335, pp. 13-15). No work practice controls were identified.

The exposure profile in Table IV.5.2-B for drywall finishers includes 15 full-shift, personal breathing zone samples of respirable crystalline silica. The median exposure is 12 $\mu g/m^3$, the mean is 17 $\mu g/m^3$, and the range is 8 $\mu g/m^3$ (limit of detection (LOD)) to 72 $\mu g/m^3$, which was the only reading above 50 $\mu g/m^3$. The 72 $\mu g/m^3$ sample was obtained for a worker performing overhead sanding directly above his breathing zone (Document ID 1335, p. 13). One other sample exceeded 25 $\mu g/m^3$ (Document ID 1335, p. 14).

Sample data from OSHA inspections between 1985 and 1996 indicate that drywall workers were at times exposed to levels of silica above the previous PEL (Document ID 1167, p. 2). These silica exposures may be the result of using joint compound with silica content or the result of a different silica exposure source at the worksite. The summary information presented in this OSHA Integrated Management Information System (IMIS) data review shows that 22 percent of the samples collected in Standard Industrial Classification (SIC) 1742 (plastering, drywall, insulation) exceeded the PEL. Because individual sample information such as job activities, sampling duration, and silica content were not provided in the review, these samples provided no basis to explain the elevated silica exposures and were not included in the exposure profile.

Baseline conditions for drywall finishers include using low-silica or silica-free joint compounds and manual sanding without specific work practices or other controls. All of the results in the exposure profile are associated with these baseline conditions.

Table IV.5.2-B Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Construction Workers: Drywall Finishers											
	Exposure Summary			**Exposure Range**			**Exposure Profile**				
Drywall Finishers	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**		**<25 (μg/m³)**	**≥25 and ≤50 (μg/m³)**	**>50 and ≤100 (μg/m³)**	**>100 and ≤250 (μg/m³)**	**>250 (μg/m³)**
Drywall Finisher	15	17	12	8	72		13 (87%)	1 (6.5%)	1 (6.5%)	0 (0%)	0 (0%)
Drywall Finishers Total	**15**	**17**	**12**	**8**	**72**		**13 (87%)**	**1 (6.5%)**	**1 (6.5%)**	**0 (0%)**	**0 (0%)**

Notes: All samples are personal breathing zone (PBZ) results and represent 8-hour time-weighted average exposures.
Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.
Percentages may not add to 100 percent due to rounding.

5.2.3 Additional Controls

Based on the one sample in the exposure profile (Table IV.5.2-B) that showed one exposure over the final PEL of 50 μg/m^3, OSHA finds that additional controls will be necessary to achieve the PEL for some drywall finishers some of the time (e.g., when overhead work places the breathing zone close to the silica exposure source). Additional controls could include substitution, ventilated sanders, wet methods, and pole sanders.

Substitution

The primary source of exposure for drywall workers is the use of silica-containing joint compounds. In cases of elevated exposure, the best control mechanism is substitution: changing to a joint compound that does not contain silica. NIOSH has indicated that there are a number of commercially available compounds that do not contain silica; OSHA therefore has concluded that substitution in new construction is possible most of the time. A representative of the National Association of Home Builders (NAHB), Mr. Gerald Howard, agreed, stating that much of the drywall joint compound currently used in residential construction has very low silica content and members can resolve any concerns with respect to silica exposure by making sure to use low silica containing product (Document ID 2296, Attachment 1, p. 30).

However, some joint compounds that do not list silica as an ingredient might still contain small amounts of silica, and during remodeling projects drywall finishers might be exposed while refinishing existing drywall surfaces that had used silica-containing joint compound (Document ID 1335, p. iii). Representatives from the Leading Builders of America (LBA) and the Construction Industry Safety Coalition (CISC) expressed concern about the reliability of controlling exposures by substituting silica-free joint compound during home construction. They cited NIOSH HETA-74-0078-2660 (1997), in which one worker performing sanding on low-silica or silica-free joint compound experienced a silica exposure of 80 μg/m^3 (Document 1335, p. 14).

CISC critiqued OSHA's findings for drywall finishers, asserting that "silica-free" joint compound is effective in keeping exposures below the proposed PEL only if it is "truly silica free" (Document ID 2319, pp. 38-40). CISC claims there are "significant concerns that silica-free joint compound in fact contains more than just trace amounts of silica and thus could result in significant exposures to silica under some conditions of use." This argument assumes noncompliance with OSHA requirements for material safety data sheets, see 29 CFR 1926.59, Hazard Communication), and is largely contradicted by the NIOSH study of drywall finishers in which six different containers of joint compounds were tested for silica content. Three of these joint compounds did not contain silica and the other three compounds contained less than "minor quantities" (less than 0.5 percent) of silica (Document ID 1335, pp. 3-4, 7, 10). The researchers concluded that for the most part the results of each sample analysis agreed with the composition stated in the manufactures' material safety data sheets. The subsequent air sample results collected when applying and sanding these joint compounds with limited controls (pole sander) showed 13 of 15 samples below 25 μg/m^3 (this standard's action level) and only 1 sample above the final PEL of 50 μg/m^3 (Document ID 1335, pp. 13-15). The one sample above the new PEL was taken on an individual who was performing overhead sanding without engineering controls. Researchers noted that when workers were sanding ceilings more dust appeared to be present in the workers' breathing zone than when they were sanding flat surfaces below eye-level (Document 1335, p. 8).

The NIOSH study was conducted on drywall workers using unspecified joint compounds, and bulk sample analyses revealed that three out of six joint compounds used contained silica (Document ID 1335, p. 8). There was no specific information about the silica content of the joint compound used at the site where the excessive exposure occurred. The work that was conducted was described as 'remodeling' work, and there was no indication that existing drywall joint compound was disturbed, which may have affected the results. Significantly, the total dust exposure of this sample also exceeded the OSHA Particulates Not Otherwise Regulated (PNOR) PEL (15 mg/m^3), which demonstrates that the work performed was excessively dusty. NIOSH noted that "when workers were sanding ceiling, or in tight confines such as closets or in corners, more dust appeared to be present in the workers' breathing zone than when they were sanding flat surfaces below eye level…" (Document ID 1335, p. 8). NIOSH's recommendation was to use engineering controls, such as wet finishing techniques, and personal protective equipment to limit exposures to dusts created during drywall finishing operations (Document ID

1335, p. iv). Due to the excessive dust exposures incurred by this worker on which the 80 $\mu g/m^3$ silica sample was collected, an employer would be required under 29 CFR 1926.55 to implement controls to reduce the amount of dust in the worker's breathing zone due to the particulate alone, regardless of its silica content. Therefore, due to the potential for excessive dust when drywall finishing, dust controls are frequently required even when using silica-free joint compound.

OSHA expects that the construction industry will largely be able to control silica exposures during drywall finishing through substitution. In the construction industry in general, there is an expectation that drywall finishers usually sand only new joint compound, but might briefly encounter older joint compound occasionally while sanding areas where repairs are being made on a pre-existing joint. Additional controls may be necessary when manipulating old building materials, including existing drywall joint compound, which may or may not contain silica. When working with known or suspected silica-containing joint compound, ventilated (or vacuum) sanders, wet methods, and pole sanders are all effective methods for controlling exposure to respirable crystalline silica (Document ID 0800).

Ventilated Sanders

NIOSH tested the effectiveness of five off-the-shelf ventilated sanding systems during drywall finishing: three designed to control dust during pole sanding and two to control dust during hand sanding. Total dust area sample results revealed that all five systems successfully reduced airborne dust exposures by 80 to 97 percent (Document ID 0849, p. 820). The effectiveness of ventilated sanders was confirmed in a study by Young-Corbett and Nussbaum (2009a), which found that using a ventilated sander during drywall sanding reduced respirable dust in the PBZ by 88 percent compared with a block sander used with no controls (Document ID 1239, p. 388). Although ventilated sanders are the most effective control option after substitution and offer indirect benefits to workers and managers, there are many perceived barriers to their adoption in the workplace. Workers and managers are concerned about: 1) maneuverability in small spaces, 2) reliance on a nearby power source, 3) product cost, 4) delays in learning the new equipment, and 5) maintenance (Document ID 1240, pp. 320-323). Furthermore, some models of ventilated sanders require a water source for the unit's water filter (Document ID 0213, Appendix C).

CISC criticized OSHA's reliance on the Young-Corbett and Nussbaum study that evaluated various sanding systems during drywall finishing tasks. The criticism focused on the use of a laboratory setting, the use of students instead of construction workers, a sampling time of 5 minutes, and the lack of respirable sampling specific to crystalline silica (Document ID 2319, p. 39). While all laboratory studies have limitations, the information provided by these studies constitutes the best available data on existing engineering controls for sanding systems in drywall finishing operations. OSHA concludes that the Young-Corbett and Nussbaum laboratory study simulated actual drywall finishing operations in the construction industry. The participants in the study were provided with instruction on the proper use of each sanding tool (Document ID 1239, p. 388). The sampling time and non-silica dust sampling were appropriate because of the repeated measures comparing dust generation rates of the four drywall sanding tools (Document ID 1239, p. 386).

In discussing the NIOSH study of drywall finishers, CISC expressed concern that pole sanders or sanders equipped with dust collection systems cannot be used in tight spaces and may result in quality issues (Document ID 2319, pp. 113-114). OSHA has not received any information or evidence in the record indicating that pole sanders or ventilated sanders cannot be used in tight spaces. CISC also pointed out that the NIOSH researchers acknowledged that some commercially available ventilated sanders lacked sanding head flexibility (Document 2319, p. 39; 0213, p. iv). The NIOSH researchers specified in their report that this was a subjective comment obtained from a questionnaire and that an additional control device, not incorporated into the experimental design, was tested and was able to overcome most of the flexibility problems (Document ID 0213, p. iv).

Certain defined types of experimental data are not intended to exactly replicate workplace conditions, but OSHA finds these data are useful in evaluating the effectiveness of controls. Studies may be intentionally designed to eliminate extraneous factors that would interfere with a correct interpretation of a control method's capacity to reduce silica emissions and associated exposure levels. Far from being a drawback, these studies typically are designed by the investigators to answer specific questions regarding the effectiveness of dust controls. The resulting data may be obtained under isolated conditions that ensure no additional sources of exposure are present. This exposure information can objectively show how well a control method works in an environment where other sources of silica are also controlled (e.g., as might occur on a well-controlled work site, or a site where only one source of silica exposure is active at a time). Sample results from the controlled condition are also routinely compared by investigators to the sample results for the uncontrolled condition. The resulting ratio shows the exposure reduction efficiency for the control method, independent of work rate variability, variations in construction materials, or other factors that do not relate to the individual control's functional performance. When available, this type of information is invaluable for ranking the benefits of one control method compared to another. As stated earlier in this section, the preferred control for drywall finishers is the use of commercially available joint compounds that do not contain silica. In the event that a company uses a silica-containing joint compound, or a worker comes into contact with existing silica-containing joint compounds, the use of ventilated sanders is a viable and feasible option for controlling dust as demonstrated by these studies (Document ID 0213; 1239). OSHA concludes that ventilated sanders provide a feasible and effective control for silica dust if silica-containing joint compound is used.

Wet Methods

The Young-Corbett and Nussbaum study (2009a) found that a wet sponge sander reduces respirable breathing zone dust concentrations generated from simulated drywall finishing tasks by 60 percent compared with a block sander used with no controls (Document ID 1239, p. 385). A wet sponge sander, which is a sponge with an abrasive surface, is one type of wet method. Other wet methods include wiping a clean, damp sponge over the still damp joint compound to smooth the seam and rinsing the sponge in a bucket of water as it becomes loaded with compound, or wetting dried joint compound with a spray bottle and sanding with sandpaper (Document ID 0213, App. C; 1240, p. 316). Although wet methods are technologically simple and can be used wherever a water source is available, a telephone interview of 264 drywall finishing companies found that less than 10 percent of these firms reported using them regularly (Document ID 1240, p. 318). Workers and managers have concerns about the finished texture, increased work time, mess, and adding moisture to the product, which could harm the product and delays painting (Document ID 0678; 0848; 0213; 1218; 1240). LBA and CISC noted that the Young-Corbett and Nussbaum (2009a) study did not recommend wet methods because the wet sponge performed poorly in terms of ease of use and perceived productivity (Document ID 2269, p. 16; 2319, p. 40). Although the study did note some difficulties using wet methods, OSHA continues to consider it a viable option for reducing exposures, given that it was found to reduce respirable dust by 60 percent (Document ID 1239, p. 385), and OSHA suggests that the use of a heat gun can expedite the drying process if necessary.

CISC objected to sanding with wet methods because it could result in an inferior end quality texture (Document ID 2319, p. 40). The companies who “rarely” or “never” used wet methods to control dust when drywall sanding cited quality and productivity concerns (Document ID 1240, p. 320). The major reasons were that it was hard to achieve the desired texture, it reintroduced moisture into the board, it took too much time, it was not cost effective, it was easier and faster to sand dry compound, and it was more difficult to sand wetted compound (Document ID 1240, p. 320). However, a survey of 264 drywall finishing firms, employing a total of 25,782 workers, revealed that in 2009 roughly half of these companies were using wet methods “always,” “often” or “sometimes” (Document ID 1240, pp. 318-19). This self-reported data indicates that the technology currently exists that makes the use of wet methods feasible for use in the field.

The LBA questioned the validity of OSHA demonstrating technological feasibility from the exposure reduction levels found in a study (Document ID 2269, pp. 16-17) using a laboratory setting versus a real world test. As OSHA explained in earlier in this subsection on additional controls (see discussion under the heading Ventilated Sanders), OSHA believes that the data from controlled environments is useful in assessing the effectiveness of controls.

Pole Sanders

A pole sander is a drywall finishing tool that incorporates a handle of various lengths with a base to hold the abrasive material for sanding. The pole sander creates distance between the worker and the point at which dust is generated reducing dust levels in the breathing zone (Document ID 0849, p. 821). Data from the Young-Corbett study found that a pole sander is almost as effective as a wet sponge sander, reducing respirable breathing zone dust concentrations generated from simulated drywall finishing tasks by 58 percent compared with a block sander with no controls (Document ID 1239, p. 388).

In the event that a joint compound containing silica is used, OSHA concludes that the use of pole sanders is a feasible control for reducing exposure to silica dust during sanding operations in the drywall finishing industry.

5.2.4 Feasibility Finding

The exposure profile in Table IV.5.2-B shows that 93 percent of silica exposures are at or below the 50 μg/m^3 PEL and 87 percent are below the action level of 25 μg/m^3. Therefore, OSHA concludes that most drywall finishers are currently at or below the PEL.

The preferred control for drywall finishers is the use of commercially available joint compounds that do not contain silica and therefore result in zero exposure. In the event that substitution is not practical, or during renovation work where silica-containing joint compound may be present, other available control options include ventilated sanders, wet methods, and pole sanders. Based on studies quantifying reductions in total dust levels when using ventilated sanders, OSHA estimates that the silica exposure of all drywall finishers can be reduced to levels at or below 50 μg/m^3 (Document ID 0800, p. 820; 1239, pp. 388-389). OSHA determined this estimate by reducing the highest drywall finisher reading summarized in Table IV.5.2-B (72 μg/m^3) by 80 percent, the minimum amount by which ventilated sanding equipment reduced respirable dust in the NIOSH study of drywall sanding techniques (Document ID 0213, p. iv). OSHA also concludes that the use of pole sanders and wet methods can reduce the silica exposure drywall finishers to levels at or below 50 µg/m^3 under circumstances when they offer a more convenient form of dust control. OSHA reached this conclusion by reducing the highest drywall finisher reading (72 µg/m^3) by 58 and 60 percent, the amounts by which pole sanding and wet methods, respectively, reduced total respirable dust (Document ID 1239, p. 388).

Accordingly, OSHA has determined that on the rare occasions when silica-containing joint compound might be encountered, exposures of less than 50 µg/m^3 can be achieved for most drywall finishers most of the time by using ventilated sanding equipment. Therefore, the standard is technologically feasible for the task of drywall finishing.

Removal of Drywall Finishers from Table 1

The entry on Table 1 for drywall finishers included in the proposed rule was removed in the final rule because drywall finishers can use drywall compound that does not contain silica, in which case, drywall finishing with silica-free substitutes would not be covered by the final rule. Sanding silica-free joint compound can potentially generate high levels of respirable nuisance dust that does not contain silica and for which respiratory protection may be needed in some situations. Therefore, OSHA removed the entry indicating that respiratory protection is not required when sanding drywall compound.

In the event that the use of silica-free joint compound is not possible, or during renovation work where silica-containing joint compound might be present, ventilated sanders, pole sanders, and wet sanding methods provide other available control options. Based on studies quantifying reductions in respirable dust levels when using ventilated sanders, OSHA concludes that the silica exposure of all drywall finishers can be effectively reduced to levels at or below the PEL (Document ID 0800; 0213; 1239) and therefore finds that the standard is technologically feasible for construction workers engaged in drywall finishing.

5.3 HEAVY EQUIPMENT OPERATORS AND GROUND CREW LABORERS

5.3.1 Description

Workers in this job category operate a variety of wheeled or tracked vehicles ranging in size from large heavy construction equipment (such as bulldozers, scrapers, loaders, cranes and road graders) to smaller and medium sized utility vehicles (such as tractors, bobcats and backhoes) with attached tools that are used to move, fracture, or abrade rock, soil, and demolition debris. Attachments can include augers, backhoes, buckets, hammers, hoe-rams, blades, draglines, rippers, scrapers, shovels, and trenchers (Document ID 1431, p. 3-34). In this section, OSHA analyzes both heavy equipment operators and the laborers who assist them; for both groups, exposures to respirable dust and respirable silica are expected to be fairly low. Operators generally spend most of their working time seated at some distance from the point of tool action. While larger heavy equipment has the potential to generate greater amounts of respirable dust, the operators of such equipment are typically positioned farther from the source of dust (at the point of tool action) than operators of smaller equipment. Dust control methods, primarily the use of water suppression, are similar across all types and sizes of equipment.

Table IV.5.3-A provides an overview of the tasks performed by heavy equipment operators, which include loading and dumping rock and soil, as well as demolition debris from concrete or masonry structures. When these materials contain crystalline silica, dust generated during these activities is a primary source of exposure for the equipment operators and for laborers working in the vicinity (see Exposure Profile, Table IV.5.3-B). Workers who operate heavy equipment typically spend most of their working time in an operator’s seat. In contrast, ground crew laborers may on occasion work in closer proximity to the point of tool action (Document ID 3589, Tr. 4185). Equipment and operations reviewed here do not include rock or concrete drilling rigs, rock crushers, asphalt or concrete milling machines, drivable saws, or tunnel boring machines; these types of equipment and operations are reviewed in other sections of the feasibility analysis.

5.3) Heavy Equipment Operators and Ground Crew Laborers

Table IV.5.3-A
Job Categories, Major Activities, and Sources of Exposure of Heavy Equipment Operators and Ground Crew Laborers

Job Category*	Major Activities and Sources of Exposure
Heavy Equipment Operator	From an operator's seat, manipulating tractor or vehicle-based implements (e.g., backhoe, crane, power shovel, excavator, hammer, dump truck) to perform activities such as excavation, loading, and dumping of rock, concrete, soil, and other construction materials and debris during earthmoving and demolition. • Dust from demolition activities, the breakdown of construction materials, and the transport of construction debris. • Dust from abrading or fracturing during rock and earthmoving activities (rock ripping, hoe-ramming) or from load transfer of silica-containing materials. • Fugitive dust from the movement of heavy equipment on silica-containing material (e.g., haul roads, work sites).
Ground Crew Laborer Assisting Heavy Equipment Operator	Working near heavy equipment supporting the heavy equipment operator (applying dust suppressant, spotting, clearing debris). • Dust from demolition activities, the breakdown of construction materials, and the transport of construction debris. • Dust from abrading or fracturing during rock and earthmoving activities (rock ripping, hoe-ramming). • Fugitive dust from the movement of heavy equipment on silica-containing material (e.g., haul roads, work sites).

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.
Sources: Document ID 1431, pp. 3-34--3-37; 1720, Table IV.C-53, p. IV-395; 3583, Tr. 2388, 2440; 3589, Tr. 4185.

In the PEA, OSHA did not distinguish between different kinds of work involving the use of heavy equipment. OSHA included all earthmoving work, as well as demolition work, within the category of "Heavy Equipment Operators." Furthermore, Table 1 of the proposed rule described these operations as "Use of Heavy Equipment During Earthmoving." Several commenters requested clarification on what uses of heavy equipment OSHA intended to cover by the entry on Table 1 in the proposed rule. The

International Union of Operating Engineers (IUOE) did not believe that earthmoving should be the focus, stating:

> [T]his activity does not fracture or abrade silica-containing materials, and thus, does not expose heavy equipment operators to high concentrations of respirable silica….There are earthmoving activities, such as "rock ripping," which fracture or abrade silica-containing materials (Document ID 2262, p. 6).

The IUOE's position was supported by Martin Turek, Assistant Coordinator and Safety Administrator for IUOE Local 150, who testified that "it is unlikely that moving soil or clay will generate respirable silica in concentrations … above the [proposed] PEL" (Document ID 3583, Tr. 2358). Brad Sant, Senior Vice President of Safety and Education at the American Road and Transportation Builders Association (ARTBA) also felt OSHA should differentiate between typical earth moving and moving concrete debris. He stated:

> So if you're doing blasting or something where you know you're breaking up the material, that's a high hazard area and that's someplace where you really need to pay attention. If you're moving dirt that's clay, that's not likely to have a lot of silica, that's something we could just set aside. And so you're really going to focus on the hazardous areas that are known hazards and deal with it in a little more thoughtful way (Document ID 3583, Tr. 2258-2259).

The IUOE recommended that the "standard make clear that earthmoving and demolition are not the same construction activity" (Document ID 2262, p. 15). They suggested that standard earthmoving activities, such as site clearance and road preparation, should be analyzed separately from demolition activity. They also recommended that OSHA target the standard to address heavy equipment operations that can rip or abrade soil or rock in such a way as to cause exposure to respirable silica dust. Examples of operations IUOE identified as potential sources of exposure to respirable silica dust include using a hoe-ram attachment on a backhoe to break up boulders into smaller rock, and ripping soil and rock when "a shank is attached to the back of a bulldozer and pulled through the ground." (Document ID 4234, IUOE Post Hearing Brief Part 1, pp. 10-11).

In their post hearing brief, IUOE recommended that OSHA adopt the following definition of earthmoving: "Earthmoving as used on Table 1 means an activity that fractures or abrades silica-containing materials in such a manner as to generate airborne concentrations of respirable silica at or above the action levels. Earthmoving does not include demolition or underground construction" (Document ID 4234, pp. 9-10). The director of Occupational Safety and Health for the Laborer's Health and Safety Fund of North America agreed with IUOE. He testified that the Agency should reconsider how demolition is treated in Table 1, stating that "Demolition, by its nature, involves the crushing of construction materials which contain silica" (Document ID 3589, Tr. 4185). ARTBA also agreed with IUOE that the material being moved can be a more important consideration than the operation itself:

> You can be moving huge amounts of material in an earthmoving operation where there is very little silica content and have very little exposures. Where on the opposite end, you could be moving crushed granite or something like that that has a very high [silica] content …where exposures can be high (Document ID 3583, Tr. 2256).

In response to these comments and testimony, OSHA agrees that it is appropriate to separate demolition and other activities that abrade or fracture silica-containing material from other earthmoving tasks, such as site preparation and road development, which involve, but do not abrade or fracture, silica-containing material. OSHA has restructured its exposure profile and technological feasibility analysis accordingly.

5.3.2 Exposure Profile and Baseline Conditions

The exposure profile presented in the PEA included 24 full-shift time-weighted average (TWA) personal breathing zone (PBZ) respirable quartz readings. These sampling results were obtained from four NIOSH reports, five OSHA Special Emphasis Program (SEP) inspection reports, and one journal article (Document ID 1431, p. 3-34). In response to comments, the exposure profile in the FEA was reorganized and updated with four samples obtained from the OSHA Information System (OIS) (Document ID 3958) and eleven samples from three studies submitted by a commenter (Document ID 4073, Attachments 9a, 10a, and 10c). After close review of the samples used in PEA exposure profile, four samples were removed: one sample for a loader operator loading earth into trucks underground since it was taken during tunnel development; one sample for a crane operator lifting and placing new construction materials in support of the drilling rig since it did not involve handling materials containing silica; and two samples for water truck drivers supporting a walk-behind masonry saw because they did involve the operation of heavy equipment. (Document ID 0192; 0226; 1431).

The final exposure profile in Table IV.5.3-B includes 35 samples of respirable crystalline silica for heavy equipment operators. The median is 12 μg/m^3, the mean is 26 μg/m^3, and the range is 4 μg/m^3 to 170 μg/m^3. Of the 35 samples, 3 of the samples (8.6 percent) are above 50 μg/m^3.

The new data from the OIS include exposure measurements taken on three different demolition sites. All three demolition sites used wet methods. A backhoe operator who was demolishing concrete inside a large garage had a TWA exposure of 43 μg/m^3, and the laborer assisting the backhoe operator had no detectable silica exposure. A sample for an operator of a hoe-ram, which was being used to break-up concrete slabs, showed a TWA exposure of 49 μg/m^3. No detectable silica exposures were found for an operator using a skid steer to move demolition debris and an excavator to load the debris in a truck (Document ID 3958). These four sample results were added to the exposure profile.

Four personal air samples added to the exposure profile were collected during an evaluation of employees' exposures to respirable silica dust during the demolition and processing of a concrete foundation (Document ID 4073, Attachment 10a, p. 7). Two heavy equipment operators (one using an excavator to demolish a concrete foundation and load the debris into a truck and another who fed the transported material to a mobile crusher using a loader) were assessed over two days. Only one of the four personal air samples measured a respirable crystalline silica concentration above the limit of detection (15.0 μg/m^3) (Document ID 4073, Attachment 10a, pp. 9-12). The evaluation report did not mention dust control methods other than the appropriate use of respirators.

Another two personal air samples added to the exposure profile were collected during a separate evaluation of employees' exposures to respirable silica dust at the same site

(Document ID 4073, Attachment 10c, p. 7). One sample was collected for a loader operator loading concrete debris into a pulverizing machine. The loader was equipped with a sealed cabin with filtered air. No respirable crystalline silica was detected. The other sample was collected for a bobcat operator who pushed and layered pulverized concrete by dragging a steel beam across the area until the material was level. Water was applied to the pulverized material to limit dust emission. Respirable crystalline silica was detected in the Bobcat operator's sample, but it was below 12.0 μg/m^3.

Three personal air samples added to the exposure profile were collected during a study to characterize workers' exposures to respirable silica during demolition, as well as to evaluate the efficacy of dust suppression methods for reducing dust exposures at two demolition sites (Document ID 4073, Attachment 9a, p. 3). Two laborers applied water, using hoses near the excavators, to suppress dust. Another held a hose on a fire truck. Water atomizing spraying systems designed to suppress dust after it becomes airborne were used on site. Results showed two of the laborers exposed below 12.0 μg/m^3. For the third laborer, the study reported a respirable crystalline silica exposure of 31.0 μg/m^3.

Two additional personal air samples were added to the exposure profile for employees engaged in work directly related to heavy equipment operation during demolition tasks. Two of the samples are from a survey report on the demolition of plaster ceilings. One laborer assisted a skid-steer loader operator by spraying water on the debris (including plaster ceiling) with water. The other laborer assisted a track-hoe operator by spraying water on the ceiling and debris as the plaster ceiling was pulled down. Their estimated 8-hour TWA exposures were 37 and 49 μg/m^3, respectively (Document ID 0858, pp. iv, 7). This group of employees (engaged in work directly related to heavy equipment) is supplemented by a personal air sample already mentioned above in the description of OIS data added to the exposure profile. This laborer experienced no detectable silica exposure while spraying water on debris as an assistant to a backhoe operator demolishing concrete inside a large garage (Document ID 3958).

As previously discussed, the exposure profile divides the tasks performed by heavy equipment operators and their laborers/assistants into two types: 1) demolition and activities that fracture or abrade crystalline silica-containing material; and 2) non-abrading or non-fracturing earthwork, such as excavation and load transfer of silica-containing materials. OSHA considers employees to be engaged in a given type of task if they are either operating the equipment to perform the task or assisting the heavy equipment operator who is performing the task. Assisting includes, but is not limited to, applying wet dust controls, spotting, and maintaining a safe work space.

Based on the exposure profile presented in Table IV.5.3-B, OSHA estimates that 91 percent of heavy equipment operators and the laborers who assist them have respirable crystalline silica exposures at or below the PEL of 50 μg/m^3. Heavy equipment operators spend most of their working time seated at some distance from the dust source, and their work is usually done outdoors in open spaces under various weather conditions. Heavy equipment operators are typically seated 2-3 meters above the point of dust generation (Document ID 3998, Attachment 5b 5, p. 120). The exposure profile shows that 92 percent of equipment operators performing demolition or fracturing or abrading of silica-containing materials are exposed at or below 50 μg/m^3, and 88 percent of heavy equipment operators not involved with the demolition or fracturing or abrading of silica-containing materials are exposed at or below 50 μg/m^3. Also, according to the exposure profile, laborers who assist heavy equipment operators during demolition all have exposures at or below 50 μg/m^3. The exposure profile contains no information specific to ground crew laborers assisting heavy equipment operators performing non-abrading or non-fracturing earthwork (excavating, grading, load transferring). Heavy equipment operators performing these tasks usually do not need direct assistance from laborers. Occasionally, these heavy equipment operators will need assistance, such as spotting or grubbing. Workers who are not operating the heavy equipment, and workers who are performing jobs nearby, may be called on to help and may be exposed to fugitive dust in the process (Document ID 3998, Attachment 13q 13, p. 1; 2116, p. 17). It is likely that these laborers spend most of their shifts performing activities that are covered by other sections of OSHA's technological feasibility analysis (e.g., jackhammering).

Demolition and rock and earthwork activities that fracture or abrade crystalline silica-containing material involve machines equipped with augers, backhoes, buckets, hammers, hoe-rams, blades, draglines, rippers, and trenchers (Document ID 1431, p. 3-34). Demolition occurs mostly outdoors; however, in some cases, smaller to medium-size heavy equipment (such as track-hoes or bobcats) can be operated inside buildings or other structures. Restricted air movement in an enclosed area can result in the accumulation of airborne dust and an increased potential for high exposures in poorly ventilated spaces. The exposure profile contains several measurements associated with demolition conducted inside buildings. The demolition of roads and building infrastructure involves the breaking, chipping, and crushing of silica-containing material; these are inherently dusty operations that are typically conducted outdoors.

Much non-silica-abrading and non-silica-fracturing earthmoving involves machine excavation and fill or backfill. Typical earthmoving activities in this category involve roads, causeways, dams, levees, canals, and berms. Tasks include land grading to reconfigure the topography of a site or to stabilize slopes; roadway excavation; and stripping or clearing excess earth for site preparation. Significant atmospheric dust arises from the mechanical disturbance of granular material. Dust generated from these open sources is termed "fugitive" because it is not discharged to the atmosphere in a confined flow stream. Common sources of fugitive dust include unpaved roads, aggregate storage piles, and heavy construction operations. For these sources of fugitive dust, the dust is generated by two basic physical phenomena: 1) pulverization and abrasion of surface materials by application of mechanical force through implements (tracks, blades, etc.); and 2) entrainment of dust particles by the action of turbulent air currents, such as wind erosion of an exposed surface. Emissions will vary depending on: the characteristics of the material being disturbed (such as moisture content, particle sizes, and weight); the nature of the loading and removal activity; dust control procedures; and wind (Document ID 3637, pp. 3-10, 3-11).

A representative of Fann Contracting, Inc., a company that performs highway construction projects primarily in northern and eastern Arizona, stated:

> Exposure to potential silica containing dust from construction in Arizona is much greater than potential exposure to silica containing dust in Missouri or Oregon or Alaska due to soil characteristics and

> environmental conditions, along with the proposed rule lumping maritime and general industry indoor industries with outdoor construction activities, yet OSHA is trying to draft a nationwide rule that one size fits all but there are too many weather and environmental variables across the entire United States to take into account (Document ID 2116, p. 3).

While there is regional variation in climate and the silica content of the soil, the commenter provided no evidence that would allow OSHA to assess the potential effects of regional differences on silica exposures among heavy equipment operators and laborers. OSHA recognizes that environmental conditions may impact the amount of water required to suppress dust in a given situation and expects employers to account for variation by adjusting the amount of water used or the frequency of water applications. Water used as a dust suppressant has little residual effect on some types of soil, roads, or work sites and may need to be re-applied at the dust source. Applying a mixture of water and surfactants or salts provides better fugitive dust control for some locations (Document ID 0548, pp. 1, 2; 1540, pp. 253, 254; 0933, pp. 56, 57).

Table IV.5.3-B shows that approximately 7.7 percent of operators, and no laborers, involved in demolition, abrading or fracturing activities have exposures exceeding 50 $\mu g/m^3$ (N=19). Roughly 12 percent of operators involved in non-abrading and non-fracturing earthwork have exposures above that level (N=16). Although the median (12 $\mu g/m^3$) and mean (26 and 25 $\mu g/m^3$, respectively) exposures are similar for demolition, abrading and fracturing operators and for operators performing non-abrading and non-fracturing earthwork, the latter have a wider range of exposures (maximum result of 170 $\mu g/m^3$).

OSHA notes that the air sampling data in the profile reflect low exposures associated with the use of wet methods or the extensive use of calcium chloride. The data for demolition, abrading, and fracturing operators and laborers includes nineteen samples taken at ten sites. Two sites did not use wet methods to suppress dust, while eight sites used wet methods (and one of those eight sites used a sealed cab in addition to wet methods) (Document ID 3958, Rows 5, 16; 0228, pp. 5, 9; 0858, pp. 6-7; 0226, p. 11; 0170, p. 12; 4073, Attachment 10a, p. 7).

The data for non-abrading and non-fracturing earthmoving tasks includes sixteen samples taken at eight sites; nine of those samples (56 percent) were taken when water or calcium chloride were used for dust suppression. One heavy equipment operator used a sealed cab at a site without water suppression (Document ID 3958, Row 954; 0226, p. 11; 0228, p. 9; 0133, p. 17; 0716, p. 16; 4073, Attachment 10c, p. 7).

Authors drawing on data from a variety of sources have reported slightly higher exposure levels for heavy equipment operators than what is reported in the exposure profile; however, their data sets included operators of particularly dusty equipment that OSHA addresses in other sections of this technological feasibility analysis (see Sections IV-5.8 – Millers Using Portable or Mobile Machines, IV-5.9 – Rock and Concrete Drillers, and IV-5.10 – Mobile Rock-Crushing Machine Operators and Tenders) (Document ID 3998, Attachment 5b 5, pp. 112, 117).

Working with a large set of construction data, Flanagan et al. (2006) reported a geometric mean silica exposure of 50 μg/m^3 for 102 workers operating many types of heavy equipment (Document ID 0677, p. 147; 0677, Attachment 2). For the 45 measurements that were associated with the specific task of demolition, the geometric mean was lower, at 30 μg/m^3. Thirty measurements taken for workers specifically operating backhoes, excavators, bulldozers and bobcats for demolition, road work, tunnel, and other industrial operations tended to be even lower, with a geometric mean of 10 μg/m^3; this was the lowest result reported among the various construction tool or equipment categories evaluated. As noted by CISC, the authors did not provide detailed information about controls or sample durations (Document ID 2319, pp. 41-42). However, the authors did report that the median sample time for the entire construction database was 219 minutes. These results, which were not expressed as 8-hour TWA values, confirm that many heavy equipment operators already experience silica exposure levels of 50 μg/m^3 or below (Document ID 0677, pp. 146-147). As compared to workers performing many other types of construction activities, heavy equipment operators are more often engaged in tasks lasting more than four hours. Of the 23 samples in the exposure profile for which the sample duration was available, 19 (83 percent) exceeded 240 minutes;, the median sample duration was 469 minutes (Document ID 0133, pp. 9, 11, 12, 14, 15, 17; 0170, pp.

11, 12, 13; 0226, p. 11; 0228, pp. 9, 15; 0716, pp. 16, 56; 0858, p. 7; 1431, pp. 3-34, 3-37; 3958, Rows 5, 16, 237; 4073, Attachment 9a, p. 3; 4073, Attachment 10a, p. 7; 4073, Attachment 10c, p. 5, 7).

OSHA reviewed several studies received during the comment period indicating that demolition conducted by heavy equipment operators typically results in TWA exposures at or below 50 μg/m^3. Bello and Woskie (2014) measured exposures for an excavator operator during demolition; the operator's exposures ranged from 9 to 13 μg/m^3 (Document ID 4073, Attachment 9a, p. 3). A study of silica exposures among Canadian construction workers reported average exposures of 30 μg/m^3 for heavy equipment operators during demolition (Document ID 3747, p. 8). The same authors reported that eight 12-hour TWA silica exposures on operators of heavy equipment during "earthmoving" operations ranged from less than 7 to 29 μg/m^3 (Document ID 3747, p. 79).

Baseline operating conditions for heavy equipment operators engaged in demolition or fracturing or abrading silica-containing materials are operating heavy equipment without a sealed cab using water as a dust suppressant. The majority (92 percent) of silica exposures for these workers in OSHA's exposure profile are less than or equal to 50 μg/m^3 (Document ID 0133, pp. 9, 11, 12, 14, 15, 17; 0170, pp. 11, 12, 13; 0226, p. 11; 0228, pp. 9, 15; 0716, pp. 16, 56; 0858, p. 7; 1431, pp. 3-34, 3-37; 3958, Rows 5, 16, 237; 4073, Attachment 9a, p. 3; 4073, Attachment 10a, p. 7; 4073, Attachment 10c, pp. 5, 7). One of the three samples in the profile involving heavy equipment operators using only water as a dust suppressant during demolition activities shows exposures above 50 μg/m^3 (see Table 26-OL).

Baseline operating conditions for laborers engaged in demolition or tasks involving abrading or fracturing silica-containing material involve using water and/or calcium chloride as a dust suppressant. For the samples included in the exposure profile, the use of a dust suppressant was indicated for all laborers engaged in tasks using heavy equipment (Document ID 3958, Row 5; 0858, p. 7; 4073, Attachment 9a, p. 3). Exposures for these employees were at or below 50 μg/m^3.

5.3) Heavy Equipment Operators and Ground Crew Laborers

Baseline operating conditions for heavy equipment operators not abrading or fracturing silica-containing material are operating heavy equipment with a cab with the windows or doors open. Use of dust suppressants (water or calcium chloride) to minimize dust was indicated for just over half of the samples (9 out of 16). The majority (88 percent) of silica exposures for these workers in OSHA's exposure profile are less than or equal to 50 μg/m^3. The use of dust suppressants appears to provide protection, as the majority of heavy equipment operators performing these tasks had exposures below 25 μg/m^3 (Document ID 1431, pp. 3-34, 3-37; 3958, Row 237; 0133, pp. 9, 11, 12, 14, 15, 17; 0226, p. 11; 0228, p. 9; 0716, pp. 16, 56; 4073, Attachment 10c, pp. 5, 7).

OSHA found (above in this subsection) that ground crew laborers or workers assisting heavy equipment operators excavating, grading, or load transferring have little potential for direct exposure to silica. Water is frequently applied to work sites for dust suppression and to aid in soil compaction decreasing the risk to employees not assigned to specific tasks (Document ID 3747, p. 126; 1533, p. 57; 2116, p. 31). Where the application of dust suppressants is not sufficient, laborers could be exposed to large amounts of respirable dust (e.g., while surveying, performing maintenance, or flagging). At an earthworks work site in Alberta, Canada, large dust plumes were observed generated by heavy equipment where workers were nearby (Document ID 3747, pp. 61, 82-84).

Phillip Rice from Fann Contractors, Inc., stated that EPA (or in Arizona the Arizona Department of Environmental Quality or ADEQ) rules and regulations requires the use of water spray systems to be installed and operated continuously on all material transfer point locations, using water spray or equivalent on haul roads, and where mobile equipment operate around a crusher to keep dust down. He noted that the water does help keep the dust down if used as required (Document ID 2116, p. 31). OSHA believes that when dust is controlled at the source, such as applying water during earthmoving activities and on haul roads, laborers and bystanders are not exposed above 50 μg/m^3.

Table IV.5.3-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Construction Workers: Heavy Equipment Operators and Ground Crew Laborers

	Exposure Summary			Exposure Range			Exposure Profile				
Heavy Equipment Tasks	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**		**< 25 (μg/m³)**	**≥ 25 and ≤ 50 (μg/m³)**	**> 50 and ≤ 100 (μg/m³)**	**> 100 and ≤ 250 (μg/m³)**	**> 250 (μg/m³)**
Demolition/Abrading/Fracturing Equipment Operator	13	26	12	11	87		9 (69.2%)	3 (23.1%)	1 (7.7%)	0 (0%)	0 (0%)
Demolition Laborer	6	25	22	8	49		3 (50%)	3 (50%)	0 (0%)	0 (0%)	0 (0%)
Excavating/Grading/Load Transfer Equipment Operator	16	25	12	4	170		14 (87.5%)	0 (0%)	1 (6.2%)	1 (6.2%)	0 (0%)
Heavy Equipment Operators Total	**35**	**26**	**12**	**4**	**170**		**26 (74.3%)**	**6 (17.1%)**	**2 (5.7%)**	**1 (2.9%)**	**0 (0%)**

Notes: All samples are personal breathing zone (PBZ) results and represent 8-hour time-weighted average exposures.
Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.
Percentages may not add to 100 percent due to rounding.

Table IV.5.3-C compares silica exposures among heavy equipment operators with the silica exposures of laborers engaged in the same task. This data is a subset of the exposure profile (Table IV.5.3-B). In each instance listed, the laborer provided water for dust control during demolition activities. The heavy equipment operators' exposures are higher than the laborers' exposures except when the operator is in a sealed cab.

Table IV.5.3-C
Comparison of Exposures Between Heavy Equipment Operators and Assisting Laborers

	8-Hour TWA RCS, µg/m³				
Heavy Equipment	**Operator**	**Laborer**	**Laborer Task**	**Controls**	**Silica Containing Material**
Backhoe	43.3	12.0	Spraying water on debris.	Water	Concrete
Excavator	87.0	49.0	Spraying water on debris	Water	Plaster
Bobcat	49.0	37.0	Spraying water on debris	Water	Plaster
Excavator	Less than 9	31.0	Holding hose	Water/Sealed Cab-Operator	Brick Building
Excavator	Less than 9	12.0	Holding hose	Water/Sealed Cab-Operator	Brick Building
Excavator	Less than 9	8.0	Holding hose	Water/Sealed Cab-Operator	Brick Building

5.3.3 Additional Controls

The exposure profile in Table IV.5.3-B shows that approximately 9 percent (3 out of 35 samples) of heavy equipment operators have exposures above the final PEL of 50 µg/m^3. Therefore, OSHA finds that the additional controls described below will be necessary to achieve the PEL for these overexposed workers.

Enclosed Cabs

In situations where heavy equipment operators have elevated exposures to respirable crystalline silica during the demolition and fracturing or abrading of silica-containing materials, a properly ventilated enclosed cab under positive pressure with filtered air can be used to reduce exposures. Rappaport et al. (2003) reported an 85 percent reduction in exposures among heavy equipment operators performing highway construction activities in enclosed cabs as compared to operators in open cabs (10 μg/m^3 versus 65 μg/m^3) (Document ID 3998, Attachment 5b 5, pp. 119-120). Maintaining cabs in good operating condition is a part of reducing operator exposures to respirable dust. NIOSH has reported that studies show properly maintained cabs can attain dust reductions of between 44 and 100 percent for dozers (Document ID 1540, p. 258).

Pannell and Grogin (2000) reported that pressurized, enclosed cabs without high-efficiency filtration can provide a high degree of protection for operators performing excavation work where the silica content of the soil is unusually high (Document ID 0952, pp. 14, 16). For 44 samples obtained for workers operating a water wagon or a scraper with pressurized, enclosed cabs not equipped with high-efficiency filtration, the investigators reported mean respirable dust results of 72 μg/m^3 for each group (over sampling periods of 4- to 5-hours) (Document ID 0952, p. 15). These respirable dust values were roughly 80 to 90 percent lower than the results obtained for operators of open-cab equipment, who had mean respirable dust exposures of 426 μg/m^3 (four results for grader operators), 672 μg/m^3 (40 results for dozer operators), and 837 μg/m^3 (10 results for workers operating a second dozer) (Document ID 0952, p. 15). Respirable dust samples collected inside and outside a scraper showed that the pressurized, enclosed cab reduced the operator’s exposure by nearly 90 percent (Document ID 0952, p. 16). The project in this study involved constructing a solid low-level radioactive waste disposal facility, which was unusual in that the 64,000 cubic meters of soil that was excavated contained up to 65 percent silica in a semi-arid environment, creating unusually high respirable silica exposures. The authors recommended the following actions, among others, to minimize exposures: (1) use equipment furnished with environmentally controlled pressurized cabs; (2) use water spays for dust suppression; and (3) regularly clean cab interiors to prevent re-suspension of tracked-in dust (Document ID 0952, p. 17).

NIOSH has recommended several design and operational features for cabs in order to minimize operators' exposures to respirable dust during construction activities (Document ID 0839, pp. 2-3). The NIOSH recommendations are as follows:

- Cabs should be equipped with a recirculation filter that continuously filters the air circulating within the cab to eliminate dust that has entered the cab (e.g., on shoes, or through an open door);
- The inlet for intake air should be strategically located so that it avoids, as much as possible, the equipment's major dust sources. Typically, this means high above ground level;
- Cabs should avoid the use of floor heaters or any discharge of clean air low in the cab, which entrains dust from the floor and dirty work clothes before entering the worker's breathing zone. Ideally, air flow would circulate from the top of the cab to the bottom, and recirculation pick-up would occur low in the cab; and
- Cabs must be well maintained and kept clean. Filters must be changed regularly so that they do not become overloaded with dust, and seals must be maintained to preserve pressurization inside the cab. A gritless, natural base sweeping compound should be applied to the floor of the cab to bind dirt and dust tracked in during normal work activities. The compound should also be used for regular housekeeping activities (Document ID 0839, pp. 2-3; 1540, p. 233).

CISC commented that OSHA's reliance on two samples for enclosed cabs and 17 samples for unenclosed cabs in the PEA was insufficient to assess the exposures of heavy equipment operators who work all across the country in widely varying environments. In addition, CISC noted that the study by Pannel and Grogin, described above, did not analyze pressurized cabs with high-efficiency filtration (Document ID 2319, pp. 41-42). In addition to the data in OSHA's exposure profile, the research shows that enclosed cabs are effective in greatly reducing silica exposures among heavy equipment operators (Document ID 3998, Attachment 5b 5, pp. 119-120; 0952, pp. 14, 16). Table IV.5.3-C also shows that heavy equipment operators' exposures exceeded the exposures of their assisting laborers except for when the operators were in enclosed cabs. In response to CISC's comment about the lack of literature on high-efficiency filtration, OSHA has removed the requirement for high-efficiency filtration from the regulatory text and now only requires 95 percent efficiency.

In its post-hearing submission, IUOE identified several companies that retrofit enclosed cabs or manufacture equipment used for air filtration and pressurization, including Sy-Klone, Clean Air Filters Company, Red Dot Corporation, Polar Mobility Research Ltd., and MI Air Systems (Document ID 4025, p. 11).

Use of Wet Methods or other Dust Suppressants

The application of water has been shown to be effective in controlling dust containing respirable crystalline silica (Document ID 4073, Attachment 8e, pp. 14-15; 0839, p. 2; 1540, p. 61; 1533, pp. 56-60). Tank trucks equipped with hoses and nozzles can provide water or other dust suppressants during earthmoving tasks that cover large areas, haul roads, and job sites in general. In addition, in many instances, laborers assist heavy equipment operators by applying water or other types of dust suppressants to material being demolished, abraded, or fractured.

In one instance, a heavy equipment operator with an exposure concentration of 87 $\mu g/m^3$ was using a track-hoe without an enclosed cab, indoors on the ninth floor of a building, pulling down plaster ceiling. The laborer assisting the operator sprayed the ceiling with water as it was pulled down. This laborer's exposure was below 50 $\mu g/m^3$ (Document ID 0858, p. 7).

Use of water or other dust suppressants during the operation of heavy equipment can address exposures among bystanders, such as employees who do not operate the heavy equipment or who are performing jobs nearby at the site (Document ID 3998, Attachment 13q 13, p. 1).

Water mist can be delivered to points where silica-containing material is being disturbed by water truck and manual spraying, or by large atomized misting devices (e.g., by Dust Boss or Buffalo Turbine) that permit water mist to be delivered from farther distances (Document ID 4234, Attachment 4, p. 2; 4073, Attachment 4a). In some cases, dust suppressants have been applied using spray equipment attached directly to the tool on a large excavator (Document ID 1217, pp. 6, 11, 12). A study by Addo and Sanders (1995) offers support for the effectiveness of dust suppressants. The study examined three chemical dust suppressants (lignosulfate, calcium chloride, and magnesium chloride) applied to an unpaved roadway for four and a half months and found that, compared to an untreated roadway, the suppressants reduced fugitive dust emissions by 50 to 70 percent (Document ID 1533, p. 63).

NIOSH described several test results of watering haul roads with control efficiency ranging from 40 percent to 95 percent. The control efficiency for water can be highly variable as it is dependent upon the frequency of the water application, the type of road material in question, traffic, and weather conditions (Document ID 1540, p. 252). In a report on the characteristics of fugitive dust generated from unpaved mine haulage roads (Organiscak and Reed), the authors found that “road wetting was very effective in suppressing the respirable dust generated by the haulage trucks” (Document ID 4073, Attachment 8e, p. 15). The most common method of haul road dust control is surface wetting with plain water, but other methods include adding hygroscopic salts, surfactants, soil cements, bitumens, and films (polymers) to the road surface (Document ID: 1539, p. 69). Road material used for unpaved mine haulage roads are similar to unpaved haulage or construction roads. Dust controls such as wet methods can therefore be applied similarly to minimize exposures to haulage road fugitive dust.

Several hearing participants addressed the effectiveness of wet methods and other dust suppressants. In most situations where dust is present, utility excavators are already requiring the use of wet methods, and in some situations respirators, to control dust exposures, and these control methods appear to be working (Document 3583, Tr. 2241). A representative of the National Rural Electric Cooperative Association (NRECA) stated that use of wet boring methods plus enclosed-cab excavators results in no detectable respirable crystalline silica exposures for employees performing excavation work (Document ID 3583, Tr. 2277). Kyle Zimmer, a representative of IUOE Local 478, testified that calcium chloride is regularly used as a dust suppressant during site work in cold weather because chloride compounds lower the freezing point of water (Document ID 3583, Tr. 2342). He also testified that the variables that affect silica concentrations are often highly predictable and that a competent person can adjust controls to adapt to changing conditions (Document ID 3583, Tr. 2351).

As demonstrated by OSHA's exposure profile data and the other evidence in the record, dust suppression methods (such as wet methods) are a commonly used and effective means for reducing exposures among heavy equipment operators and laborers to 50 μg/m^3 or below.

5.3.4 Feasibility Finding

Table 1 of the final rule for construction requires employers to use specified engineering controls with heavy equipment unless the employer assesses and limits exposures in accordance with paragraph (d). With respect to heavy equipment used in demolition or the abrading or fracturing of silica-containing material, Table 1 provides that when only one employee is engaged in the task, the operator must be in an enclosed cab or when other employees are engaged in the task, the operator must be in an enclosed cab and the employer must ensure that water and/or dust suppressants are applied as necessary to minimize dust emissions. For heavy equipment used for earthmoving tasks involving silica-containing material that do not involve demolition or abrading or fracturing (including excavating, grading, and load transfer), Table 1 provides that when only one employee is engaged in the task, the operator must be in an enclosed cab or the employer must ensure water or dust suppressants are applied as necessary to minimize dust emission or when other employees are engaged in the task, the employer must ensure that water and/or dust suppressants are applied as necessary to minimize dust emissions, in which case there is no requirement for an enclosed cab. The evidence presented in this section shows that use of the specified dust control systems result in greatly reduced worker exposures to respirable crystalline silica. As discussed above, water use for dust control is widely practiced where heavy equipment is used for demolition and other earthmoving operations, and environmentally controlled cabs are readily available on new equipment and can be retrofitted on existing equipment.

Feasibility Finding for Demolition and Abrading or Fracturing Silica-containing Materials

Enclosed cabs and the application of dust suppressants have been demonstrated to be effective means for reducing exposures in heavy equipment operators during demolition or tasks involving the abrading or fracturing of silica-containing materials.

OSHA finds that the use of an enclosed cab can effectively keep exposures to 50 μg/m^3 or below for heavy equipment operators. When laborers are present, the use of wet methods or other dust suppressants will keep exposures at or below 50 μg/m^3 most of the time.

OSHA concludes that most heavy equipment operators and laborers engaged in the demolition, abrading, or fracturing of silica-containing materials are currently exposed to silica levels at or below 50 μg/m^3. (12 of 13 samples in the exposure profile for heavy equipment operators, and all 6 samples for laborers doing demolition activities, were 50 μg/m^3 or below.) For workers who are currently exposed above 50 μg/m^3, the controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or below in most operations, most of the time. Therefore, OSHA finds that the standard is technologically feasible for workers doing this work.

Feasibility for Earthmoving Activities Involving Silica-containing Materials other than Demolition or Fracturing or Abrading

OSHA concludes that most heavy equipment operators doing earthmoving work involving silica-containing material (other than demolition, fracturing, or abrading), are currently exposed to silica levels below 50 μg/m^3. (For heavy equipment operators involved in earthmoving tasks such as excavation, grading, and site preparation, 14 of the 16 sample results in the exposure profile are below 25 μg/m^3.) For workers who are currently exposed above 50 μg/m^3, the controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or below in most operations, most of the time. Therefore, OSHA finds that the standard is technologically feasible for workers doing this work.

5.4 HOLE DRILLERS USING HANDHELD OR STAND-MOUNTED DRILLS

5.4.1 Description

This section covers workers in the construction industry who use handheld drills to create clearly defined holes for attachments (e.g., anchors, bolts, hangers) or for small openings for utility pass-throughs in concrete and other silica-containing construction materials. Workers use common electric drills, pneumatic drills, handheld core drills, stand-mounted drills, rotary drills, rotary hammers, percussion hammer drills, or other impact drills to drill holes.[173] The portability and light weight of handheld drills allow workers to operate them at any angle. For practical reasons, drillers often must remove the dust and debris that build up in the bottom of the hole. Occasionally, hole drillers use compressed air to blow dust from holes (Document ID 1391, pp. 24, 33). Workers also often dry sweep the work area. A worker operating a common drill and a rotary bit may employ a technique known as pecking, in which the operator removes the drill briefly from the hole and continues to run the drill to allow the accumulated chips and dust to fly off the rotating bit (Document ID 1431, p. 3-39). At least one gas-powered drill includes a self-cleaning design to clear the hole of dust by continuously forcing air through the chuck and drill shank (Document ID 1253, p. 1). Drilling may be performed only briefly or intermittently or might be done continuously during the work shift (Document ID 1431, p. 3-39). Handheld drills can be mounted on stands or rigs, for example when drilling overhead, to improve precision and/or to allow the operator to use the drill without having to support its weight (Document ID 4073, Attachment 7b, p. 1).

[173] As proposed, Table 1 had separate entries for “Rotary Hammers or Drills” and “Jackhammers and Other Impact Drillers.” OSHA received comments from Thethe Power Tool Institute suggesting that impact drills be covered by the entry for “Rotary Hammers or Drills,” rather than by the “Jackhammers and Other Impact Tools” entry (Document ID 1973, Attachment 1, p. 4). NIOSH also commented on the potential for confusion, noting that a rotary hammer or drill is technically an impact driller (Document ID 2177, Attachment B, pp. 32-33). Therefore, the entry for handheld or stand-mounted drills in final Table 1 covers activities related to the use of impact and rotary hammer drills. Chipping and breaking activities, which are associated with more intense silica exposures, are covered by the entry for jackhammers and handheld power chipping tools.

This section does not address impact tools used to perform chipping or breaking activities, which are addressed in Section IV-5.5 – Jackhammers and Other Powered Handheld Chipping Tools. In regards to core drills, only small, handheld core drills with bits up to a few inches in diameter are covered by this section. This section does not address the use of portable and mobile hole saws used to produce large holes or openings. That equipment is discussed in Section IV-5.6 – Masonry and Concrete Cutters Using Portable Saws.

Table IV.5.4-A summarizes the job categories, major activities, and primary sources of silica exposure for workers in this industry.

Table IV.5.4-A
Job Categories, Major Activities, and Sources of Exposure of Hole Drillers Using Handheld or Stand-Mounted Drills

Job Category*	Major Activities and Sources of Exposure
Hole Driller	Create pilot holes; drill holes for attachments (e.g., anchors, bolts, hangers) or for openings to assist in lifting slabs; drill small diameter holes for access through walls and other structures. • Dust from action of drill bit. • Dust raised by sweeping, brushing, and/or using compressed air to clear holes (including housekeeping).

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.
Sources: Document ID 1431, pp. 3-39-3-40; 1253, p. 1.

5.4.2 Exposure Profile and Baseline Conditions

In the PEA, OSHA reviewed 14 sample results associated with handheld hole drilling activities. These samples were collected in settings that included work in multilevel structures, on a bridge, and during outdoor rock drilling operations. These sample results were extracted from three NIOSH reports, one OSHA Special Emphasis Program (SEP) inspection report, and two published articles (Document ID 0229, pp. 9, 12; 1253, p. 7; 0847, pp. 5-6; 0155, pp. 74-76, 88-89; 1423, p. 833; 0798, p. 77).

Three samples presented in the preliminary exposure profile for “jackhammers and impact drillers” have been moved from that section to the final exposure profile for hole drillers because they are associated with drilling that more closely aligns with the task description for hole drillers. Two of those 3 samples were taken when workers were drilling holes in a concrete bridge pier with a drill hammer. The results of those 2 samples were both below the limit of detection (LOD) (Document ID 0138, pp. 10-19). The third sample, with a result of 118 μg/m^3, involved air drilling holes into concrete to install rebar (Document ID 0019, pp. 50-52).

OSHA has supplemented the samples from the PEA with 4 sample results submitted to the rulemaking record from OSHA's Information System (OIS) database. Three of the 4 OIS samples had results below the LOD of 12 μg/m^3 (Document ID 3958, Rows 806, 825, 828). Work activities in these three OIS inspections were described as a worker drilling holes on an interstate median; a sheet metal worker (employed by a plumbing or HVAC contractor) drilling to hang units (OSHA assumes the worker was hanging units indoors) with no exposure controls used; and a carpenter drilling a concrete structure outdoors to install concrete forms, with no controls indicated. The fourth OIS hole driller sample was for a worker described as air drilling on an interstate median, with an exposure result of 128 μg/m^3 (Document ID 3958, Row 808).

OSHA's final exposure profile in Table IV.5.4-B includes 21 samples of respirable crystalline silica for hole drilling using handheld equipment. The median is 48 μg/m^3, the mean is 64 μg/m^3, and the range is 12 μg/m^3 to 286 μg/m^3. Of the 21 samples, 10 (roughly 48 percent) are above 50 μg/m^3, and five (approximately 24 percent) exceed 100 μg/m^3.

Of the 21 8-hour TWA PBZ respirable silica results summarized in the exposure profile, 8 samples represent hole drilling indoors on concrete with no use of engineering controls or dust-suppressing work practices (Document ID 1423, p. 833; 1431, p. 3-40; 0155, pp. 74-76, 88-89; 0798, p. 77; 1720, pp. IV-402-403; 3958, Row 825). Both ordinary drills and, more routinely, percussion or rotary drills were used for drilling holes into concrete and other substrates containing silica. Dry sweeping, brushing, the use of compressed air, and pecking[174] are also baseline practices that can contribute to dust exposures.

As summarized in Table IV.5.4-B, hole drillers working indoors on concrete with no controls had a median respirable silica exposure of 59 μg/m^3 and a mean exposure of 80 μg/m^3, with overall exposures ranging from 12 μg/m^3 to 286 μg/m^3. The highest indoor sample result (286 μg/m^3) was recorded in Lofgren (1993) for a worker performing dry drilling on a wall on the lower level of a concrete parking garage where air circulation was poor (Document ID 1423, p. 833).[175] This study also reported 2 other sample results for workers performing the same tasks at the same worksite; those workers had exposures of 260 μg/m^3 (for 110 minutes) and 110 μg/m^3 (for 177 minutes), which were converted to 8-hour TWAs of 41 μg/m^3 and 60 μg/m^3, respectively. These other 2 sample results were also included in the exposure profile.

The Construction Industry Safety Coalition (CISC) questioned OSHA's use of the Lofgren data, suggesting that OSHA had "cherry-picked" the data by excluding the 260 μg/m^3 and 110 μg/m^3 results (Document ID 2319, pp. 43-44). Although not explicitly stated in the PEA, OSHA did include those 2 sample results in the preliminary exposure profile, and they are also included in the final exposure profile. In accordance with the procedures in Section IV-2 – Methodology, OSHA adjusted the sample results (with sample durations of 110 and 177 minutes) to 8-hour TWA values using the assumption that no additional silica exposures occurred during the un-sampled portion of the shift (Document ID 1423, p. 833).

CISC also noted that sample results in Hallin (1983) (Document ID 1391) contain exposure results of 1740 μg/m^3 and 720 μg/m^3 for workers using a percussion drill and hammer drill, and questioned why those sample results were not included in the exposure profile (Document ID 2319, p. 45). The data in Hallin were samples taken in Sweden in the 1980s (Document ID 1391). As explained in Section IV-2 –

[174] A drilling operation that periodically retracts the drill bit to clear chips.

[175] The Lofgren (1993) study reported the sample as 300 μg/m^3 collected for 457 minutes. This is equivalent to an 8-hour TWA exposure of 286 μg/m^3 assuming no exposure for the remainder of the shift.

Methodology, the data in the exposure profiles only include samples obtained in the U.S.; moreover, data obtained prior to 1990 is not included in the exposure profiles.

McKernan et al. (2002) contained a sample result of 60 μg/m^3 (58 μg/m^3 as an 8-hour TWA) for a worker drilling concrete and brick without controls to install rebar at an indoor construction site (Document ID 0798, p. 77). This sample is also included in the profile.

The exposure profile includes 3 samples from an OSHA SEP report of workers drilling a concrete floor indoors with pneumatic drills to make holes to help lift out floor sections. Two of the 3 sample results were reported as "below LOD," with adjusted 8-hour TWA values of 67 μg/m^3 and 69 μg/m^3, while the third sample had an 8-hour TWA value of 48 μg/m^3 (Document ID 0155, pp. 74-76, 88-89).

The Agency obtained the remaining sample for indoor operations from the most recent OIS data, (Document ID 3958, Row 825). The work activities described for this sample result involved a sheet metal worker employed by a plumbing or HVAC contractor drilling to hang units. No engineering controls were used, and the sample result was below the limit of detection (12 μg/m^3).

The exposure profile shows 13 sample results for outdoor operations (or other mixed controls, including when the work location and work practices were not specified). Seven of these samples were obtained from three NIOSH studies; 3 samples, previously included in the PEA profile for jackhammer operators and impact drillers, were from two SEP reports; and 3 samples were obtained from the OIS database (Document ID 0847, pp. 5-6; 0229, pp. 9 and 12; 1253, pp. 3 and 7; 0138, pp. 10-19; 0019, pp. 50-55; 3958, Rows 806, 808, 828). Among hole drillers working outdoors (or in mixed or unspecified conditions), the median exposure was 30 μg/m^3 and the mean exposure was 54 μg/m^3, with overall exposures ranging from 12 μg/m^3 to 130 μg/m^3.

Eight of the 13 sample results for this exposure category were at or below 50 μg/m^3. Two of these 8 sample results are from the OIS database (Document ID 3958, Rows

806, 828). Two other sample results below 50 µg/m^3 are from an SEP inspection report for workers drilling holes in a concrete bridge pier with a drill hammer (both sample results below the LOD) (Document ID 0138, pp. 10-19). Two other sample results below 50 µg/m^3 were obtained from a NIOSH study in which two workers spent an entire 8-hour shift alternately drilling 2-inch holes through brick and steel and installing masonry anchors in exterior and courtyard walls. These workers had exposure values of 14 µg/m^3 and below the LOD of 12 µg/m^3 (Document ID 0229, pp. 9, 12). Additionally, 2 sample results below 50 µg/m^3 were obtained from another NIOSH study that reported exposures as less than or equal to the LOD of 30 µg/m^3 (Document ID 1253, p. 7).

In the same study, NIOSH also obtained 2 samples reported as 120 µg/m^3 and 130 µg/m^3 (Document ID 1253, pp. 3, 7). NIOSH investigated outdoor rock drilling operations where workers operated 75-pound or 30-pound gas-powered drills by hand.[176] The larger drill was designed to generate compressed air (20 to 30 pounds per square inch [psi]) that it forced through the shank to clear the hole. This drill was considerably faster and resulted in higher 8-hour time-weighted average (TWA) exposures (120 µg/m^3 and 130 µg/m^3) than did the use of the smaller, slower drill that did not include a forced air feature. As previously noted, two 8-hour TWA sample results associated with the smaller drill were both less than or equal to the limit of detection (30 µg/m^3). NIOSH noted that the workers rarely operated either size drill more than 3 hours a day because they are heavy and difficult to control; therefore, the 8-hour TWAs that OSHA uses in the exposure profile assume that the workers did not drill beyond the sampling period and had no additional silica exposure for the remainder of the day (Document ID 1253, pp. 1, 3, 7).

CISC asserted that because this NIOSH study involved drilling in the Rocky Mountains, it can “hardly be representative of hole drilling using handheld drills for

[176] Although NIOSH investigators collected five PBZ samples, only four were included in the exposure profile. The sample that was excluded was a 20-minute sample that did not collect any dust (total or respirable) (Document ID 1253, p. 7). Since there was no respirable mass detected in the filter, and the period sampled was short, OSHA could not use this sample to characterize the nature of exposures during this drilling activity.

all of construction” (Document ID 2319, p. 45). CISC did not elaborate on the reason that it is not representative. The type of rock the workers drilled contained quartz concentrations between 15-23 percent (Document ID 1253, p. 4). OSHA believes that the sampling results from this study are among the best evidence available to OSHA to characterize exposures of workers performing hole drilling with handheld drills.

Three other hole driller sample results for “other mixed conditions” were above 50 $\mu g/m^3$. One was for a worker described as air drilling on an interstate median, with an exposure of 128 $\mu g/m^3$ (Document ID 3958, Row 808). Another elevated sample result (118 $\mu g/m^3$), for a worker air drilling holes to install rebar, was obtained from an SEP report (Document ID 0019, pp. 50-55). The remaining sample was obtained from a worker performing outdoor and uncontrolled handheld drilling as part of bridge demolition; the reported exposure concentration was 780 $\mu g/m^3$ (73 $\mu g/m^3$ as an 8-hour TWA) (Document ID 0847, pp. 5-6). Area sample results as high as 2,150 $\mu g/m^3$ (sample duration not specified) from this operation indicate that a considerable amount of respirable dust was generated in the absence of exposure controls. The area samples and presence of another worker on the bridge performing silica-generating tasks (concrete sawing) suggest that silica emissions from other nearby workers may have contributed to the exposures of the outdoor handheld drill operator (Document ID 0847, pp. 5-6).[177]

The sample results presented in the exposure profile represent the best data available to OSHA for estimating the exposures of workers drilling holes with handheld equipment. Although somewhat limited, these data indicate that outdoor drilling most often results in worker exposure levels at or below 50 $\mu g/m^3$, and that exposures do not generally exceed 50 $\mu g/m^3$ unless contributing factors (such as the use of forced air combined with large, aggressive drill size, or emissions from other nearby silica

[177] As discussed in IV.2 – Methodology, OSHA assumes that the sampling period encompasses the duration of the silica-generating task, and that the worker was not exposed to silica during the unsampled portion of the shift. Section IV.2 discusses the impact of secondary exposures and the importance of controlling all silica-generating activities at the source.

generating activities) make the job particularly dusty. No other exposure data for hole drillers was submitted to the rulemaking record.

Table IV.5.4-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Construction Workers: Hole Drillers Using Handheld or Stand-Mounted Drills

	Exposure Summary			Exposure Range		Exposure Profile				
Hole Drillers Using Handheld or Stand-Mounted Drills	**N**	**Mean (µg/m^3)**	**Median (µg/m^3)**	**Min (µg/m^3)**	**Max (µg/m^3)**	**< 25 (µg/m^3)**	**≥ 25 and ≤ 50 (µg/m^3)**	**> 50 and ≤ 100 (µg/m^3)**	**> 100 and ≤ 250 (µg/m^3)**	**> 250 (µg/m^3)**
Indoors, concrete substrate, no controls	8	80	59	12	286	1 (12.5%)	2 (25%)	4 (50%)	0 (0%)	1 (12.5%)
Other mixed conditions	13	54	30	12	130	6 (46.2%)	2 (15.4%)	1 (7.7%)	4 (30.8%)	0 (0%)
Hole Drillers Using Handheld Drills Total	**21**	**64**	**48**	**12**	**286**	**7 (33.3%)**	**4 (19%)**	**5 (23.8%)**	**4 (19%)**	**1 (4.8%)**

Notes: All samples are personal breathing zone (PBZ) results and represent 8-hour time-weighted average exposures.
Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.
Percentages may not add to 100 percent due to rounding.

5.4.3 Additional Controls

The exposure profile in Table IV.5.4-B shows that approximately 48 percent (10 out of 21 samples) of hole drillers have exposures above the final PEL of 50 μg/m³. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. The median exposure for hole drillers is 59 μg/m³ when dry drilling indoors on concrete without controls, but just 30 μg/m³ for other conditions (generally outdoors). Although the data used by OSHA for the exposure profile indicates that drilling outdoors will generally yield lower exposures than drilling indoors, the data also shows that exposures in excess of 50 μg/m³ can occur, particularly when workers are using larger drills. Local exhaust ventilation (LEV) is the primary option available for reducing exposure levels among hole drillers both indoors and outdoors.

Local Exhaust Ventilation

Shepherd et al. (2009) found that, compared with uncontrolled drilling, using dust collection cowls connected to portable vacuums reduced silica exposures by 91 to 98 percent (Document ID 1142, p. 49). The researchers tested four combinations of two cowls and two vacuums (all commercially available, including a bellows-style cowl and a telescoping ring cowl) in multiple 1-hour trials. For each trial, the worker-subjects used a 6.9 amp hammer drill with a 3/8 inch bit to continuously drill a series of 3-inch holes between shoulder and waist height in a vertical concrete wall. For half of the randomized trials, the test wall was located indoors in a large enclosed space (100 feet by 60 feet by 30 feet, similar to a warehouse), with several operators each using the four combinations of equipment. The wall was moved outdoors for the other half of the trials. In this case, the investigators found no statistical difference between indoor and outdoor trials for the various equipment combinations. Average respirable quartz levels varied among the different cowl/vacuum combinations, but all combinations resulted in personal breathing zone (PBZ) exposures of 28 μg/m³ or less during these periods of constant drilling. In contrast, periods of uncontrolled drilling resulted in a geometric mean exposure level of 308 μg/m³ (Document ID 1142, p. 42). Although the investigators note that exposure levels may vary for different drill types and drill bit sizes, OSHA estimates that even moderately effective ventilated dust collection cowls would still result in silica exposure levels that are 50 μg/m^3 or less during periods of intense drilling and that 8-hour TWA values would be even lower.

CISC raised several issues with the use of the Shepherd et al. study. CISC stated that the study consisted of only 1-hour drilling in controlled conditions in a laboratory setting; the LEV systems did not reduce *inhalable* exposures to 50 μg/m^3; and the vacuums would require frequent filter changes to maintain effectiveness. Additionally, CISC stated that the Shepherd study mentioned that hood designs for portable handheld hammer drills needed to be examined and that technical improvements were needed to capture particles more efficiently (Document ID 2319, pp. 45-46).

Although the Shepherd study contains short-term laboratory data, OSHA still finds it relevant to evaluating the effectiveness of using LEV as a control for handheld and stand-mounted drills. Experimental studies under controlled conditions, like the Shepherd study, can objectively show how well a control method works in an environment where other sources of silica are also controlled (e.g., as might occur on a well-controlled work site, or at a site where only one source of silica exposure is active at a time). Sample results from the controlled condition are also routinely compared by investigators to sample results obtained for uncontrolled conditions. The resulting ratio shows the exposure reduction efficiency for the control method, independent of work rate variability, variations in construction materials, or other factors that do not relate to the individual control's functional performance. OSHA acknowledges that there are limitations to experimental data, but believes that the Shepherd study provides useful information about the effectiveness of LEV.

The Shepherd study evaluated the effectiveness of LEV in reducing three size fractions of dust particles (respirable, thoracic, and inhalable). Respirable sized particles are those capable of entering the gas-exchange (alveolar) regions of the lung, and, as explained in the PEA, have a 50-percent cut-point of 4.0 μm (Document ID 1455, p. xvi; 1720, p. IV-20). Thoracic-sized particles have a 50 percent cut-point of 10 μm. And inhalable-sized particles may deposit anywhere in the respiratory tract and have a 50 percent cut-point of 100 µm (Document ID 1834, p. 13; 1540, p. 280). The mass concentration of silica collected in the inhalable fraction was nearly ten times higher than it was in the respirable fraction for all LEV configurations tested (Document ID 1142, p. 46).

Contrary to CISC's assertion, the Shepherd study demonstrates that it is possible to reduce respirable silica levels to 50 µg/m^3 or less (Document ID 1142, p. 49). The respirable silica sample results reported in Table 1 of the Shepherd study show that all four LEV systems tested reduced exposures below 50 µg/m^3, and two of the LEV configurations reduced silica exposures below 25 µg/m^3, during the sampled period (Document ID 1142, pp. 46-47). While Shepherd does recommend further study of hood design for portable hammer drills, this is to reliably achieve exposures below 25 µg/m^3, improve capture of larger, non-respirable particles, and improve ease of use and acceptance in the field (Document ID 1142, pp. 48, 50).

Additionally, although the study pointed out that vacuums would require frequent filter changes, filter changes are a common work practice for effective dust collection systems, and OSHA does not consider the need to change a filter evidence of infeasibility. As a general matter, controls need to be frequently evaluated to ensure proper and effective operation; examination of controls is consistent with good industrial hygiene practices. Additionally, technology is available to prevent clogging of the final filter and thus maintain sufficient vacuum airflow rates. Vacuum filters with cyclonic pre-cleaners or filters with an automatic backflush system can be used, with several such self-cleaning vacuum dust collection systems commercially available (Document ID 3791, p. v; 3998, Attachment 10, pp. 20, 29-30, 38). Employers opting to follow Table 1 must use dust collectors with a filter cleaning mechanism in order to maintain airflows sufficient to achieve effective capture at the hood.

Proposed Table 1 did not specify the amount of air flow required for the dust collection system. 77 FR at 56495. CISC questioned why the Table 1 specifications in the proposed rule did not set parameters for the functioning of the dust collection system for hole drillers (Document ID 2319, p. 107). In the final rule, OSHA has revised Table 1 to specify that the dust collection system for handheld and stand-mounted drills must provide the airflow recommended by the tool manufacturer or greater.

In an earlier study of vacuum suction dust control devices conducted in Sweden, Hallin (1983) evaluated rotary and percussion hammers equipped with various LEV systems and various drill bit sizes (Document ID 1391). During the study, the tools were operated indoors, usually in a test room designed to mimic a small enclosed construction area with poor air circulation (one air change per hour). Under these conditions, the study showed that the use of LEV resulted in a 57-percent reduction in the median respirable quartz exposure level for workers drilling 50-millimeter-deep holes in concrete with 6-millimeter drill bits (from a median of 140 $\mu g/m^3$ without LEV to a median of 60 $\mu g/m^3$ with LEV-equipped tools). Hallin found an 85-percent reduction in the median respirable quartz exposure level for workers drilling 80-millimeter-deep holes in concrete with 10-millimeter drill bits (295 $\mu g/m^3$ without LEV compared with 45 $\mu g/m^3$ with LEV). In this study, each LEV system consisted of a suction-type connection and a dust extractor. Hallin's test readings are concentration values (rather than calculated 8-hour TWAs) and were based on short sample durations (ranging from 60 to 180 minutes of intensive drilling). The workers did not use compressed air to clean the holes during these tests, which took place in a room approximately 15 feet by 18 feet by 8 feet (Document ID 1391, pp. 11, 13, 24).

CISC commented that the use of the Hallin study is an example of OSHA's inadequate analysis of the effectiveness of controls, given that the Hallin study was performed indoors under test room conditions. Additionally, silica levels were estimated from a composite of respirable dust samples, and individual PBZ samples were not collected (Document ID 2319, p. 46). OSHA believes that as a controlled study, the Hallin study is instructive; it can objectively show how well a control method works in an environment where other sources of silica are also controlled. Additionally, OSHA believes that the conditions of the study – small and enclosed areas with poor circulation – resemble drilling in real-world conditions. The study shows that the levels of respirable quartz were reduced by 57 and 85 percent in two different trials.

The Hallin study also indicated a greater potential for overexposure during overhead drilling performed indoors. Drilling without controls for 120 minutes in a concrete ceiling with a percussion drill resulted in respirable quartz concentration exposures of 1,740 μg/m^3 (435 μg/m^3 as an 8-hour TWA) (Document ID 1391, p. 15). When the same model of percussion drill was fitted with a dust collector, the respirable quartz reading for a 180-minute sample was 80 μg/m^3 (an 8-hour TWA of 30 μg/m^3) (Document ID 1391, pp. 15, 22). Another uncontrolled overhead drilling trial using a hammer drill for 120 minutes produced a respirable quartz concentration exposure of 720 μg/m^3 (180 μg/m^3 as an 8-hour TWA) (Document ID 1391, p. 16).

Based on the Hallin study, OSHA stated in the proposal that it was unable to confirm that using a cowl and dust collector would sufficiently protect workers, and proposed to exclude overhead drilling from the tasks and controls on Table 1. 78 FR 56274, 56460. Additionally, OSHA agreed with the recommendations made by the Hallin study that overhead drilling is ergonomically stressful and should not be performed consistently throughout a full shift. 78 FR at 56460.

OSHA received a number of comments related to overhead drilling. The Sheet Metal and Air Conditioning Contractors National Association commented that overhead drilling should be included on Table 1, noting that it can be done as safely as other work postures if it was done as directed on Table 1 (i.e., no visible dust) (Document ID 2226, Attachment 1, p. 2). The Power Tool Institute recommended a new entry for overhead drilling with carbide bits, stating that drilling with carbide bits limits the amount of material removed (Document ID 1973, p. 6). The Power Tool Institute also recommended that, when used with a hood or cowl and HEPA-filtered dust collection system, no respiratory protection be required for up to four hours of drilling, and that a half-mask respirator with an APF of 10 be permitted when drilling for greater than four hours (Document ID 1973, p. 6). OSHA believes that, due to the ergonomically stressful nature of overhead drilling, it is unlikely that overhead drilling would be performed consistently throughout a full shift. Ms. Chris Trahan, reading a statement from Laurie Shadrick on behalf of the United Association of Journeymen and Apprentices of the Plumbing and Pipefitting Industry of the United States, Canada and Australia, noted that drilling may only take up 3-5 percent of work time for a worker installing hangars (Document ID 3581, Tr. 1584).

CISC questioned whether, in light of the Hallin study result, exposures during overhead drilling could be controlled to 50 μg/m^3 (Document ID 2319, p. 45). OSHA finds that the Hallin study shows that, when effective controls are implemented, exposures can be reduced to 50 μg/m^3 or less, most of the time, when performing overhead drilling. The Hallin study reports two sample results during controlled overhead drilling, with adjusted 8-hour TWAs of 30 μg/m^3 (based on a sample result of 80 μg/m^3 in a 180-minute sample) and 17 μg/m^3 (based on a sample result of 68 μg/m^3 in a 120-minute sample) (Document ID 1391, p. 22).

Additionally, evidence in the record shows that technology has developed since the Hallin study was published in 1983. Ms. Trahan, reading a statement on behalf of the United Association of Journeymen and Apprentices of the Plumbing and Pipe Fitting Industry of the United States, Canada and Australia, noted that “the industry is seeing an increase in the use of local exhaust ventilation for overhead drilling, including [integrated] dust collectors and add-on controls” (Document ID 3581, Tr. 1584). OSHA received testimony that an overhead drill stand (referred to as an overhead drill press by the commenter), was developed with a vacuum attachment that addresses both ergonomic and silica hazards (Document ID 3581, Tr. 1673, 1705). OSHA encourages the use of such drill stands, as they reduce ergonomic stressors and allow the driller to stand at a greater distance from the point of contaminant generation. Use of a stand-mounted drill is expected to reduce silica exposures, both by increasing the distance to the worker’s breathing zone and through the local exhaust ventilation that is integrated into the stand.

Upon review of the evidence in the record, OSHA has determined that it is appropriate to cover overhead drilling in the Table 1 entry for handheld and stand-mounted drills.

There are commercially available controls that can reduce exposures. As the Hallin (1983) study shows for controlled overhead drilling, 8-hour TWA exposures can be reduced to levels to or below 50 $\mu g/m^3$.

OSHA finds that exposures from drilling (including overhead drilling) will be lower when performed using effective LEV in areas supplied with general (or natural) ventilation. NIOSH studies of exposure controls for lead-based paint removal showed that adding dilution ventilation to enclosed work areas reduced airborne lead fume concentrations by nearly half (45 percent, from 22 $\mu g/m^3$ to 12 $\mu g/m^3$ of lead) during lead paint removal by the heat gun method (Document ID 1274, p. 3).[178] Accordingly, paragraph (c)(2) of the final rule requires general exhaust ventilation as needed to minimize the accumulation of visible airborne dust for tasks performed indoors or in enclosed areas.

CISC commented that many hoods or cowls are not designed for dust collection (Document ID 2319, p. 108). The National Utility Contractors Association (NUCA) stated that no drills are currently manufactured with a bag/HEPA filter (Document ID 2171, p. 10). However, OSHA received evidence of commercially available engineering controls (Document ID 4073, Attachment 4a). Ms. Eileen Betit, testifying on behalf of the Building and Construction Trades Department (BCTD) of the AFL-CIO, discussed the increasing variety of commercially available ventilated drills, noting that one drill manufacturer introduced a hollow drill bit that suctions the dust as the hole is being drilled (Document ID 3581, Tr. 1673). Additionally, Charles Austin, an industrial hygienist representing the International Association of Sheet Metal, Air, Rail and Transportation (SMART), testified that there are commercially available hammer drills with built-in dust collection systems, as well as dust collection systems that can be attached to HEPA vacuums, that can be used when drilling holes in concrete and masonry for installation of duct work (Document ID 3581, Tr. 1588-1589). Based on the evidence in the record, OSHA has determined that several

[178] Fumes are very small particles, the largest of which (1 micrometer) are in the lower end of the respirable size range (DiNardi, 2003 – Document ID 0623, p. 1268). Like silica particles, fumes remain airborne rather than settling out of the air during a work shift.

manufacturers produce LEV dust removal systems for a variety of tool types, including most models of drills (Document ID 0566; 0629, p. 1; 1671; 0736; 3998, Attachment 10, pp. 20-21, 27, 33, 39, 42; 4073, Attachment 4b, Slides 12 - 18).

When the LEV cowl is supplied with its own dust collection bag, both Hallin and Shepherd suggest that better dust capture is achieved by removing the bag and attaching a vacuum hose in its place, using a commercially available adaptor and vacuum source (Document ID 1391, p. 23; 1142, p. 43). OSHA expects that, for most tools, a dust control system using an appropriate vacuum will provide the most reliable dust capture.[179]

Local exhaust ventilation can also be used to effectively control exposures during the use of small, handheld core drills. These drills can be fitted with vacuum attachments consisting of a cowl with a vacuum port that fits around the annular coring bit and draws dust from the cutting area, or a suction feature that pulls air from the already-hollow center of the coring bit (Document ID 3998, p. 19). LEV systems are commercially available for core drills up to 3.25 inches in diameter (Document ID 3501, p. 6; 3998, p. 22). In hearing testimony, Mr. Joel Guth of iQ Power Tools described effective local exhaust controls for core drills (Document ID 3585, Tr. 3000). Sampling data submitted to the record by iQ Power Tools reported a sample result of 28 $\mu g/m^3$ during the use of a handheld core drill equipped with local exhaust ventilation. This study assessed full-shift personal breathing zone exposures for a worker performing 200 cuts with a handheld core drill using a 3” diameter bit. This study noted a typical frequency of 25 – 200 cuts per day and assessed maximum exposure conditions for this tool type (Document ID 3501, pp. 6-7).

Based on the evidence in the record, OSHA has determined that there are effective controls for hole drilling using handheld and stand-mounted drills that can reduce

[179] The Precast/Prestressed Concrete Institute (PCI) asserted that requiring rotary hammers to be equipped with a hood or cowl with HEPA vacuum systems could turn a one-person operation into a two-person operation. PCI stated that an additional worker may be needed to hold and move the equipment as the work progresses (Document ID 4029, p. 3). OSHA does not believe this will be necessary, as the hole driller can simply push the wheeled vacuum system to new work locations as the work progresses. Wheeled vacuum systems vary in size; some are quite compact and easy to move (Document ID 3998, Attachment 10, pp. 20-22, 29-30, 37-38).

exposures to 50 μg/m^3 or below. These controls include using handheld drills equipped with commercially available shroud or cowling with a dust collection system that has sufficient airflow as recommended by the tool manufacturer, a filter with 99 percent or greater efficiency, and a filter cleaning mechanism.

Dust Capture Devices

Peter Chaney, Director of Safety and Health for the Mechanical Contractors Association, noted that Table 1's specifications for handheld hole drillers did not include other types of effective silica dust control devices and equipment, such as dust collection cups on drill bits (Document ID 2143, p. 3). OSHA acknowledges that a simple, non-ventilated dust barrier that captures dust at the point of generation may be effective for an "employee who drills only an occasional small hole in the course of a day" (Document ID 1533, pp. 40-41). For example, WorkSafe BC, the workers' compensation control board for British Columbia, Canada, notes that dust caps and dust bubbles fit between the drill and the working surface (on the end of the drill) and are useful for overhead ceiling and wall drilling (Document ID 4072, Attachment 19, p. 2).

WorkSafe BC recommends use of a dust cap as an alternative to vacuum dust collection when only a few (i.e., 12 or fewer) holes will be drilled in a wall or ceiling (Document ID 4072, Attachment 19, pp. 3-4; Attachment 14, p. 17). These may be useful for existing drills for which commercially available local exhaust attachments are not available. However, WorkSafe BC recommends that in addition, half-face, HEPA-filtered respirators be used (Document ID 4072, Attachment 14, pp. 5, 17). No WorkSafe BC or other exposure data was submitted to the record addressing the effectiveness of these devices, but OSHA notes that the WorkSafe BC occupational exposure limit is 0.025 mg/m^3 (25 μg/m^3).

The Hallin study describes a 120 minute overhead drilling trial using a percussion drill with a Hilti rubber cup as the dust collection device that resulted in an exposure of 680 μg/m^3 (170 μg/m^3 as an 8-hour TWA) (Document ID 1391, p. 22).

Based on the available data and the lack of sufficient evidence to show the extent to which this type of control can reduce exposures, OSHA has decided not to include dust capture devices as an option on Table 1.

Work Practices

As noted in Table IV.5.4-A, dust raised by sweeping, brushing, and/or using compressed air to clean holes can be a significant source of silica exposures for hole drillers. Implementation of work practice controls is an important component of reducing exposure from this source. Careful work practices are necessary to prevent settled dust from being re-suspended and entering the worker's breathing zone. When vacuum cleaners are used, OSHA recommends that that they be equipped with HEPA-filters.

The use of ventilated tools can eliminate some housekeeping needs. When a tool equipped with integrated local exhaust (vacuum dust collection) is used, there will be less accumulated dust that will need to be removed from surfaces, thereby minimizing worker exposures and reducing the amount of housekeeping needed. In hearing testimony, Deven Johnson, Director of Training, Health and Safety for the Operative Plasterers and Cement Masons International Association, explained that when the dust is collected as it is generated and passes through a HEPA-filtered container, "you don't need anybody else to clean it up. It's already contained." (Document ID 3581, Tr. 1594). Moreover, BCTD submitted Return on Investment (ROI) calculations showing that workers spend less time performing housekeeping and clean-up activities when handheld drills with integrated dust collection systems are used (Document ID 4073, Attachments 7a and 7b).

Work preplanning can also be an effective strategy for reducing silica exposures associated with the use of handheld and stand-mounted drills. WorkSafe BC recommends, in its silica exposure control plan guidance, that project planning be used to reduce silica exposures. For example, by planning formwork to reduce the need for drilling, or by scheduling drilling when the concrete is still wet, project work will pose less of an exposure concern (Document ID 4072, Attachment 14, p. 7).

Proper maintenance of exposure controls is essential to ensure their effectiveness. BCTD recommended that OSHA require employers to inspect and ensure proper function of tool LEV controls before each use of a rotary hammer or drill (Document ID 4223, Appendix 1, pp. 8-9). Similarly, a U.K. Health and Safety Executive document titled “Controlling construction dust with on-tool extraction” recommends that employers check controls for proper function before each use, conduct weekly maintenance checks of the hood or ducting, airflow, and filter cleaning mechanisms, and replace filters when needed. This document also recommends servicing and systematic testing at least every 14 months (Document ID 3756, Attachment 4, p. 3). Although OSHA agrees that the regular inspection of controls is essential to ensuring proper function, the interval of inspection that is necessary may vary by tool. As such, OSHA believes that tool manufacturers are in the best position to determine an appropriate inspection interval; employers must follow manufacturers’ instructions.

Compressed Air Cleaning

The practice of sweeping or brushing debris from the hole appears to contribute to exposures among workers drilling in concrete. The use of compressed air to clean the holes also increases exposures, regardless of whether the air is blown by the drill (a design feature of some drills) or by a worker using a compressed air nozzle.

Although OSHA recognizes that the complete elimination of compressed air cleaning or dry brushing or sweeping may not be possible in every situation, OSHA believes that improved cleaning techniques, e.g., using a high-efficiency particulate air (HEPA)-filtered vacuum, can often be used instead of, or as a supplement to, cleaning with compressed air. These alternative cleaning methods can reduce silica exposures. Hallin reported that airborne respirable quartz readings were 55 percent lower when holes were cleaned with a suction probe before being blown clean with compressed air (Document ID 1391, pp. 32 - 33).

OSHA received a number of comments related to the use of compressed air. BCTD recommended that OSHA require employers to use HEPA-filtered vacuuming or wet methods to clean accumulations of silica and prohibit the use of compressed air, dry sweeping, and dry brushing to clean contaminated clothing or surfaces (Document ID 2371, Attachment 1, pp. 32-33). PCI, on the other hand, expressed concern regarding a prohibition on dry sweeping, brushing, and compressed air cleaning, stating that in many cases, they are the only feasible cleaning methods (Document ID 2276, p. 10). PCI noted that anchor holes must be blown clean to obtain adequate adhesion, and recommended that the use of compressed air and dry sweeping be allowed unless exposures will exceed 50 µg/m^3 (Document ID 2276, pp. 10-11).

OSHA has determined that there are a number of feasible alternatives to using compressed air. At least one tool manufacturer offers an anchor system with "no hole cleaning requirement whatsoever," due to the use of a drill with a ventilated drill bit (Document ID 4073, Attachment 4b, Slide 12). Another manufacturer offers a "hole cleaning kit" for large hammer hole drilling, which consists of a doughnut-shaped dust collection head that attaches directly to a vacuum cleaner hose. The head is placed against the surface to be drilled and captures dust generated as the hole is drilled (Document ID 4073, Attachment 4b, Slide 17). This hole cleaning kit also includes two sizes of hole cleaning tubes. Such a control could be used with existing as well as new drills (e.g., Document ID 3998, Attachment 10, p. 42).

CISC, noting that the larger drill described in the NIOSH study (Document ID 1253, p. iv) forced compressed air through the drill shank, asked whether OSHA would permit the use of heavy equipment that incorporates compressed air in the drilling action (Document ID 2319, p. 45 n. 8). Compressed air, when used with effective ventilation control as a part of a design feature for optimal drill performance would not violate the rule's restrictions on use of compressed air for cleaning.

The exposures reported by NIOSH when a 75-pound rock drill with a forced air feature was used exceeded 50 µg/m^3 (exposures of 120 µg/m^3 and 130 µg/m^3) (Document ID 1253, pp. 1, 7). However, this drill did not have LEV integrated into the design of the tool. In some cases, both compressed air and LEV are an integral part of a tool, and are designed to work in concert. For example, RR926, a research report by the UK Health and Safety Executive titled "On-tool controls to reduce exposure to respirable dusts in the construction industry" describes a study by Potts and Reed that studied the effectiveness of compressed air jets "to further improve containment of dust-contaminated air" inside a ventilated shroud on a surface drill. This study found that this system reduced the dust concentration outside the enclosure by approximately 50 percent (Document ID 3791, p. 11). Similarly, Hallin reported that airborne quartz readings were 40 percent lower when "blowing through a suction disc" as compared to blowing holes clear with compressed air with no exhaust capture (Document ID 1391, pp. 32-33). OSHA acknowledges that such specially designed systems may be effective in controlling respirable silica exposures, and expects that such systems would employ compensating LEV with an exhaust air flow rate greater than the flow rate of the forced air feature.

Data suggest that decreasing workers' reliance on blowing or dry sweeping drilling debris can reduce exposures by approximately 50 percent (see, e.g., Document ID 1391, pp. 32 - 33). Holes can be cleaned using portable HEPA-filtered vacuums with extension wands, or commercially available hole cleaning kits connected to HEPA-filtered vacuum dust collection systems (Document ID 3998, Attachment 10, p. 42). This 50-percent reduction would bring exposure levels to 50 μg/m^3 or below for all the drill operators who are currently exposed to silica at levels between 50 μg/m^3 and 100 μg/m^3. OSHA believes that reducing reliance on unventilated drills that blow air down the hole will provide the same degree of exposure control as reducing the use of other forms of compressed air to clean holes.

5.4.4 Feasibility Finding

Paragraph (c) of the construction standard gives employers the option of following Table 1, which includes specified engineering and work practice controls for workers operating handheld and stand-mounted drills; alternatively, the employer must assess and limit exposures in accordance with the more traditional regulatory approach of compliance with the PEL contained in paragraph (d). When drilling holes using handheld or stand-mounted tools, such as small core drills, rotary hammers, hammer drills, or other handheld impact drills, Table 1 requires employers to ensure use of a drill equipped with a commercially-available shroud or cowling with a dust collection system. The dust collector must provide at least the minimum air flow recommended by the manufacturer, have a filter with 99 percent or greater filter efficiency, and include a filter cleaning mechanism. The tool must be operated and maintained in accordance with the manufacturer's specifications to minimize dust emissions. A HEPA-filtered vacuum must be used when cleaning drilling debris from holes. OSHA finds that when dust controls on handheld or stand-mounted drills are fully and properly implemented, TWA exposure levels will remain at or below 50 µg/m^3; therefore, Table 1 does not require the use of respiratory protection.

Several drilling equipment manufacturers sell dust extractors or dust collectors with filtration systems to minimize dust escaping into the work area. Some of these include Bosch, DeWalt, Hilti, Metabo, and iQ Power Tools (Document ID 3998, Attachment 10; 4073, Attachment 4a; 3501, pp. 6-7). OSHA has determined that it is feasible for employers to obtain controls for handheld drills that meet the specifications in Table 1.

Based on the data in the record, OSHA concludes that roughly half of workers using handheld drills are currently exposed to silica levels below 50 µg/m^3. For workers who are currently exposed above 50 µg/m^3, the controls described in this section can be implemented to reduce silica exposure levels to 50 µg/m^3 or below in most operations, most of the time. Additional controls, such as fitting an LEV cowl and vacuum suction to a drill (as described by Shepherd et al. (Document ID 1142, p. 49)), can reduce exposures to 50 µg/m^3 or below for even the most highly-exposed workers operating handheld drills (i.e., the 24 percent that OSHA estimates, based on Table IV.5.4-B, are exposed to silica levels greater than 100 µg/m^3). As discussed in the additional controls section, the use of a stand-mounted drill is expected to reduce silica exposures, both by increasing the distance to the worker's breathing zone and through the local exhaust ventilation that is integrated into the stand. Research presented in Shepherd et al. (2009), shows the exposure reduction achieved by commercially available test equipment. The study reported that uncontrolled drilling produced mean exposures of 308 µg/m^3 during continuous drilling. In contrast, several combinations of drill cowls and portable vacuums reportedly reduced silica exposures among drillers by at least 90 percent (to levels of 28 µg/m^3 or less) (Document ID 1142, p. 46). This study demonstrates that commercially available controls can reduce even the highest sample values in the exposure profile to levels at or below 50 μg/m^3. Therefore, OSHA finds that the standard is technologically feasible for workers using handheld and stand-mounted drills.

5.5 JACKHAMMERS AND OTHER POWERED HANDHELD CHIPPING TOOLS

5.5.1 Description

Hand-operated breaking and chipping power tools and equipment, commonly known as jackhammers, pavement breakers, breaker hammers, percussion or chipping hammers, needle guns, and related tools (collectively, "jackhammers, percussion/chipping hammers, and other powered handheld impact tools") are used at construction sites for fracturing silica-containing material (Document ID 1431, p. 3-44; 2177, Attachment B, p. 32). These tools deliver rapid repetitive blows to fracture rock, concrete, asphalt, or masonry during demolition, repair and renovation, or excavation. Workers typically use these types of tools with the point of impact within one to five feet of the breathing zone, and they can hold the equipment at any angle, including overhead, depending on the weight of the tool (a limitation in some cases) and the configuration of the structure being chipped (Document ID 1431, p. 3-44). Construction workers who use rotary or impact drills for drilling holes in concrete are covered in Section IV-5.4 – Hole Drillers Using Handheld or Stand-Mounted Drills.

During the hearings, George Kennedy of the National Utility Contractors Association (NUCA) stated that jackhammering is one of the construction activities most likely to expose employees to silica (Document ID 3583, Tr. 2255). Workers can use chipping breaking and impact drilling equipment for short periods of time of two or three hours or for as long as seven hours based on a review of selected OSHA inspection reports (Document ID 1431, p. 3-44). With regard to estimating the typical duration of use, Flanagan et al. (2006) recorded worker activities, in addition to worker exposures, during a wide range of construction activities, including "demolition with handheld power tools." Of the 41 samples for which the duration of the task was recorded, the median task time was 231 minutes (range 30 to 473 minutes) (Document ID 0677, p. 147 and Attachment 2).

At some job sites where a large volume of concrete must be removed (e.g., bridge deck renovation), several jackhammer operators might perform pavement breaking simultaneously in the same general area, increasing the dust concentration in the area.

Handheld chipping operations frequently use dry sweeping to clear larger chipping debris from the work area and use handheld blowers or compressed air to remove fine dust from the chipped surface (Document ID 1431, p. 3-44), which can result in higher worker exposures. High exposures can also occur when demolition of silica-containing materials by heavier jackhammers and smaller chipping or percussion hammers takes place indoors where dust emissions can build up if mechanical ventilation is not available.

Table IV.5.5-A summarizes the major activities and the primary sources of silica exposure for workers using jackhammers, percussion/chipping hammers, and other powered handheld impact tools.

Table IV.5.5-A
Major Activities, and Sources of Exposure of Workers Using Jackhammers and Other Powered Handheld Chipping Tools

Application Group	Major Activities and Sources of Exposure
Jackhammer, percussion/chipping hammers, and other powered handheld impact tools	Chipping and breaking concrete, stone, and masonry during demolition, renovation, and excavation. • Dust from chipping or breaking action of the tool. • Dust raised by sweeping, brushing, and/or using compressed air to clear the work surface (housekeeping).

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.

5.5.2 Exposure Profile and Baseline Conditions

The PEA exposure profile included respirable quartz samples for jackhammering and chipping hammers at multiple commercial and highway construction sites, including a bridge, from NIOSH reports, numerous OSHA Special Emphasis Program (SEP) inspection reports, data from CJ Shields of the OSHA North Aurora Area Office, a published article, and a New Jersey state construction partnership report by ERG for the 2008 Technological Feasibility Study of Regulatory Alternatives for a Proposed Crystalline Silica Standard for Construction (Document ID 1431, p. 3-45; 1720, pp. IV-410 – IV-411).

Table IV.5.5-B presents the exposure profile updated from the PEA based on the data available in the record. The updated profile includes 37 additional samples from the OSHA OIS database for respirable crystalline silica exposure conducted between 2011 and 2014 (Document ID 3958). The updated exposure profile excludes seven samples previously included in the PEA based on sampling dates prior to 1990. Also, three samples on impact drillers were removed from the exposure profile on jackhammers and added to the profile on hole drillers, since the use of impact drills is now discussed in Section IV-5.4 – Hole Drillers Using Handheld or Stand-Mounted Drills.

The exposure profile in Table IV.5.5-B includes 134 samples of respirable crystalline silica for workers using jackhammers and other handheld power chipping tools. The median is 126 μg/m^3, the mean is 250 μg/m^3, and the range is 12 μg/m^3 to 2,350 μg/m^3. Of the 134 samples, 93 (almost 70 percent) are above 50 μg/m^3, and 72 (approximately 54 percent) exceed 100 μg/m^3.

Compared to the PEA, the FEA shows a decrease in overall median exposures from 140 to 126 μg/m^3, an increase in the percent of samples at or below 50 μg/m^3 from 26.6 to 30.6 percent, and a slight decrease from 33.0 to 31.3 in the percent of samples over 250 μg/m^3.

Of the 134 respirable quartz readings summarized in the exposure profile, 66 sample results (49 percent) represent jackhammering outdoors under uncontrolled conditions. These results range from less than or equal to the limit of detection (LOD) to 624 μg/m^3 and have a median of 148 μg/m^3 and a mean of 194 μg/m^3. This category included 23 results that exceeded 250 μg/m^3; thirteen of these were from bridge deck job sites (Document ID 0912, pp. 2-3). The elevated results may have resulted from having multiple jackhammers working side by side, using compressed air as a cleaning technique, and cross exposure from other highway equipment (Document ID 1431, p. 3-45).

Five of the results in the exposure profile (4 percent) represent jackhammering outdoors while attempting wet dust control methods. Under these conditions, exposures ranged from 12 μg/m^3 to 639 μg/m^3, with a median of 140 μg/m^3 and a mean of 226 μg/m^3. There is not enough information available to determine how the water suppression was applied for four of these five samples. Although sample durations and silica concentrations in the raw material in these four trials are comparable to outdoor trials with no engineering controls, the resulting exposures were somewhat higher than for uncontrolled operations. One possible reason for this result is that the water dust suppression control was not applied optimally.

Thirty-two of the results in the exposure profile represent the use of jackhammers, percussion/chipping hammers, and other powered handheld impact tools indoors under uncontrolled conditions. These results range from less than or equal to 12 μg/m^3 to 2,350 μg/m^3 and have a median of 111 μg/m^3 and a mean of 404 μg/m^3.

Eleven of the results in the exposure profile represent the use of powered handheld impact tools (chipping hammers, impact drills) indoors while attempting wet dust control methods. Under these conditions, exposures range from 12 μg/m^3 to 880 μg/m^3, with a median of 260 μg/m^3 and a mean of 328 μg/m^3.

The twenty remaining results (15 percent) were collected during chipping and breaking activities performed under a variety of “other conditions” (e.g., a complex mixture of tasks, use of a variety of tools, unknown locations (indoors or outdoors), and/or use of a constructed enclosure around the activity). These exposures ranged from 12 μg/m^3 to 1,144 μg/m^3, with a median of 13 μg/m^3 and mean of 152 μg/m^3.

OSHA also evaluated other sampling results not available for inclusion in the profile. In a review of exposure monitoring data from a variety of published and private sources, Flanagan et al. (2006) reviewed 178 respirable quartz samples associated with the use of jackhammers or chipping guns in construction and found a geometric mean of 150 μg/m^3 for those samples (Document ID 0677, Attachment 2). This mean is consistent with the exposure profile provided in Table IV.5.5-B, where the median outdoor and indoor baseline levels are 130 and 111 μg/m^3 respectively, with more than half of all workers using chipping and breaking equipment exposed above 100 μg/m^3. OSHA’s and Flanagan’s data sources likely overlap because they draw from much of the same published literature and some of the same unpublished sources. The overlap is explained in Section IV-2 – Methodology.

A report addressing silica exposures during underground tunnel construction summarized respirable quartz concentrations for workers using chipping equipment in the tunnel. Over the periods monitored, the geometric mean exposure level for 10 workers operating chipping guns was 70 μg/m^3, with a range of 9 μg/m^3 to 1,640 μg/m^3 (Document ID 0562, p. 637). These samples contained a mean quartz content of 11.9 percent with a range of 2.3 to 23.6 percent. The exposures of the tunnel chipping gun operators are lower, although similar, to the median indoor baseline samples of the profile (111 μg/m^3).

OSHA also takes note of an international study conducted by Nij et al. (2004) that collected samples from construction workers in the Netherlands (i.e., concrete drillers, tuckpointers, and demolition workers) whose tasks involved the use of jackhammers and other dust-generating tools (Document ID 0836, p. 192). The authors reported silica results for 14 samples from eight workers who were drilling concrete with jackhammers and hammer drills. Results ranged from 36 μg/m^3 to 4700 μg/m^3, with a mean exposure of 1090 μg/m^3 and geometric mean exposure of 420 μg/m^3. Silica results for 21 samples from 10 demolition workers ranged from 38 μg/m^3 to 1,300 μg/m^3, with a mean exposure of 250 μg/m^3 and geometric mean of 140 μg/m^3. These results provide some support for those documented in the exposure profile Table IV.5.5-B, however it is important to note that, in addition to jackhammering, the demolition workers performed activities such as using drills, excavators equipped with breakers, welding, sawing, and clearing of rubble, and the drilling operators also performed recess milling and sawing on concrete or lime sandstone. So, it is not known how much time or to what extent the silica exposures were attributable to jackhammering alone.

As reflected on the exposure information in Table IV.5.5-B, most construction workers who use jackhammers, chipping/ percussion hammers, or powered handheld impact tools work outdoors without engineering controls or dust-suppressing work practices. When comparing exposures from indoor and outdoor work, exposure results obtained indoors with and without use of wet suppression have higher maximum and mean values than results obtained from outdoor work. For example, the mean indoor-baseline (water controls not indicated) exposure level is 404 µg/m^3 compared to 194 µg/m^3 for outdoors-baseline (water controls not indicated), with 78 percent of samples above 50 µg/m^3 for indoors, compared to 73 percent for outdoors. The exposure profile contains 16 samples for which the description of the control methods indicated that wet methods were used for dust suppression; 11 samples taken indoors with a median of 260 µg/m^3 and 5 samples taken outdoors with median of 140 µg/m^3 (Document ID 3958, Rows 8, 522-523, 723-725, 1064-1066; 1143, Rows 63, 183-184; 0019, p. 67; 0079, p. 31). When wet methods were used, then median sample result was almost twice as high indoors compared with outdoors.

Because visible dust levels can build up when working indoors due to decreased air circulation, it is more likely that methods of dust control will be attempted when working indoors (i.e., 25.6 percent of indoor samples applied water, compared to 6.7 percent of outdoor samples).

For the samples taken outdoors, the median value for samples taken when wet methods were used (140 µg/^{3}) was only slightly lower than the median value when control methods were not used (148 µg/m^3). For samples taken indoors, the median value when wet methods were used (260 µg/3) was substantially higher than the median value when no control methods were used (111 µg/m^3). The higher median dust level for samples in which wet methods were used during jackhammering indoors runs counter to the concept of dust suppression using wet methods. A closer examination of these sample data provides several possible explanations. Three of the 4 highest samples in the indoor/water applied category (all three > 600 µg/m^3) were obtained during an OSHA inspection that describes three individuals jackhammering a concrete ramp in a large pool area (Document ID 3958, Rows 1064, 1065, 1066). The high silica exposures may have been the result of multiple, concurrent jackhammering operations in an enclosed area. The control description of water suppression lacked sufficient detail to determine the type of wet method used, and how it was applied, in this operation. Another possible explanation is that wet methods in this case were used due to the presence of higher than expected levels of respirable dust during this project, so that without the use of wet methods, silica exposures levels would have been even higher. Removing these 3 samples from the 11 samples on indoor jackhammering with wet methods would result in a median level of 104 $\mu g/m^3$, slightly lower than indoor jackhammering with no controls used. This result is similar to the comparison of jackhammering outdoors with wet methods used and jackhammering outdoors with no controls used.

The final exposure profile below compiles the best available exposure monitoring data of workers using jackhammers, percussion/chipping hammers, and other powered handheld impact tools. This exposure monitoring data, as described in more detail above, was obtained under a range of conditions. Therefore, the monitoring data distribution results reflected in the final exposure profile in Table IV.5.5-B represent the best available evidence of these workers’ existing exposure levels.

Table IV.5.5-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Construction Workers: Demolition Workers Using Jackhammers and Other Powered Handheld Chipping Tools

	Exposure Summary			Exposure Range		Exposure Profile				
Demolition Workers Using Jackhammers and Handheld Power Chipping Tools	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**	**< 25 (μg/m³)**	**≥ 25 and ≤ 50 (μg/m³)**	**> 50 and ≤ 100 (μg/m³)**	**> 100 and ≤ 250 (μg/m³)**	**> 250 (μg/m³)**
Outdoor - baseline	66	194	148	12	624	11 (16.7%)	7 (10.6%)	10 (15.2%)	15 (22.7%)	23 (34.8%)
Outdoor with water applied	5	226	140	12	639	1 (20%)	0 (0%)	0 (0%)	3 (60%)	1 (20%)
Indoor - baseline	32	404	111	12	2,350	7 (21.9%)	0 (0%)	8 (25%)	8 (25%)	9 (28.1%)
Indoor with water applied	11	328	260	12	880	3 (27.3%)	0 (0%)	1 (9.1%)	1 (9.1%)	6 (54.5%)
Other	20	152	13	12	1,144	11 (55%)	1 (5%)	2 (10%)	3 (15%)	3 (15%)

5.5.3 Additional Controls

The exposure profile in Table IV.5.5-B shows that almost 70 percent (93 out of 134 samples) of workers using jackhammers and other handheld powered chipping tools have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

Seventy-three percent of workers using jackhammers, chipping hammers or other powered handheld impact tools when working outdoors without any controls, were exposed to silica at levels above 50 μg/m^3. Seventy-eight percent of the workers using these tools indoors without any controls (baseline conditions) were exposed to silica at levels above 50 μg/m^3. As a result, controls will be required to reduce these operators' exposures. Additional, properly-implemented controls may need to be used by some workers already using some form of control. Control options include LEV and wet suppression methods, which, as Table IV.5.5-B indicates and studies discussed below show, will reduce respirable silica exposures significantly. OSHA judges that these methods are technologically feasible and if properly implemented will reduce exposures to the lowest feasible level.

Wet Methods

Various studies have demonstrated that properly used wet methods can substantially reduce respirable silica levels by 90 percent and higher (Document ID 0865; 0867; 0838; 0914; 1267, pp. 493-494; 2177, Attachment D, p. 19). NIOSH studies that examined water spray devices designed to optimize dust suppression (directed mist or solid cone nozzle) have found that dust and/or silica is reduced from 72 to 90 percent at a flow rate of approximately 350 milliliters per minute (ml/min) for jackhammers operated outdoors (Document ID 0865; 0867; 1267, pp. 493-494).

In a study by NIOSH, two workers were sampled to investigate reductions achieved through the use of a water spray attachment on jackhammers (Document ID 0867). The RCS sample results for the trials conducted for dry jackhammering ranged from 380 μg/m^3 to 2800 μg/m^3. The RCS sample results for trials conducted when using the water spray attachment ranged from 50 μg/m^3 to 320 μg/m^3, after excluding a trial during which the water spray nozzle was clogged. The water spray attachment used by worker 1 delivered approximately 250 ml of water per minute and reduced exposures to RCS by 39 percent compared to no control. The water spray attachment used by worker 2 delivered approximately 300 ml of water per minute and reduced exposures to RCS by 77 percent compared to no control. The authors observed that water applied at these flow rates did not add a substantial amount of water to the work surface (Document ID 0867, p. 17).

Information submitted to the docket by NIOSH includes a presentation from the Hazards Control Department of the University of California Lawrence Livermore National Laboratory, showing that wet suppression reduced respirable dust by 81 percent for outside work and 95 percent for inside work and reduced silica concentrations by 86 percent for outside work and 98 percent for inside work. The reductions resulted in mean exposure levels of 48 μg/m^3 for inside work and 65 μg/m^3 for outside work (Document ID 2177, Attachment D, p. 19).[180]

Although not commercially available at this time, the record shows a number of examples of water suppression systems that have been developed and tested and are ready for commercial introduction (Document ID 0741; 0838; 0914; 2177, Attachment D, pp. 4-7; 3732, Attachment 3, p. 10). During the hearings, Ken Hoffner of the joint labor management New Jersey Laborers' Health and Safety Fund described the system it has developed and tested. The system demonstrates “that the application of wet controls and respiratory protection for the jackhammer and impact drilling activities listed in Table 1 will achieve compliance with the recommended PEL” (Document ID 3589, Tr. 4213). Mr. Hoffner estimated that the water suppression system the Fund developed costs about $350, could supply up to six jackhammers at the same time, and has run without repair for eight years (Document ID 3589, Tr. 4234-4237).

During the hearings, some commenters argued that water may not be available on site, that in cold climates it may be an unworkable control, and that it may introduce slip

[180] This experimental study was a simulation conducted in a fabricated enclosure, so was not included in the exposure profile since it did not represent field data. There were four samples collected of dry inside jackhammer work, with exposures ranging from 860 μg/m^3-1600 μg/m^3 of respirable crystalline silica. There were four samples collected using wet suppression while jackhammering inside, with exposures ranging from <30 μg/m^3 -100 μg/m^3).

hazards or runoff issues (Document ID 2319, p. 110; 2171, p. 4; 3589, Tr. 4229-4230, 4296). However, comments and hearing testimony described current contractor practices to make water available on worksites and to adapt to harsh winter conditions in construction (Document ID 4207, p. 2; 3585, Tr. 2932, 3059, 3062, 3094; 3583, Tr. 2341; 3589, Tr. 4229-4230, 4296). OSHA understands the concerns about possible slip hazards from the use of water, however, NIOSH investigators noted that the relatively low water flow rates (300 ml/min) used to suppress dust during jackhammering did not result in a substantial accumulation of water on work surfaces. Proper implementation of wet methods will include training operators to avoid using more water than necessary and taking measures to contain any runoff to prevent the accumulation of water on walking and working surfaces.

The information reviewed by OSHA indicates that water spray controls, when properly designed and used, can reduce typical breathing zone concentrations outdoors by 72 to 98 percent (midpoint of 85 percent) (Document ID 0838; 0865; 0867; 1267, pp. 493-494; 2177, Attachment D, p. 19; 0914). Applying a reduction of 72 percent to the sample results from the exposure profile, OSHA estimates that water spray controls could reduce the median silica exposure level for workers using jackhammers, chipping hammers, and other powered handheld impact tools outdoors from a median of 148 μg/m^3 to 41 μg/m^3 TWA. Applying a 72 percent reduction to outdoor baseline condition samples, OSHA estimates that 43 percent of exposures will exceed 50 μg/m^3. Field trials of water controls (described above) show that water spray systems mounted on jackhammers have reduced silica exposures to at or below 100 μg/m^3. For the water suppression to be effective, it must: 1) provide sufficient water mist (flow rate optimized); 2) provide a suitable droplet size and pattern (the correct nozzle); and 3) be appropriately directed at the point of impact (Document ID 0548).

Local Exhaust Ventilation

LEV systems present an additional control option for reducing the respirable quartz exposures of impact drillers. The available information on LEV dust control systems for chipping and breaking equipment suggests that some local exhaust ventilation systems might be nearly as effective as certain wet methods. NIOSH tested two tool-mounted

LEV shrouds: one custom built, the other a commercially available model during work with chipping hammers. Comparing multiple short–term samples, NIOSH found that use of the shrouds resulted in respirable dust levels between 0.6 and 1.38 mg/m^3, a reduction of 48 to 59 percent from uncontrolled conditions (Document ID 1267, 0865). In a separate evaluation, NIOSH evaluated workers using 25- or 30-pound jackhammers to chip concrete from inside concrete mixer truck drums. During 90- to 120-minute periods of active chipping, mean silica levels decreased 69 percent (from 970 µg/m^3 to 300 µg/m^3) when the workers used a tool-mounted LEV shroud in these enclosed spaces (Document ID 0862, pp. 10-11). When they used a combination of LEV and general exhaust ventilation for additional dust control, there was an improvement to a 78 percent reduction in the silica level (Document 0862, p. 12).

During a separate manufacturer-sponsored test at an indoor demolition site, a LEV shroud mounted on a breaker hammer with a bag-style vacuum fitted with a high-efficiency particulate air (HEPA) filter reduced the number of 5-micron-sized (respirable) particles by 27 percent (Document ID 0667, p. 2). A company representative noted that this result could have been improved if the trial had involved the optimal airflow rate recommended for shrouds (120 cubic feet per minute [cfm]) by use of another type of vacuum (Document ID 0651).

Several powered impact tool manufacturers currently offer LEV options (Document ID 1288, p. 2; 1700). Other companies specialize in manufacturing after-market cowls or exhaust ventilation systems for various handheld tools such as jackhammers and chipping equipment (Document ID 0566; 1264, pp. 4-9; 1266, pp. 9-28; 1671; 1366; 1399; 3806, pp. 272-273, 276).

As with grinding and tuckpointing operations, it is likely that many of the recommendations about vacuum design that would aid in maintaining adequate air flow would apply to the use of LEV for jackhammers, chipping/percussion hammers, and other powered handheld impact tools including use of cyclonic pre-separators, vacuums with two vacuum cleaner motors in parallel combined with a large filter area and a gauge indicating filter pressure to assist workers in determining when it is time to run a filter cleaning cycle (Document ID 0600, pp. 884-886; 0731, pp. 382-384; 0863, pp. 9-10).

Work Practices

OSHA believes that if jackhammer, chipping/percussion hammer, and other powered handheld impact tool operators were provided vacuums rather than using compressed air to clean work surfaces, additional exposure reductions would be possible, especially in indoor environments (Document ID 0933, p. 49; 3799, p. 2). Although there are no individual studies that show the cumulative benefit of using vacuuming in combination with wet methods or LEV systems, the prevention of dust accumulation and re-suspension of settled dust will contribute to the overall exposure reduction achieved by tool-based control systems.

5.5.4 Feasibility Finding

Paragraph (c) of the construction standard gives employers the option of following Table 1, which includes specified engineering and work practice controls for workers operating jackhammers and other powered handheld chipping tools; alternatively, the employer must assess and limit exposures in accordance with the more traditional regulatory approach of compliance with the PEL contained in paragraph (d). For workers operating jackhammers and other powered handheld chipping tools, Table 1 requires employers to use either a tool with a water delivery system that supplies a continuous stream or spray of water at the point of impact or a tool equipped with a commercially available shroud and dust collection system. If an employer uses the dust collection option, it must ensure that the tool is operated and maintained in accordance with the manufacturer's instructions to minimize dust emissions and that the dust collector provides at least the air flow recommended by the manufacturer, has a filter with 99 percent or greater efficiency and has a filter cleaning mechanism. For both the wet methods and dust collection options, Table 1 requires the use of a respirator having an assigned protection factor (APF) of 10 whenever an employee is expected to operate a jackhammer or other powered handheld chipping tool indoors or in an enclosed area regardless of duration or outdoors for more than four hours per shift. When multiple jackhammers are used simultaneously in close proximity, specified exposure control methods (Table 1) on each of the jackhammers will be required so that an operator of one jackhammer with controls is not exposed to dust created by another jackhammer used without controls.

Based on data summarized in Table IV.5.5-B, OSHA concludes that most (almost 70 percent) of operators of jackhammers, chipping hammers, or other powered handheld impact tools currently experience exposures above 50 μg/m^3. Evidence in the record demonstrates that water spray suppression systems reduce respirable crystalline silica exposures substantially, where the system is well designed and properly implemented and maintained. Two published studies (Document ID 0867, 0914), as well as OSHA's analysis of the exposure reduction achieved from the baseline profile, indicate that TWA exposures can be reduced to 50 μg/m^3 or less most of the time by using water to suppress dust when jackhammering outdoors for less than four hours per work shift. While tested designs for water spray on jackhammers exist, OSHA has not identified any integrated water spray systems for jackhammers that are commercially available at this time. However, these spray systems can be assembled from readily available hardware and materials using instructions from NIOSH and the New Jersey Laborers' Health and Safety Fund (Document ID 0741; 3589, Tr. 4234-4237). Therefore, OSHA finds that the Table 1 option of using wet systems when operating these tools is technologically feasible and effective.

OSHA's exposure profile contained no exposure data on the use of shrouds and local exhaust systems. However, studies have shown that LEV systems can reduce exposures from 26 to 60 percent for jackhammers breaking concrete (Document ID 1267; 0865; 0651; 0667). The reductions, however, are substantially less than those reported with the use of water suppression (72 to 98 percent) (Document ID 0867, p. 3; 2177, Attachment D, p. 19). One study of LEV controls for jackhammers found respirable dust concentrations in the breathing zone ranging from 0.6 to 1.38 mg/m^3. The corresponding respirable quartz exposures would range from about 180 to 410 μg/m^3 (assuming a quartz content of 30 percent, which is on the high side of what is usually seen in concrete and other silica-containing construction materials) (Document ID 1267, p. 493). Another study of a jackhammer equipped with LEV used in a confined space (concrete truck drum) found a silica exposure reduction of about 69 percent (Document ID 0862, pp. 3, 10-11). These reductions, while still substantial, would result in exposures substantially above 50 μg/m^3 in indoor or enclosed conditions, where there can be visible dust accumulation (Document ID 4073, Attachment 15j), or outdoors where work patterns require operation beyond the median task time (231 minutes) (Document ID 0677). OSHA finds that the Table 1 option of using tools equipped with LEV systems is technologically feasible in that commercially available integrated systems have demonstrated the ability to significantly reduce respirable silica exposures. Several manufacturers currently offer LEV options (Document ID 0542; 1700; 1288). Other companies specialize in manufacturing after-market ventilation systems for various handheld tools, such as jackhammers and chipping equipment (Document ID 1264; 1266; 1366).

OSHA concludes that approximately 70 percent of workers using jackhammers and other handheld powered chipping tools are currently exposed to silica levels above 50 μg/m^3. For workers who are currently exposed above 50 μg/m^3, the controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or below in most operations, most of the time, when performed outdoors for fewer than four hours per shift. As indicated by the exposure profile (Table IV.5.5-B), jackhammering is most often conducted outdoors. And, based on the median task duration of 231 minutes (as well the physical exertion required while jackhammering), most jackhammering tasks are performed for fewer than four hours per shift. Therefore, OSHA finds that the standard is technologically feasible for workers using jackhammers and other handheld powered chipping tools. OSHA also finds that existing controls cannot reliably reduce TWA exposures to 50 μg/m^3 or below when operating jackhammers and chipping guns indoors or in enclosed areas, or when operating jackhammers or chipping guns outdoors for more than four hours in a shift. Supplemental respirator use is required in those situations.

5.6 MASONRY AND CONCRETE CUTTERS USING PORTABLE SAWS

5.6.1 Description

Portable and handheld power masonry and concrete saws are commonly found on construction sites where they are used to perform a wide variety of cutting activities, including cutting and resizing bricks, roofing tiles and concrete blocks and stone; cutting segments, including cores, out of existing pavement or masonry structures; cutting to straighten an edge or to weaken a structure in preparation for demolition; cutting grooves for utility installations; and cutting fiber-cement board. Exposures to respirable dust containing silica at levels above the previous PEL can occur when workers are using portable saws without effective dust controls.

For the purpose of describing control methods, OSHA has grouped portable masonry and concrete saws into five categories based on size and available controls: 1) handheld power saws; 2) specialty handheld power saws for cutting fiber-cement board; 3) rig-mounted core saws or cutting machines; 4) walk-behind saws; and 5) drivable saws.[181]

Two of these groups, specialty saws for cutting fiber-cement board and core cutting machines, have been added since the Preliminary Economic Analysis (PEA). OSHA added these groups in response to comments from the fiber-cement board industry, which provided substantial data on control technology (a specially-configured saw) for controlling silica exposures when saw operators cut fiber-cement board (Document ID 2322, Attachment B-F, Attachment H, pp. 1-7), and the Construction Industry Safety Coalition (CISC), which identified additional hole drilling processes and types of work related to installing fiber-cement board (Document ID 2319, pp. 19-21; 3580, Tr. 1279).

The following paragraphs describe the five groups of portable masonry saws:

Handheld power saws: Handheld power saws (also referred to as cut-off, chop, quickie, or handheld masonry saws) are normally fitted with 9 to 14 inch diameter blades and powered by small capacity combustion engines, electricity, or compressed air. These

[181] The unifying feature of all these saws is a blade that cuts a full or partial depth channel in the material, usually for the purpose of cutting away a portion of the material. Masonry and concrete saws typically produce a straight cut, but the cut is circular in the case of concrete coring machines.

saws can be used to cut concrete, masonry, and stone. Circular saws fitted with smaller blades ranging from 5 to 8 inches in diameter can also be used for smaller cuts in concrete and masonry (Document ID 0615, pp. 2, 24-28).[182] Two types of blades are commonly used: diamond tip and resin composite abrasive, with specialty variations also available. The diamond blades can be used either wet or dry (Document ID 0607; 0615, pp. 24-28).

When using a handheld saw, the operator holds the saw with both hands and leans over the work, which is typically between ground level and waist height. The cutter's breathing zone is often within arm's length of the point of dust generation (Document ID 0615, pp. 24-28). The worker's close proximity to the source creates the potential for high concentrations of respirable crystalline silica in the worker's breathing zone, resulting in elevated silica exposure values (summarized in Table IV.5.6-B, the exposure profile for this group of workers).

Handheld power saws cutting fiber-cement board: These specialized saw configurations consist of blades (typically 8 inches in diameter or less, with four to eight teeth) specifically designed for cutting fiber-cement board (Document ID 2322, Attachments A-I, p. 9, Attachment B, p. 8). The blades are fitted to a circular saw (or occasionally to other saws) with dust reduction designs (Document ID 2322, Attachments A-I, p. 9, Attachment B, p. 8). Although a form of handheld saw, this saw configuration (for fiber-cement board) is addressed separately in the FEA because it has been specifically designed and extensively tested by a member of the fiber-cement siding industry and by NIOSH for controlling the silica exposures of installers who perform cutting in that industry, and the saw is intended specifically for use on fiber cement board (Document ID 2322, Attachments A-I, pp. 5, 9, Attachment B, pp. v, 8). Fiber-cement board, produced with silica sand containing up to 45 percent silica, is used as siding and fascia applied to the exterior of buildings, so cement fiber boards are normally cut

[182] Although blades are usually 14 inches or smaller, larger blades are available for some equipment (Document ID 0615, p. 28).

outdoors (Document ID 2322, p. 11, 39, see also photos in Attachments B-F; 4139 [4139 is a duplicate/final copy of 2322, Attachment B]).

Rig-mounted core saws or drills: Saw operators use core saws to perform core cutting (also called core drilling, boring, or concrete coring) to create round holes for pipes, ducts and conduits to pass through walls, ceilings and floor slabs made of concrete, masonry or other materials that may contain silica. Core cutting machines (also called core drills) use a thin continuous round cutting surface on the round end of a cylindrical coring tool (“bit”) (see photographs in Document ID 0679, pp. 18-20). The annular bit’s cutting surface rotates around a central arbor (spindle) that runs through the center of the otherwise hollow cylindrical bit and attaches to an electric, hydraulic, or pneumatic power drive (Document ID 0615, p. 32). The machine is typically attached to the surface being drilled (bolted on via a rig for stability) (Document ID 3998, Attachment 13e, pp. 4, 9-photographs of core drill bolted to wall with rig), but for small or shallow holes the core drilling equipment can be handheld (Document ID 0675, p. 1098; 0679, pp. 18-21; 3501, p. 6). When the rotating diamond core cutting bit is applied to solid material, the bit cuts away a thin circle of material. The cut separates the central “core” of material, within the circumference of the bit, from its surroundings, leaving the core generally intact as it is removed from the hole (Document ID 3501, p. 6).[183] The cylindrical bit can be large; for example, NIOSH described a coring operation used to produce holes 2 to 31 inches in diameter in large sections of concrete conduit (Document ID 0898, p. 6).[184]

[183] In contrast to rig-mounted coring equipment, which allows workers to remove most of the material from the hole intact as a solid block by using a cylindrical cutting tool bolted to the surface being cut, the more familiar solid-tip drill bits (which tend to be smaller than most rig-mounted core drill bits) pulverize the material in their path, so the entire volume of solid material from the resulting round hole is turned to dust. Handheld drills using bits of this type or using small coring bits (up to a few inches in diameter) are covered in Section IV.5.4 – Hole Drillers Using Handheld or Stand Mounted Tools, while the large rig-based drills (usually mounted on vehicles or trailers) are addressed in Section IV.5.9 – Rock and Concrete Drillers.

[184] The coring operation occurred at a manufacturing plant producing construction materials (in a covered bay with only general dilution ventilation) where concrete conduit (large pipe), such as is used for water mains, was custom cored to allow fittings (i.e., junctions with other pipes) to be installed (Document ID 0898).

Coring cutting is typically a wet process. Water cools the blade, which is easily damaged if it becomes hot, and dust control is an added benefit (Document ID 3580, Tr. 1415; 3581, Tr. 1584; 3585, Tr. 2902).

Walk-behind saws: Walk-behind saws, also known as slab or green saws, are used to cut expansion joints or slabs out of existing pavement. Workers operate the equipment from behind using a control bar or handle(s) so that their breathing zone is typically five or more feet from the cutting blade. As walk-behind saws are used to cut pavement, they are most commonly used outdoors; however, they can also be used indoors (Document ID 1431, p. 3-63).

Drivable saws: A drivable saw operator typically sits in an open cab about 15 feet away from the pavement cut point, guiding the saw to make long cuts. This type of work is common for utility installations along roadways. The blade housed by this vehicle can be large (e.g., 8 feet in diameter and 2 inches thick) and is typically equipped with a water-fed system for cooling the blade. Because of their size, drivable saws are typically used outdoors (Document ID 1431, pp. 3-63 – 3-64).

Table IV.5.6-A summarizes the major activities and sources of silica exposure for workers using different types of portable and handheld masonry saws.

Table IV.5.6-A
Activities and Sources of Exposure of Masonry and Concrete Cutters Using Portable and Rig Mounted Power Saws

Task/Tool	Major Activities and Sources of Exposure
Handheld (Cut-off/Chop/Circular) Power Saw Operator	Using handheld power saw to cut bricks, concrete blocks, tiles (i.e., wall, floor, roofing), and small sections of concrete structures (e.g., pavement, curbs, walls). • Dust generated by cutting action of the abrasive blade in concrete or masonry.
Handheld Power Saw Operator cutting fiber-cement board (blade 8-inch or less)	Using handheld power saw to cut fiber-cement board. • Dust generated by cutting action of the abrasive blade in fiber-cement board.
Rig-mounted Core Saw Operator (wet process)	Using low speed rig-mounted, water-fed equipment to cut cores (i.e., remove cylindrical segments) from materials containing silica, such as concrete, stone or masonry (e.g., walls, floor slabs, ceilings). • Dust generated by cutting action of the abrasive blade.

Table IV.5.6-A Activities and Sources of Exposure of Masonry and Concrete Cutters Using Portable and Rig Mounted Power Saws	
Walk-Behind Saw (Slab Saw) Operator	Manipulating wheeled saw using handles. Cutting existing pavement, typically to form expansion joints or to cut slabs (or margins) of pavement sections to be removed by other tools. • Dust generated by cutting action of the abrasive blade in concrete or asphalt.
Drivable Saw Operator	Controlling saw from an open cab to make long cuts in existing pavement (e.g., to install underground utilities). • Dust generated by cutting action of the abrasive blade in concrete or asphalt.

5.6.2 Exposure Profile and Baseline Conditions

In the PEA, OSHA reviewed 91 time-weighted average (TWA) personal breathing zone (PBZ) respirable quartz results for workers using portable saws to cut concrete, masonry and related materials on construction sites. The updated exposure profile adds 12 samples from OSHA compliance inspections available through OSHA's Information System (OIS), two samples from a study published by Flanagan et al. in 2001, two samples from a NIOSH study published in 2000, and additional samples provided during the comment period by the James Hardie Building company (96 samples) and the National Roofing Contractors Association (3 samples) (Document ID 3958; 0675; 0898; 2322; 4022). The added data included 14 samples for workers dry cutting with portable handheld power saws outdoors, one sample for a worker dry cutting with a portable handheld power saw indoors, four samples for core drillers using wet methods, 21 samples for workers using saws (with specialty blades of less than 8 inches) for cutting fiber-cement board without other controls, and 75 samples for workers using specially configured circular saws (with specialty blades of less than 8 inches) for cutting fiber-cement board with local exhaust ventilation.

In the FEA, OSHA has made several adjustments to the subcategories into which handheld power saws are grouped to make the groupings more specific. These adjustments include renaming the subgroups previously affiliated with data labeled as "Indoors or location unspecified" to produce subgroups that more clearly indicate that the cutting took place either indoors or outdoors, using either wet methods or dry cutting. OSHA evaluated all handheld saw samples and organized them into the revised subgroups based on working conditions and sampling location, and on whether water was used during cutting (regardless of whether the water was used effectively or not). A total of 16 samples from the PEA were realigned in the process, including four samples where wet methods were used indoors.[185]

The final exposure profile in Table IV.5.6-B for construction workers using portable saws to cut concrete, masonry and related materials includes 83 samples with a median value of 110 μg/m^3, a mean of 288 μg/m^3, a range of 6 to 10,318 μg/m^3. For outdoors, the profile contains 65 samples taken when cutting dry with a median of 130 μg/m^3, and 5 samples with a median of 19 μg/m^3 when cutting wet. For indoors, 3 samples taken when cutting dry had a median exposure of 1490 μg/m^3 compared to a median of 50 μg/m^3 for the 10 samples taken when cutting wet.

Baseline Conditions for Handheld Power Saw Operators

Baseline conditions for construction workers using handheld saws typically involve outdoor cutting on concrete or masonry with no engineering or work practice controls in place (78 percent of samples). When used without dust controls, handheld masonry saws can generate very high levels of respirable dust. The exposure profile presented in Table IV.5.6-B shows that the median 8-hour TWA respirable silica exposure level for masonry cutters working outdoors without controls is 130 μg/m^3, with approximately 72.3 percent of samples over 50 μg/m^3 and 15 percent over 250 μg/m^3 and a maximum exposure of 1,472 μg/m^3. By comparison, for five samples obtained for workers using handheld saws

[185] Samples that previously had been grouped as “indoors or location unspecified” were evaluated and reassigned (indoors or outdoors) based on information in the record. In some cases, location is inferred from the task description. For example, sawing on “floor” or “ceiling” was judged to have taken place indoors, as those terms are rarely associated with an outdoor environment, while sawing activities on “pavement” were placed in an outdoor group, as the term “pavement” is widely used for outdoor surfacing. In some cases, descriptions of other samples collected at the same construction site were consulted to obtain additional insight into the nature and location of the worksite. The previous group of samples “indoors or location unspecified” (eight samples) or “indoors or location unspecified-wet methods” (four samples) were divided into the current four groupings: 1) “outdoors, dry cutting”; 2) “outdoors, wet cutting” 3) “indoors, dry cutting”; and 4) “indoors, wet cutting”. Additionally, four samples previously grouped with “outdoor, wet methods” were moved to the category for “indoors, wet cutting.”

outdoors with wet methods to control dust, the median exposure value is 19 μg/m^3 and the maximum value is 154 μg/m^3.

Median exposure levels tended to be higher for workers using power saws indoors compared to similar work performed outdoors, regardless of whether controls were used. As shown in the exposure profile (Table IV.5.6-B), the median exposure of 50 μg/m^3 for wet cutting indoors is roughly 2.5 times higher than the median exposure of 19 μg/m^3 for wet cutting outdoors. And the median exposure for dry cutting indoors is more than 11 times higher than the median exposure for dry cutting outdoors (1,490 compared to 130 μg/m^3). Location also affects the portion of workers with exposures exceeding 50 μg/m^3. When saw operators performed cutting indoors with water, 50 percent of samples (5 of 10) were over 50 μg/m^3, compared with only 20 percent (1 of 5) over 50 μg/m^3 when sawing was performed outdoors with water. The three indoor dry cutting samples are greatly influenced by a single high value based on a 350-minute sample with a 14,150 μg/m^3 silica concentration (10,318 μg/m^3 as an 8-hour TWA), which was reported for a plumber who used a handheld saw to dry-cut slabs out of concrete bathroom floors indoors on each level of a 16-story building. A floor-stand fan aimed at an open window was the only attempt at dust control (Document ID 0846, p. 6).

The National Roofing Contractors Association submitted data from monitoring three roofers installing clay tiles on a residential roof using a dry 14-inch tile cutting saw (Document ID 4022, Attachments 1, 2). The samples were taken for 197, 198, and 202 minutes (Document ID 4022, Attachment 2, Appendix D). For these samples, the investigator indicated that the unsampled periods of the shifts were expected to have the same exposure concentration as was measured during the portion of the shift that was monitored (Document ID 4022, Attachment 1, pp. 2, 7, Appendix D). The two roofers who performed the majority of the tile cutting had quartz concentration exposures of 160 and 300 μg/m^3. However, the supervisor who did not do as much tile cutting had a quartz exposure of 33 μg/m^3 (Document ID 4022, Attachment 1, Appendix D). OSHA has converted these exposure concentrations to 8-hour TWAs (assuming exposures continued at the same levels during the unsampled periods), and has included these exposure results in the exposure profile.

The Concrete Sawing and Drilling Association (CSDA) submitted "Best Practices - Silica Data Analysis Chart," which compiles silica exposure data for workers using various construction tools, including various handheld and wall- (rig-) mounted power saws (Document ID 3497). Patrick O'Brien (representing CSDA) explained that the chart is based on all sawing and drilling data CSDA has collected over the last decade (Document ID 3585, Tr. 2900, 2907). The chart's introduction states that it contains exposure results collected by association member jobsites and from NIOSH (Document ID 3497, p. 1). It is unclear whether the results in CSDA's Best Practice document are individual PBZ samples. Some results are presented as a range of exposures, suggesting that the result represents multiple samples. Other results appear to be area samples, rather than PBZ samples. For example, OSHA matched several area samples in a NIOSH study (Linch, 2002) to results provided in CSDA's document (Document ID 0784, pp. 216-217). Further, although the chart reports the sample duration and the result, it is unclear whether the result is a concentration value or an 8-hour TWA. Finally, as CSDA stated that some of the results are from NIOSH, there appears to be some overlap between the results in the chart and NIOSH data that are already part of the exposure profile. Accordingly, although OSHA has insufficient information to include the data in the exposure profile (see IV-2 – Methodology), OSHA has considered this data and found it useful in evaluating the effectiveness of controls

In addition to the documents that contributed individual results to the exposure profile, OSHA reviewed a study by Flanagan et al. (2006) that summarized 65 results for workers using handheld saws (part of a larger set of construction silica exposure data compiled by the authors) (Document ID 0677, p. 147-Table II). The authors reported an overall geometric mean quartz concentration of 130 $\mu g/m^3$ for the sawyers using handheld saws, but provided no other information specific to this group (Document ID 0677, p. 147). The geometric mean reported by Flanagan et al. (2006) is in the same range as the information OSHA has summarized for this job category in Table IV.5.6-B, which shows a median of 110 $\mu g/m^3$ for the general category of handheld saw operators. OSHA also reviewed another construction silica dataset, compiled by Flanagan (2009), and determined that it is substantially similar to that summarized in the 2006 paper (Document ID 0677; 0677, Attachment 2). OSHA did not incorporate the individual exposure data reported by

Flanagan into the exposure profile because it overlaps with several sources of data that OSHA has already included in the exposure profile. While not used in the profile, these supplemental sources of exposure data provide additional information on expected exposure levels for workers using portable saws.

Another report from Flanagan et al. (2001) provides summary exposure information for workers using rig-mounted (but hand-guided) wall saws indoors. This equipment was used with a water feed and was associated with a median concentration value of 130 $\mu g/m^3$ (range 60 to 220 $\mu g/m^3$) for three samples (with a mean sampling time of 294 minutes) (Document ID 0675, p. 1098-Table I). The authors attributed at least one of the elevated exposures to work practices common among inexperienced workers who closely watch the progress of the blade, putting "their breathing zone . . . in the particle spray zone" (Document ID 0675, p. 1098). More experienced workers tended to stand back out of the spray (particularly when cutting walls with hand-guided saws on tracks) (Document ID 0675, p. 1098). The authors also indicated that to represent "worst case" conditions, they elected to monitor indoor work sites where jobs with long task durations were scheduled (Document ID 0675, p. 1097).[186]

Operators typically use handheld saws for brief, intermittent periods; however, the process might be repeated numerous times over the course of a shift (Document ID 1431, p. 3-63). During the rulemaking, OSHA received additional information indicating that most workers use handheld saws for less than two hours a day. Rashod Johnson of the Mason Contractors Association of America (MCAA) and Chairman of the ASTM E34 subcommittee on silica in construction from 2003-2013 stated: "90 minutes is actually a really long time to be cutting something. The vast majority of [cuts] are under 15 minutes in any given day" (Document ID 3581, Tr. 2911). Mr. Johnson explained that when more

[186] This strategy of selecting only work sites with long-duration ("full-shift") sawing jobs both allowed the investigators to evaluate "worst-case" conditions and also helped ensure that silica exposure results were above the limit of detection (LOD). The authors note that "many jobs do not involve such extensive periods of cutting, with workers often working at two or three job sites per day. Time spent commuting between sites and cleanup for each job provided periods of minimal or no exposure" (Document ID 0675, p. 1100).

cutting is necessary, the sawyer uses a cutting station that has a different set of engineering controls (Document ID 3581, Tr. 2911).

Dan Smith, Director of Training at the Bay Area Roofers and Waterproofers Training Center, stated that less than fifty percent of their commercial work involves cutting concrete tile and that this percentage is far lower in residential roofing (Document ID 3581, Tr. 1597). When cutting is performed, it is usually half an hour to 45 minutes a day (Document ID 3581, Tr. 1598). Middaugh et al. (2012) explained that concrete cutting in roadway construction is frequently performed with a handheld saw, noting that "typical curb cutting is performed for less than 2 hours per day" (Document ID 3610, pp. 157, 162). Additionally, a database of silica exposures in construction tasks shows similar times, as the median sample time for workers cutting brick, concrete and stone with a handheld portable saw was 101 minutes (range 9-447 minutes) (Document ID 0677, Attachment 2). At a construction site visited by OSHA, a worker using a water-fed handheld saw spent 40 percent (160 minutes, or 2 hours and 40 minutes) of a 401-minute monitoring period cutting a concrete floor (Document ID 0169, pp. 5-7).[187] Based on the information in the record, OSHA concludes that, most of the time, handheld power saw operators use the saw for two hours or less per shift.

Baseline Conditions for Handheld Power Saw Operators Cutting Fiber-Cement Board

Baseline conditions for construction workers using handheld power saws to cut fiber cement board are based on exposure data from five reports (two reports by NIOSH and three reports from a member of the fiber-cement board industry) that were provided to OSHA during the rulemaking (Document ID 4139; 2322, Attachments B-F). OSHA notes that the two NIOSH reports (Document ID 2322, Attachments B and C) were also entered in the record individually (as Document ID 4139 and 3998, Attachment 4a). The saws used in these reports were fitted with commercially-available, specially designed blades intended for cutting fiber-cement board (an exterior siding and underlayment

[187] OSHA calculated a respirable silica measurement less than or equal to 21 μg/m^3 (the LOD) for the period of this sample (12 μg/m^3 as an 8-hour TWA μg/m^3), and the concrete being cut contained 9 percent silica (Document ID 0169, pp. 5-7).

product) (Document ID 2322, Attachments A-I, pp. 6). Operators using these saws work outdoors cutting fiber-cement board products (siding, fascia) that are placed on the exterior of buildings (Document ID 2322, Attachments A-I, p. 6, Attachment D, pp. 11-13 [photographs]; 3998, Attachment 4c, p. 5-Figure 2; 4138, pp. v, 2, 5-Figure 2).[188]

The five reports from which data for the exposure profile is drawn conducted breathing zone sampling for workers using several types of saws with and without various forms of dust reduction measures, representing conditions and practices currently in use by the industry. These five reports contributed a substantial number of data points to the exposure profile. One earlier (EPBH 358-11a) and two later (EPHB 358-14a and -15a) NIOSH reports in the record evaluated prototype saws that were still under development (by a member of the fiber-cement board industry and a saw manufacturer) and are not commercially available. As such, exposure results for trials with these saws are not representative of exposures of workers in the U.S. and are not included in OSHA's exposure profile (Table IV.5.6-B).

The exposure profile for the cutters operating a variety of saws configured for fiber-cement board is presented in Table IV.5.6-B. The profile shows a mean 8-hour TWA exposure of 63 μg/m^3 and a median exposure of 21 μg/m^3 for 21 saw operators using various saws fitted with the specialty blade, but no controls. The highest 8-hour TWA exposure for this group, 605 μg/m^3, was obtained over a sampling period of 290 minutes for a siding cutter at a siding installation site. The cutter's primary activity was to use an uncontrolled circular saw to cut boards to lengths as the installer (another worker) requested them (Document ID 2322, Attachment D, p. 6). Although it was a typical fiber-cement siding installation, sampling notes indicate that this saw operator brushed accumulated dust off his clothing during the sampling period. The notes mention that the dust from the worker's clothing might have influenced the worker's exposure for the day (Document ID 2322, Attachment D, p. 6).

[188] The data sources are: Document ID 2322, Attachments B-F; 4139 (4139 is a duplicate/final copy of 2322, Attachment B).

The exposure profile also summarizes the exposure results for 75 operators using saws fitted with special cutting blades designed for fiber-cement board and some form of "dust collector" (but not always of a design with vacuum suction). These workers had a mean 8-hour TWA exposure of 11 μg/m^3 and a median exposure of 7 μg/m^3, although elevated exposures (maximum exposure of 76 μg/m^3) occurred with some saw/control configurations that proved less reliable (for example, saws attached to a dust receptacle, without the benefit of a vacuum dust collection device) (Document ID 2322, Attachments A-I, pp. 19-20). The fiber-cement board products being cut contained 15 to 50 percent silica, however, the respirable dust collected in the samples was 0 percent to 12 percent silica and percentages in the lower half of that range were most typical (Document ID 2322, Attachment D, pp. 5-10, Attachment E, pp. 5-9, Attachment F, pp. 5-10). OSHA also notes that the exposure results for the sawyers who were using dust controls might be lower than typical exposures for operators of the same equipment for cutting fiber-cement board on other worksites because these sawyers did not empty the dust from their dust collectors; other (unsampled) workers performed this task (Document ID 2322, Attachment D, p. 3, Attachment E, p. 3, Attachment F, p. 3).

In summary, saw operators cutting fiber-cement board use a variety of commercially available saws configured for this purpose with a specifically designed blade; some of these saws are equipped with LEV. Using portable saws without engineering controls can result in elevated exposures, although using LEV on dust collection saws with specially designed blades 8 inches or less reduces exposures to less than 50 μg/m^3 most of the time (in Section IV-5.6.3 under the heading Additional Controls for Handheld Power Saws Cutting Fiber-Cement Board).

<u>*Baseline Conditions for Rig-Mounted Core Saw or Drill Operators*</u>

In developing the PEA, OSHA reviewed information on core saws (core drills) and determined that operators generally experienced little or no silica exposure during this low-speed process, which is already performed using water-fed equipment as a standard practice (Document ID 0675; 0898). Accordingly, OSHA's preliminary exposure profile did not include any sample results for core cutters. During the rulemaking hearing, Holes, Inc., a company that performs concrete cutting, wall sawing, slab sawing, core drilling, concrete breaking, and demolition tasks, provided additional information regarding task process, scheduling, bits, tools, and wet methods used during concrete core drilling (Document ID 3580, Tr. 1435, 1447, 1484, 1534-1535). Holes, Inc. also agreed with CISC that OSHA considered too narrow a list of construction tasks in the proposal (Document ID 3580, Tr. 1363). OSHA has therefore evaluated rig-mounted core saws in the final exposure profile.

The record contains few exposure results for workers using core cutting machines (core drills). The final exposure profile in Table IV.5.6-B for core saws includes four sample results, all of which are below 50 μg/m^3. These four samples were obtained indoors and range from 11 to 29 μg/m^3 (median 12 μg/m^3, mean 16 μg/m^3). Two of the samples were taken for an operator who was coring 6-inch holes in an 8-inch thick wall over two days. These samples were reported in summary form as ranging from 20 to 20 μg/m^3 over an average sampling time of 261 minutes, which encompassed the operator's entire exposure (Document ID 0675, pp. 1097, 1098-Table 1). Because the summary results presented could be individualized (both results were 20 μg/m^3), OSHA calculated 8-hour TWAs of 11 μg/m^3 from the reported results.[189] These sample results were obtained at a construction site where other wet sawing techniques were also used, sometimes resulting in exposures to other (non-coring) saw operators, exceeding 50 μg/m^3; however, the diamond blade exposure levels associated with core sawing remained low (Document ID 0675, pp. 1097, 1098). Although most results from this study are presented in summary form, these two values are some of the only samples available for core saws. Additionally, OSHA finds there is little risk of these two samples misrepresenting the actual 8-hour TWAs, which for neither sample could exceed 20 μg/m^3 (in the worst case, if the worker performed the task for 480 minutes in one day, the 8-hour TWA would still be no higher than 20 μg/m^3).

Two additional samples from a worker using core sawing or cutting equipment with wet methods were obtained on two dates at a site visited by NIOSH (Document ID 0898, p.

[189] Flanagan et al. (2001) reports silica sample results in mg/m^3 as the concentration during the monitoring period; OSHA multiplied the samples by 1,000 to obtain values in μg/m^3 and determined the 8-hour TWA using the equation for an 8-hour TWA (Concentration1*Time1/480 minutes) from 29 CFR1910CFR 1910.1000(d)(1)(i).

3). Although technically a general industry site, the core sawing operation was performed on conduit (concrete pipe used in utilities construction, such as installing water mains) and could have been performed at the construction site (where exposures might be somewhat lower than in an indoor environment) instead of at the manufacturing site (in a 7,000 square-foot open bay with only general ventilation fans). This operator cut approximately 20 holes, 2-to 31-inches in diameter, and experienced 8-hour TWA exposures of 12 and 29 μg/m^3 on the two days sampled (Document ID 0898, p. 15).

CSDA submitted five sample results for workers using water-fed core cutting machines (tool listed as “Core Drill” or “two-speed coring rig”) indoors and outdoors. All of the results were below 50 μg/m^3 (range 10 to 40 μg/m^3) (Document ID 3497, p. 1). CSDA also provided four exposure results for the task of “wire sawing & core drilling” (Document ID 3497, p. 8). The controls for these results are listed as “water, away from sawing operation, remote control,” and the reported concentration values ranged from below the limit of detection (not further described) to 50 μg/m^3 (Document ID 3497, p. 8). As noted above, the results submitted by CSDA include area samples, and some of the results overlap with data already in OSHA’s exposure profile. Therefore, OSHA did not incorporate exposure results from the CSDA chart in the exposure profile for core cutters (Table IV.5.6-B).

Based on evidence in the record, OSHA has determined that baseline conditions for core sawing operators involve using wet methods (Document ID 0675, p. 1097; 0898, p. 6; 3580, Tr. 1415, 1435; 3581, Tr. 1584; 3585, Tr. 2902). Most core sawing machines include, and are intended to be used with, a water feed (Document ID 0679, pp. 18-21; 3580, Tr. 1415; 3581, Tr. 1584; 3585, Tr. 2902). The core sawing machines that can be used dry are not intended for use on concrete; nevertheless, a water-feed attachment is typically available either as standard or supplemental equipment (Document ID 0679, pp. 18-21). For all but the smallest holes, core sawing machines are bolted in position on the concrete surface to be cored and, compared to other cutting equipment, operate at low to moderate speeds to facilitate precision cuts. For example, a bolt-on water-fed core sawing machine capable of producing a wide range of hole sizes operates at 250 rotations per minute (rpm) when producing 5 to 14 inch holes, with a top speed of 1,000 rpm for small holes 1 to 3 inches in diameter (Document ID 0679, p. 21).[190] The data in the exposure profile reflects the best evidence available to OSHA regarding exposures among core saw operators.

Baseline Conditions for Walk-Behind Saw Operators

OSHA reviewed 20 silica sample results for workers operating walk-behind saws and found that 60 percent were at or below 50 µg/m^3. Twelve of the 20 sample results were collected when the sawing was conducted outdoors with sufficient wet methods. For these 12 samples, the median is 12 µg/m^3 and the mean is 18 µg/m^3; all 12 results were under 50 µg/m^3.[191]

The 12 walk-behind saw operators who used wet methods outdoors worked on various road construction sites (five sites total, including highway construction and interstate repair jobs), usually using water provided by a water truck (Document ID 0784, p. 216, 217-Table V; 1143, Rows 74, 75, 207, 208). Sample times ranged from 53 to 545 minutes. Four of the samples were from a site where the saws were used to cut "green" concrete (recently poured and not fully cured, rather than old or fully cured concrete) (Document ID 0784, p. 216-217).

Eight of the 20 samples for walk-behind saw operators were collected under conditions other than wet cutting outdoors (such as indoor cutting or cutting without wet methods, referred to as "other conditions" in the exposure profile), and all eight show exposure results over 50 µg/m^3. The median value of 236 µg/m^3 is almost 20 times higher than the median of 12 µg/m^3 for workers using wet methods outdoors. Four of the results for operators in "other conditions" (ranging from 65 µg/m^3 to 350 µg/m^3) were obtained by Flanagan et al. (2001) over 4 to 7 hours of indoor work involving wet sawing. In that

[190] Other drilling, cutting, and grinding equipment operates at rpm several times greater. For example, at a site where concrete coring was conducted, the coring equipment ran at 350 rpm, while a rig-mounted concrete saw used to cut a wall of the same structure operated at 2500 rpm (Document ID 0222, p. 4). A tuckpointing grinder blade operates in the range of 10,000 rpm (unloaded) (Document ID 0679, p. 25).

[191] One sample result included in the PEA originally reported as less than the limit of quantification of 61 µg/m^3 was found to be an error. The correct value (as reported by Linch (2002)) for a worker cutting with water supplied by a 4 horse power pump to the saw tip during the 231-minute sampling period is less than or equal to 20 µg/m^3 (the LOQ) (Document ID 0784, pp. 216-217-Table V).

case, a helper used a wet shop-vac to vacuum up slurry (Document ID 0675, pp. 1098-1099, Tables I and II).[192] These samples were collected at construction sites that were selected for evaluation because the sites were anticipated to represent worst-case conditions (longer than typical periods of cutting in enclosed indoor spaces). The saws were operated wet "primarily to limit wear on the expensive diamond blade" (Document ID 0675, p. 1097).

The "other conditions" category includes the highest sample result for walk-behind saw operators. The exposure result (calculated as an 8-hour TWA) of 461 μg/m^3 is associated with a sawyer cutting repair boundaries on a bridge deck under dry working conditions at a site where all seven silica samples (for the operators of a road milling machine, various saws, and jackhammers) exceeded the previous (calculated) PEL by up to 12 times (Document ID 0912, pp. 1, 5).

Two of the "other conditions" samples, with 8-hour TWA results of 172 and 298 μg/m^3, were obtained over 4 to 6 hours while the saw operators cut expansion joints in a roadway at a construction site visited by OSHA. No control measures were associated with these samples (Document ID 0111, pp. 17, 19, 22-24, 27, 28).[193] Nor were controls associated with the other exposure result (an 8-hour TWA of 140 μg/m^3, based on a 314-minute sample), obtained at a second road construction site that OSHA visited where a worker cut expansions joints (Document ID 0815, p. 2).

CSDA's Best Practices document includes 26 entries for water-fed walk-behind saws ("slab sawing") outdoors (Document ID 3497, pp. 2-4). Twenty-five of the 26 reported results were at or below 50 μg/m^3. The chart from CSDA contains a mixture of exposure results collected by association members and from NIOSH. Many of the NIOSH

---

[192] Flanagan et al. (2001) present three individual results for inside slab sawing in Table II, and OSHA was able to calculate the 8-hour TWA for the fourth sample (for "Slab saw/walk-behind (inside)"). For the fourth value, the sample duration was 241 minutes (calculated from mean duration and the three given durations) and the concentration was 130 μg/m^3 (presented as the low value in the range, and not among the other three values). The 8-hrhour TWA for this concentration is 65 μg/m^3 (130*241/480) (Document ID 0675, pp. 1098-1099, Tables I and II).

[193] Silica 8-hour TWAs calculated from respirable dust concentration, sample volume, and percent silica in the sample.

exposure data points are likely already incorporated in OSHA's exposure profile (Document ID 3497, p. 1). The exposure results in the CSDA chart are not attributed to specific sources; however, a limited comparison of 13 results in the CSDA chart were matched with results from two other studies already in the record (Document ID 0675; 0784). OSHA found that some PBZ data from the CSDA chart were already included in OSHA's exposure profile, and also found that the CSDA chart included area samples intermixed with PBZ samples (though the area samples were not identified as such). Furthermore, individual results on CSDA's chart do not necessarily represent a single worker's exposure; at least one row summarized results for four workers. For these reasons (summarized samples, area samples, and overlap with data already in the exposure profile), OSHA did not incorporate the exposure results from the CSDA chart in the final exposure profile (Table IV.5.6-B).

Based on data collected from at least six construction sites visited by OSHA and NIOSH and other published reports, OSHA has determined that walk-behind saws are commonly used with wet cutting methods (Document ID 0784, pp. 216-217; 0846, p. 8; 1143-Companies BB and OOOO). At three sites, workers sprayed water at the point where the saw blade cut pavement. At a fourth site, water was sprayed as workers cut into "fresh" concrete that had not set completely (Document ID 0784, pp. 216-217-Table V). The sampling results presented in Table IV.5.6-B indicate that wet cutting is effective in maintaining worker silica exposures at or below 50 μg/m^3; the median exposure value for work done outdoors with sufficient wet methods is 12 μg/m^3, nine of the 12 sample results for this type of work (75 percent are below 25 μg/m^3, and none of the sample results exceed 50 μg/m^3. OSHA concludes that baseline conditions for walk-behind saws include wet cutting methods.

Additional evidence in the record shows the extent to which wet methods are already used with walk-behind saws indoors. Flanagan (2009) provides some information on workplace conditions associated with walk-behind saw operator exposure samples. Of 37 samples for operators using walk-behind saws, 30 (81 percent) were associated with water as a control measure, two (5 percent) were listed as using LEV as a control, and no control status was reported for the remaining five records (Document ID 0677, Attachment 2). That 81 percent of walk-behind saw operators in the Flanagan dataset used a water dust control supports OSHA's finding that wet methods are frequently used and can be considered the baseline condition for walk-behind saws.

A database of silica exposures in construction tasks shows that the median sample time for workers using walk-behind saws was 163 minutes (range 27 to 450 minutes) (Document ID 0677, Attachment 2). Exposure monitoring is typically either task-based (for the period during which a specific task is performed) or full-shift (sampling the entire work shift). For this reason, OSHA believes that the sample duration of less-than-full-shift samples reflects the amount of time that a worker spends performing tasks associated with silica exposure.

Baseline Conditions for Drivable Saw Operators

As summarized in Table IV.5.6-B, OSHA reviewed three sample results for workers operating water-fed drivable saws. The median exposure is 33 μg/m^3. Two out of the three results (66 percent) were below 50 μg/m^3 and one was 88 μg/m^3. One of the results was less than or equal to 12 μg/m^3 (limit of detection [LOD])[194] because of low respirable dust loading on the filter during the 70-minute sample period (Document ID 1143, Company A). The result of 33 μg/m^3 was based on a 125-minute sample that recorded a respirable quartz concentration of 128 μg/m^3. The highest result of 88 μg/m^3 was based on a respirable quartz concentration of 530 μg/m^3 measured over an 80-minute sampling period during which the water discharge on the saw was clogged (Document ID 1143, Company R).

These sample results were obtained over relatively short sampling periods (70 to 125 minutes), but are presented as 8-hour TWAs based on the assumption that the workers had no additional exposures during the unsampled portion of their shifts. CISC criticized OSHA for relying on three short-term samples and argued that OSHA should not assume zero exposure during the unsampled portion of the workers' shifts (Document ID 2319,

[194] Results reported as "none detected" are assigned a value equal to the LOD. The LOD is determined individually for each sample based on the volume of air sampled and the method used to analyze the sample. See Section IV-2 – Methodology for additional information on LODs.

pp. 51-52). CISC noted that ERG’s Report found that drivable saw operators often operate the saw for 1 to 2 hours and then move to other job sites (Document ID 2319, pp. 51-52). While this situation might occur at times, there is no evidence that this was the case for these three drivable saw samples, which are from OSHA enforcement data. OSHA inspectors are instructed to sample for the entire duration of silica exposure, and OSHA believes that the samples in the exposure profile captured all of the workers’ exposures for the day they were sampled. While the samples in the exposure profile may potentially underestimate exposures for drivable saw operators, OSHA does not have information to suggest that that any additional exposures actually occurred.

Table IV.5.6-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Construction Workers: Masonry Cutters Using Portable Saws

	Exposure Summary			Exposure Range		Exposure Profile

5.6.3 Additional Controls

The exposure profile in Table IV.5.6-B shows that approximately 33 percent (69 out of 206 samples) of masonry and concrete cutters using portable saws have silica exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. OSHA has determined that wet methods are a feasible and effective means of reducing worker exposures to respirable crystalline silica when using handheld masonry saws, core sawing and cutting machines, walk-behind saws, and drivable saws. Additionally, dust extraction systems are an effective control for some types of handheld saws.

Additional Controls for Handheld Power Saw Operators

Wet Methods

Wet Methods - Outdoor Cutting

Wet cutting methods are an effective dust control method for handheld power masonry saws. Table IV.5.6-B summarizes PBZ samples for masonry and concrete cutters using handheld saws and shows that the median exposure level is 19 μg/m^3 (maximum value 154 μg/m^3) when using wet methods outdoors. In contrast, the median exposure level is 130 μg/m^3 (maximum 8-hour TWA of 1,472 μg/m^3) when using handheld power saws outdoors without controls.

These exposure results show that using wet methods effectively reduces median and maximum silica exposures and can reduce worker exposures to 50 μg/m^3 or below most of the time. Sixty percent of handheld saw operator exposures in Table IV.5.6-B (nine out of 15) were 50 μg/m^3 or below when wet methods were used, and 80 percent of exposures (four out of five) were 50 μg/m^3 or below when wet methods were used outdoors.

CSDA submitted exposure data demonstrating the effectiveness of wet methods as a silica control measure for handheld (and similar hand-guided/wall) saws used outdoors. The data on the CSDA chart shows that “open air” (as opposed to “indoors” or “enclosed area”) handheld or hand-guided sawing performed without controls produced exposure concentrations of 10 to 150 µg/m^3; exposure concentrations were lower, ranging from 10 µg/m^3 to 29 µg/m^3, when operators used wet methods (Document ID 3497, pp. 1, 5, 6).

In addition to workplace samples, OSHA evaluated studies that used controlled short-term tests to examine the influence of wet methods on saw emissions and operator exposures to respirable dust and silica. Several investigators have evaluated the effectiveness of water-based dust control options for handheld saws in controlled settings and reported exposure level reductions ranging from 90 to 96 percent with various water application methods and cutting conditions. In a laboratory study, Thorpe et al. (1999) evaluated the effectiveness of two types of water supplies commonly used with handheld saws: 1) a pressurized portable water supply; and 2) a constant water supply (Document ID 1181, pp. 443, 445-447). During this evaluation, 15-minute PBZ samples were collected during uncontrolled and controlled (i.e., water-fed) cutting of concrete slabs containing 20 percent to 40 percent silica (i.e., worst-case conditions) (Document ID 1181, p. 447). The study protocol involved short sampling durations because handheld saws are typically used intermittently to make short cuts. The uncontrolled mean silica concentration during multiple 15-minute trials of intensive cutting ranged from 1,700 µg/m^3 to 4,800 µg/m^3 (reported as 1.7 to 4.8 mg/m^3) (Document ID 1181, p. 448-Table 2).

Reductions in exposure to respirable silica dust when cutting concrete slabs using wet methods compared with no controls were for 75% for diamond blades, and 94% for resin blades when using water supplied by mains, and 75% for diamond blades and 77% for resin blades when using water supplied by a portable tank. Both sources of water were effective at reducing respirable dust, however, the portable tank needed to be periodically re-pressurized to maintain the necessary flow rate, while the water supplied from the mains provided a more constant flow rate. Both types of systems used to supply water to an integrated water delivery system would be acceptable under the table.
NIOSH found that wet methods can significantly reduce exposures to respirable dust and quartz during block cutting with handheld tools (Document ID 0868, p. 13). NIOSH evaluated the performance of a commercially available water backpack and spray attachment, pre-set by the attachment manufacturer to provide 1.4 liters per minute water

consumption (0.36 gallons per minute), for handheld saws during concrete-block cutting (Document ID 0868, pp. 8, 11). The handheld electric abrasive cutter was used outdoors to make cuts through concrete blocks laid lengthwise on a plank 17 inches above the ground. During the 5- to 10-minute trials with water-fed saws, the water-spray attachment reduced quartz exposures by an average of 90 percent from uncontrolled levels (Document ID 0868, p. 10). This study demonstrates the effectiveness of wet methods to reduce silica exposures for workers using handheld saws.

Middaugh et al. conducted a workplace field study to evaluate the effectiveness of dust controls on cut-off saws (Document ID 3610, p. 158). Air sampling was conducted for ten days at five job sites on four experienced operators using gas-powered cutoff saws with 14-inch (35.6 mm) diameter blades to cut concrete curbs (Document ID 3610, p. 159). Air sampling was conducted both with and without wet methods; sampling ranged from 4 to 16 minutes and covered the entire duration of the task (Document ID 3610, pp. 159-161). The authors reported that the dust suppression system consisted of a two-nozzle spray and a 13.3-L hand-pressurized water supply system with an optimum mean flow rate of 0.83 L/min (0.2 gal/min) (Document ID 3610, p. 159). Without controls, the average respirable silica dust concentration during the 17 sampling periods was 0.96 mg/m^3, while with wet suppression the concentration levels were reduced to an average of 0.21 mg/m^3, a 78 percent reduction (Document ID 3610, p. 162). Middaugh stated: “Although some applications may require cutting for an entire 8-hr workday, typical cutting is performed for less than 2 hours per day” (Document ID 3610, p. 162). Middaugh et al. suggests that most handheld power saw operators will have TWA exposures of 50 μg/m^3 or below when using a water spray system during typical cutting activities.

Another study in the record, Shepherd and Woskie (2013), also demonstrates that wet methods can effectively reduce 8-hour TWA exposures to 50 μg/m^3 or less when handheld saw operators cut outdoors under typical cutting conditions (Document ID 3777). Shepherd and Woskie reported silica exposures generated during a controlled workplace field study where reinforced concrete pipe was cut outdoors, using both dry and wet methods, by apprentice and journeyman construction workers (Document ID

3777, p. 65). Sampling times were less than 12 minutes. The operators used a gas-powered cutoff saw with 14-inch diameter blades to make a series of 8-foot cuts, suggesting that cutting was nearly continuous during the sampling period (Document ID 3777, pp. 65-66). The authors estimated that if this level of intensive cutting were performed outdoors with wet methods for two hours, and no other exposure occurred for the remainder of the day, 83 percent (88 out of 106) of the saw operators' 8-hour TWA exposures would be 50 µg/m^3 or below (Document ID 4073, Attachment 8a, p. 1). The authors also estimated that if operators used the water-fed saws outdoors at this same level of intensity for six hours, 61 percent of operators would have 8-hour TWA exposures of 50 µg/m^3 or below (Document ID 4073, Attachment 8a, p. 1). The authors noted that the water flow rate testing before and after certain trials indicated that the "water supply was variable" (not stable) (Document ID 3777, p. 65). Dust suppression would likely have been improved with a more consistent water supply.

CISC questioned the probative value of data from these controlled studies (Document ID 2319, pp. 49-50). OSHA has relied on both the exposure data summarized in Table IV.5.6-B and controlled studies in determining the effectiveness of using wet methods to control silica exposures when operating handheld power saws. OSHA believes that controlled studies and short-term sampling are useful in evaluating the effectiveness of the control methods. The aforementioned studies evaluate the effectiveness of wet methods to control silica exposures during the use of handheld power saws and provide useful information obtained under both experimental conditions and at construction worksites. Laboratory studies are useful for confirming the extent to which water can suppress dust. Worksite studies involving short-term samples provide information that is useful in evaluating the overall potential for worker exposures (with control methods in place) during a typical shift that involves periods of intermittent sawing interspersed between breaks in sawing (for example, to deliver or obtain more bricks, adjust the saw, or complete other phases of the job). OSHA believes these studies are useful and further demonstrate the effectiveness of wet methods.

Some commenters, while acknowledging the availability of handheld saws with integrated water delivery systems, noted that dust suppression is not the actual purpose of the water-fed saws. Mr. Rashod Johnson of Mason Contractors Association of America (MCAA) testified that:

> the vast majority of masonry saws provide water on the blade itself. Water on the blade. This is solely for the purpose of cooling off the blade. The side effect just happens to be that the dust is sometimes suppressed. Now, manufacturers of these saws are starting to explicitly state that the water used in this blade – in this system is used for cooling the blade only and should not be used to suppress dust (Document ID 3585, Tr. 2885).

NIOSH, however, pointed out that some manufacturers' manuals include recommended water flow rates specifically for dust suppression (Document ID 4233, Attachment 1, p. 5). NIOSH pointed to Stihl's manual for the model 410 and 420 cut-off machines (handheld masonry saws), which specifically recommends a water flow rate for dust suppression (Document ID 3998, Attachment 12a, pp. 9, 15, 16). This manual states: "A water attachment kit is provided with your cut-off machine and should be used to reduce dust whenever wet cutting is feasible. For dust suppression purposes, the flow rate should be at least 0.6 liters (20 fl. oz.) of water per minute" (Document ID 3998, Attachment 12a, p. 9).

NIOSH also noted that Husqvarna's product literature for the K 3000 wet states:

> [T]he Husqvarna K 3000 Wet is a power cutter… for wet applications. The machine is equipped with the dust extinguisher system DEX, where an integrated water regulator controls the water volume, ensuring an amount that is just enough to bind the dust. This gives the user the possibility of wet cutting with a minimal amount of water and slurry, both indoors and outdoors (Document ID 3998, Attachment 12f, p. 1).

Product literature from other manufacturers states that water systems are necessary for reducing dust generation (Document ID 3998, Attachments 12a, p. 4, 15-16; 12e, p. 3; 13e, p. 9 of pdf-Flushing with Water). There is ample evidence in the record that water-fed handheld saws are commercially available from a variety of sources (CS Unitec, Document ID 0615; Hilti, Document ID 0737 and 3998, Attachment 12e; Stihl, Document ID 3998, Attachment 12a; Husqvarna, Document ID 3998, Attachment 12f;

Makita, Document ID 3998, Attachment 12g; Wacker Group, Document ID 3998, Attachment 12h). In some cases the operator simply connects a hose to a factory-installed port (pre-mounted) (Document ID 3998, Attachment 12a, pp. 6, 16-see Water kit-premounted). In other cases an adaptor kit is required and is pre-packaged with certain models of the saw (Document ID 3998, Attachment 12g, p. 3-Index: Install water system). Therefore, OSHA has determined that water-fed handheld saws are commercially available, and many include recommended flow rates for dust suppression.

There are several studies and saw manufacturers that discuss optimal water flow rates for handheld power saws. In addition to Stihl's recommendation for 0.6 liters per minute, mentioned previously (Document ID 3998, Attachment 12a, p. 16), Thorpe et al. (1999) showed in laboratory tests that a water application rate of 0.5 liters per minute (0.13 gallons per minute) provided optimal dust control for the amount of water applied (96.7 percent dust reduction), while doubling the water application rate (to 1 liter per minute) improved dust control by an additional 1.2 percent (to 97.9 percent) (Document ID 0846, p. 450-Table 4). Additionally, the Wacker Group, in operating instructions for its PowerCut model BTS-11 handheld saw, recommends wet cutting and specifies a water consumption rate of 40 liters per hour, equal to 0.67 liters per minute (0.18 gallons per minute) (Document ID 3998, Attachment 12h, pp. 8, 13).

Additionally, it is possible to replace the use of handheld saws with stationary saws equipped with wet dust control systems. Mr. Hoffer, Assistant Director of the New Jersey Laborers' Health and Safety Fund, stated that after 2004, when New Jersey passed a law prohibiting the dry cutting of brick, block or other silica-containing building materials, "one of the changes I saw was …people went ahead and bought table saws, masonry table saws" (Document ID 3589, Tr. 4237). Similarly, Mr. Johnson of MCAA explained that when extensive cutting is performed, sawyers use cutting stations (with a different set of engineering controls) instead of handheld saws (Document ID 3581, Tr. 2911). Based on the evidence in the record, OSHA concludes that, in situations where handheld saws are being used to cut silica-containing materials for extensive periods of time, the use of a stationary saw with a water delivery system is an effective solution to reduce exposures to dust and silica.

Some commenters stated that using wet methods at elevated heights could create a fall hazard (Document ID 2319, pp. 111-12; 3587, Tr. 3595). Rick Olson of the Tile Roofing Institute asserted that use of wet or vacuum controls would create additional fall hazards when cutting roofing tiles and pavers on a roof. He also stated that in California and Arizona, rooftop operations with roofing tiles or pavers are given an exemption from the requirement to use a dust reduction system when using power tools for cutting, grinding or drilling those masonry materials (Document ID 3587, Tr. 3595).

However, other testimony indicates that wet dust control systems can effectively be used to reduce exposures to silica during cutting of roofing tiles and pavers. Dan Smith, Director of training for the Bay Area Roofers and Waterproofers Training Center in Livermore, California, noted that everyone on a roof is already using fall protection and that the controls are no different than an air hose or an electrical cord that would be on the job site (Document ID 3581, Tr. 1603). Mr. Smith also questioned how the use of controls could pose more of a trip or fall hazard than the "near zero visibility that is created by cutting roofing tiles dry" (Document ID 3581, Tr. 1603-1604).

Mr. Smith testified that the roofing industry in California is starting to voluntarily cut roofing tiles and pavers wet (Document ID 3581, Tr. 1600-1601, 1638). He also explained that dry cutting of roofing tiles is prohibited in the U.K., and that the National Federation of Roofing Contractors "provides guidance and training. They use wet saws on scaffolding at the roof level…they use a [water] mister on the tile saw. They use a system like the hytile… which is a tile breaking tool" (Document ID 3581, Tr. 1600-1601). Based on the evidence in the record, OSHA believes that there are alternative solutions (e.g., cutting on the ground, project planning, cutting from scaffolds rather than a roof) to address any hazards posed by the use of wet methods in the roofing industry. Additionally, testimony from the Bay Area Roofers and Waterproofers Training Center indicates that use of controls may actually increase visibility, thereby reducing potential fall hazards during roofing work (Document ID 3581, Tr. 1603-1604).

Wet Methods - Indoor Cutting

Table IV.5.6-B shows that using wet methods indoors substantially reduces operator exposures compared to uncontrolled dry cutting indoors (median of 50 µg/m^3 for 10 samples using wet methods compared to median of 1,490 µg/m^3 for three dry cutting samples) (Document ID 0177, p. 77, 79, 80; 0846, pp. 4-5).[195] Although clearly beneficial, wet methods do not always reduce indoor exposures to the same levels observed for wet cutting outdoors (in Table IV.5.6-B, the median exposure is lower (19 µg/m^3) for outdoor wet cutting samples). Furthermore, 50 percent of the ten indoor wet sawing samples were 50 µg/m^3 or below, while a higher portion, 80 percent (four out of five), of the outdoor wet sawing samples were 50 µg/m^3 or below. The exposure levels of saw operators working indoors are affected when decreased air circulation limits the rate at which airborne dust disperses. As a result, modest releases of airborne silica dust that would dissipate outdoors can build up indoors, causing exposures to be higher (Document ID 3883, pp. 4-2 – 4-3, Sec. 4.1 and 4.3.1). Based on these findings, OSHA concludes that increased general or exhaust ventilation (fans, exhaust trucks, or fresh air ducts) may be necessary to prevent the accumulation of airborne dust in the work area and consistently control silica exposures indoor. Using a HEPA vacuum to clean up dried slurry can further reduce exposures indoors.

CSDA's Best Practices chart supports OSHA's conclusion that wet methods are effective indoors, but that overexposure can still occur. In the CSDA chart, the reported indoor handheld and hand-guided (wall) sawing concentration results ranged from 40 to 260 µg/m^3 (during various sampling times) when wet methods were used (Document ID 3497, pp. 1, 5). Similarly, Ms. Kellie Vazquez of Holes Inc. anecdotally reported that to reliably achieve exposures of 50 µg/m^3, saw operators performing indoor sawing (which includes hand-guided/rig wall sawing) using wet methods would need to wear respiratory protection (Document ID 3589, Tr. 1535).

Shepherd and Woskie (2013) evaluated sawyer exposure levels during the while use of dry and water-fed handheld saws indoors (in a large garage, with large doors opened and

[195] Indoor wet cutting data sources are Document ID 0065, pp. 16, 17, 22; 0169, pp. 6-7; 0222, p. 7; and 1423, p. 2.

closed beyond the control of the researchers), as part of the same controlled field study described previously (where apprentice and journeymen cut reinforced concrete pipe) (Document ID 3777, pp. 65, 69). The study design was the same for the indoor work as for the outdoor trials. Overall (considering both wet and dry saws), during brief periods of intensive cutting, the geometric mean silica concentration was 672 μg/m^3 (reported as 0.672 mg/m^3) outdoors, but more than twice as high indoors (1,503 μg/m^3, reported as 1.503 mg/m^3) (Document ID 3777, p. 67-Table I). The authors also documented the geometric mean silica exposure concentration measured during intensive sawing when operators used a water-fed handheld saw (419 μg/m^3), and found that this was less than 10 percent of the geometric mean silica concentration measured during dry cutting (4,384 μg/m^3), demonstrating the enormous benefit that wet cutting has on silica dust emissions (Document ID 3777, p. 67). Shepherd and Woskie also reported an 85 percent reduction in exposure between worker-paired control conditions (samples for dry cutting versus wet cutting performed by individual saw operators) (Document ID 4073, Attachment 8a, p. 1).

OSHA believes that these estimations are reflective of worst-case conditions. The silica content of the respirable dust samples taken when workers were cutting reinforced concrete pipe in this study ranged from 3 to 91 percent, with a median of 21.7 percent (Document ID 3777, p. 69). Most of the samples analyzed (134 out of 137) contained less than 39 percent silica, however, three samples contained between 63 and 91 percent silica. By comparison, 71 percent of the respirable dust samples taken on handheld saw operators reported by Flanagan contained less than 15 percent silica content (Document ID 0677, p. 149). Among 12 samples for handheld saw operators included in the OIS data in the docket, the highest silica content was only 11 percent (Document ID 3958, Rows 25, 26, 259, 260, 358, 360, 488, 489, 729, 730, 791, 840). Therefore, OSHA concludes that the short-term samples in the Shepherd and Woskie study taken indoors when cutting concrete pipe with a relatively high silica content represent the upper end of exposures typically experienced when using handheld power saws.

Another study also showed that wet methods reduce exposure levels for workers using various types of water-fed saws under worst-case conditions. Flanagan et al. (2001)

reported respirable quartz levels of 240 μg/m^3 and 260 μg/m^3 for the period of tool use for an average of 130 minutes per shift, with corresponding 8-hour TWA values of 65 μg/m^3 and to 70 μg/m^3) for handheld slab saw operators who used wet methods at indoor sites (Document ID 0675, p. 1098-Table I).[196] Factors contributing to worst-case conditions included longer than normal periods of sawing, enclosed spaces, numerous concurrent operations in one space, and the use of a wet (inadequately filtered) shop vacuum – rather than a HEPA vacuum – for cleanup (Document ID 0675, p. 1097). Although exposures during wet sawing were elevated, the authors described several ways to reduce exposures. A lack of ventilation in the indoor environment might have accounted for a substantial portion of the exposures experienced by all workers in the immediate area (including helpers). The authors stated: "Since area and helper exposures are similar to the operator's exposure, the primary exposure might be due to a buildup of respirable aerosol within the enclosed space, rather than direct exposure to slurry spray. Judicious use of dilution ventilation with box fans and open doors and windows may reduce the exposure" (Document ID 0675, p. 1099). In addition, inadequately filtered vacuums can produce airborne dust through re-entrainment of already collected particles. Flanagan et al. (2001) recommended that a commercially available vacuum attachment to collect slurry be evaluated to determine its effectiveness for controlling aerosol in the respirable size range (Document ID 0675, p. 1100). Further, the operator's position – staying out of the spray plume – could reduce exposure (Document ID 0675, p. 1098).

Another factor possibly contributing to worst-case conditions in the Flanagan et al. (2001) study was the amount of time workers spent sawing. Flanagan et al. (2001) stated that the saw operators in the study spent more than the typical amount of time sawing during their shifts. "Many jobs do not involve such extensive periods of cutting, with workers often working at two or three job sites per day. Time spent commuting between sites and setup/cleanup time for each job provide periods of minimal or no exposure" (Document ID 0675, p. 1100).

---

[196] Although the authors did not report individual sampling results for most jobs, the exposure summary for operators using "Slab saw/handheld (inside)" includes only two values, so the range (high and low) provides the actual sample values.

Considering the examples of how exposures can occur during wet sawing, OSHA concludes that consistent dust control requires attention to the rate and application position of water used for wet dust suppression. Carefully managing slurry (for example, by capturing slurry before it dries, using work practices that limit the amount of slurry spray coming off the saw blade, and using a HEPA vacuum to cleanup dried slurry) can further reduce exposure levels.

Dust Extraction (Vacuum Suction, Local Exhaust Ventilation)

The exposure profile for handheld power saw operators (Table IV.5.6-B) contains one sample result for a handheld saw operated with LEV (grouped in the "indoor, dry cutting" category). This sample was obtained as a mason cut concrete block out of a wall to make room for a window, while a second worker (not monitored) held a HEPA vacuum nearby to capture dust (Document ID 3958, Row 791). The operator experienced an 8-hour TWA exposure of less than 12 $\mu g/m^3$ (the limit of detection), based on a sample in which the respirable dust exposure was also low (0.099 mg/m^3, equal to 99 $\mu g/m^3$). While this sample result showed that dust was effectively managed, an integrated dust collection system would be more reliable (since it would be attached to the tool and in the proper position at all times). Dust extraction systems are an increasingly effective form of silica dust control and evidence submitted to the record indicates that they continue to improve.

IQ Power Tools submitted evidence of the effectiveness of an integrated LEV system for a handheld gas power saw with a 12-inch blade. The saw included an integrated vacuum/filter and dust containment system. In a single 121-minute demonstration of outdoor concrete cutting, an operator used the saw to cut through both faces of 100 concrete blocks, standing in an upright position (blocks positioned at hip level in front of the operator; the operator stood more upright than the position in which a handheld saw is typically used) (CS-Unitec Catalog, 2009, Document ID 0615, pp. 24-28; 3501, p. 4). During this 2-hour period of active cutting, the operator experienced a personal exposure of 45 $\mu g/m^3$, with 17 percent silica measured in the sample (Document ID 3501, p. 4). Under tightly controlled conditions during a single 2-hour demonstration, this saw configuration shows great promise for maintaining operators' exposures at 50 $\mu g/m^3$ or below. However, OSHA finds that additional worksite testing is needed (e.g., including in the more typical cutting position) before it can confidently conclude that this saw configuration can control exposures to or below 50 μg/m^3.

The CSDA Best Practice chart includes two results of open-air hand sawing using a saw equipped with LEV. The chart shows silica exposure levels for both saw operators below an 8-hour TWA of 50 μg/m^3; however, no other information was provided about the size or design of the saw (Document ID 3497, p. 6).

Other studies show that the use of LEV reduces exposures to respirable silica, but not to the extent that exposures could be consistently maintained at or below an 8-hour TWA of 50 μg/m^3. Thorpe et al (1999) reported that an LEV system on a handheld saw with a 9-inch blade reduced mean respirable dust concentrations by over 90 percent (from 8,000 μg/m^3 to 700 μg/m^3) during periods of active concrete cutting (Document ID 1181, p. 448-Table 3).

NIOSH (EPHB 282-13) evaluated the performance of a commercially-available LEV system for handheld saws during brief trials of concrete-block cutting (Document ID 0868). The "electric abrasive cutter" was equipped with a 12-inch blade and an LEV shroud connected to a wet/dry high-efficiency particulate air (HEPA) filter vacuum cleaner with filter "pulse clean" capability[197] (Document ID 0868, p. 8). With new bags installed, this vacuum cleaner pulled 56 cubic feet per minute (cfm) through the shroud while the abrasive cutting saw was operating (Document ID 0868, p. 11). This relatively modest air flow rate reduced both silica and respirable dust exposures by 95 percent—slightly better results than obtained using a the water-spray attachment (90 percent reduction) (Document ID 0868, p. 10). Despite this substantial exposure reduction, respirable silica concentrations in the worker's breathing zone remained elevated at levels of 790 μg/m^3 to 1,100 μg/m^3 during five 10-minute trials of intensive cutting (Document ID 0868, p. 11). As explained in Section IV.5.11 – Tuckpointers and Grinders, the choice of vacuum suction device has a dramatic effect on dust control efficiency. Although not

[197] The vacuum was attached to the shroud via 3 meters of 35-millimeter (mm) (1.4-inch) diameter hose. "Pulse clean" is a self-cleaning feature involving a reverse air pulse that knocks dust from the filter.

tested by NIOSH, based on work by Collingwood and Heitbrink (2007), OSHA believes that it is reasonable to expect improved dust capture with a dust collection device that consistently offers greater air flow than the one tested by NIOSH (Document ID 0600, pp. 884-885).

A study by Meeker et al. (2009) evaluated a commercially-available LEV system used with a handheld electric abrasive saw with a 12-inch blade while cutting block or brick (Document ID 0803). Breathing zone measurements collected over brief periods (5 to 25 minutes) of controlled and uncontrolled outdoor sawing showed a 91-96 percent reduction in quartz concentrations (for example, a mean of 110 μg/m^3 when cutting block using LEV versus 2,830 μg/m^3 when using no controls) (Document ID 0803, p. 108). For three of the four combinations of saws, controls, and materials tested, the measured silica concentration ranged from less than 50 μg/m^3 to highs between 140 and 170 μg/m^3. The concentration was higher (610 μg/m^3) for one wet saw used without LEV (Document ID 0803, p. 108-Table 2). Since most workers cut intermittently even during times of active cutting (e.g., 10 or 20 seconds using the saw followed by a longer period–up to several minutes–of measuring and moving materials or equipment), 8-hour TWA values are likely to be considerably lower (Document ID 1238, p. 148).[198] Based on the highest result obtained by Meeker et al. during concentrated cutting with LEV (170 μg/m^3), OSHA estimates that a worker who cuts outdoors for 20 percent of the shift (about one-and-a-half hours) would experience an 8-hour TWA of 34 μg/m^3. Extended periods of intensive cutting and cutting indoors were not evaluated in the Meeker et al. study (Document ID 0803). Substantially higher 8-hour TWA exposures might result in enclosed areas with limited ventilation where airborne dust cannot easily dissipate. In those cases, supplemental exhaust ventilation could maintain sufficient air circulation and

[198] Sawyers make a cut (or a few sequential cuts) and then need time before the next cut to move to a new location or to reposition materials. Studying stationary saws, Yareb (2003) presented information from a real-time dust analyzer that showed bursts of 20 seconds of sawing, followed by similar or longer period (up to a minute) of repositioning. During the repositioning period, dust concentrations were reduced to nearly zero (Document ID 1238, p. 148). Yareb (2003) involved stationary saws. The repositioning period would be longer for handheld saws because the operator needs to put the saw down in order to have both hands free to reposition the material being cut.

reduce the rate at which airborne dust accumulates (Document ID 3883, pp. 4-2 – 4-3, Sec. 4.1 and 4.3.1).

Middaugh et al. (2012) evaluated a spring loaded guard/cowl with a centrifugal fan blowing into an 18.9 L canvas collection bag (not HEPA) during concrete curb cutting with a 14-inch (35.6 cm) blade (Document ID 3610, p. 156). The silica exposure concentration level measured was 33 $\mu g/m^3$ (Document ID 3610, p. 162). Middaugh stated that “Although some applications may require cutting for an entire 8-hr workday, typical cutting is performed for less than 2 hours per day” (Document ID 3610, p. 162). Assuming two hours of exposure at the measured silica level, OSHA has determined that this concentration would result in a TWA exposure of 82.5 $\mu g/m^3$. OSHA notes that the canvas dust collection bag does not offer the same level of protection as a particle air filter that is rated as 99 percent efficient for respirable size particles. The authors did not evaluate collection bag efficiency, but the bag may have permitted particles to pass, and exposure results might have been lower with a more efficient filter in place.

Croteau et al. (2002) conducted experiments on a handheld saw equipped with an LEV system exhausted at 75 cfm (Document ID 0611, pp. 458, 460, 466). This LEV set-up did not reduce respirable dust exposures compared to uncontrolled cutting (Document ID 0611, p. 458). The authors concluded that the shape of the dust collection shroud opening allowed the rotating blade to push dust away from the shroud (i.e., the blade rotated in the opposite direction than that for which the shroud was designed). The direction of the blade action is an important consideration in designing or selecting a saw shroud (Document ID 0611, p. 466).

A NIOSH HETA (2008) study evaluated an LEV-equipped handheld gas-powered saw to assess its potential for reducing respirable silica exposures at two residential building construction sites during a 2005 health hazard evaluation (Document ID 0876, p. 1). NIOSH determined that using the LEV-equipped saw did not have a significant benefit compared with the non-LEV equipped saw, LEV did not reduce exposures to acceptable levels (Document ID 0876, pp. 11, 13). However, the authors noted that the limited amount of data precluded a complete assessment of this type of control (Document ID 0876, p. 11).

CISC argued that LEV is unreliable for masonry saws (Document ID 2319, p. 50), basing this statement on OSHA's preliminary conclusion in the PEA that "the available data are not adequate to determine whether all workers using such saws can reliably and consistently achieve the proposed PEL of 50 μg/m^3" (Document ID 1720, pp. IV-438, 440). CISC offered no evidence that saw ventilation systems are unreliable. OSHA finds that LEV systems for handheld power saws are still undergoing development. The data was not adequate at the time of the PEA to determine whether saw operators' exposure levels could reliably be reduced to 50 μg/m^3 or below when using LEV. With few exceptions (Document ID 2322, Attachments A-F), the current data suggest that the saw-LEV configuration has not yet reached its full potential for managing silica exposures, particularly indoors. Nonetheless, the preceding discussion of LEV for handheld saws, as well as the next section on specialty saws for fiber-cement board siding, do show that saw manufacturers are making rapid and continuous improvement in developing LEV systems for saws.

A member of the National Utility Contractors Association (NUCA) stated that handheld saws are not manufactured with LEV dust collection systems (Document ID 2171, Attachment 1, p. 10). The Building and Construction Trades Department (BCTD), AFL-CIO and NIOSH disputed the assertion that tools with integrated dust controls are not commercially available (Document ID 2171, Attachment 1, p. 10; 3998, Attachment 10, p. 54-55, Attachment 12f; 4219, p. 5) and provided examples of such equipment from manufactures Diamond and Husqvarna (Document ID 4073, Attachment 4a). IQ Power Tools also provided evidence of its handheld saw with integrated LEV (Document ID 3501, p. 4). From the evidence in the record, OSHA concludes that handheld saws with integrated ventilation systems are readily available from commercial sources.

Operators usually use handheld saws for only a limited period of time (typically less than 2 hours) (Document ID 0677, Attachment 2; 3501, p. 4; 3581, Tr. 1597, 1598, 2911; 3610, pp. 157, 162). OSHA finds that when saw operators fully and properly implement

LEV controls for handheld saws, most of them will experience 8-hour TWA exposures of 50 μg/m^3 or below when they cut outdoors for up to four hours a day (Document ID 0803). However, when cutting with portable saws equipped with dust controls indoors, TWA exposures can be expected to exceed 50 μg/m^3 in less than four hours.

Additional Controls for Handheld Power Saws Operators Cutting Fiber-Cement Board

Local Exhaust Ventilation

Table IV.5.6-B includes 96 PBZ samples for workers cutting fiber-cement board using specialty handheld power saws to install fiber-cement siding on houses. Twenty-one operators using uncontrolled saws experienced mean silica exposures of 63 μg/m^3 (median 21 μg/m^3) with a high of 605 μg/m^3. When the saw operators used equipment with a feature (of any type) intended to capture or contain dust, the mean exposure for 75 sawyers was 11 μg/m^3 (median 7 μg/m^3) and the high was 76 μg/m^3.

LEV systems for a special configuration of handheld power saw fitted with purpose-designed polycrystalline diamond blades of less than 8 inches have proven particularly effective in controlling silica during outdoor cutting of fiber-cement board. OSHA received data from NIOSH and James Hardie Building Products, a manufacturer of fiber-cement board siding, providing information on a cooperative effort between NIOSH and a fiber-cement board industry member to evaluate controls for various saws that are either used in this industry or that are under development for the industry and to produce additional data on the effectiveness of saw/LEV configurations for cutting this this type of siding (Document ID 2322, Attachments B and C; 3579, Tr. 231-232; 3959, pp. 25-36). One type of saw performed more reliably than the others and at this time appears to be the best available technology for minimizing silica exposures while cutting fiber-cement board. OSHA has focused this technological feasibility analysis on that saw design (a handheld, dust collecting model, fitted with a special purpose blade (8 inches or less) and a dust collection device rated to draw 200 cfm.

Several NIOSH studies at fiber-cement siding installation sites demonstrate the effectiveness of the handheld dust-collecting saw, with special purpose blade, and vacuum dust collection system having a rated airflow capacity of 200 cfm when cutting fiber-cement siding (one form of fiber-cement board). These studies include NIOSH study numbers:

- EPHB 358-11a (Document ID 4138);
- EPHB 358-12a (Document ID 2322, Attachment B) (also in the record as Document ID 4139);
- EPHB 358-13a (Document ID 2322, Attachment C) (also in the record as Document ID 3998, Attachment 4a);
- EPHB 358-14a (Document ID 3998, Attachment 4b); and
- EPHB 358-15a (Document ID 3998, Attachment 4c).

Exposure data from the two NIOSH reports submitted by James Hardie under Document ID 2322 (i.e., EPHB 358-12a and EPHB 358-13a), and from three other reports from a consultant (also submitted as part of Document ID 2322, Attachments D-F) are included in the exposure profile (Table IV.5.6-B). These five reports evaluated several types of saws with and without various forms of dust reduction measures, representing the wide range of equipment currently in use by the industry.

During these five NIOSH studies, siding cutters on construction sites cut a variety of fiber-cement board siding products containing up to 50 percent silica (Document ID 4139, p. 11; 3998, Attachment 4c). NIOSH sampled a total of 21 worker-days at four different construction sites when operators primarily used handheld dust-collecting saws, with special purpose blades (slightly less than 8 inches in diameter), for cutting fiber-cement board, and vacuum dust collection systems rated at 200 cfm. All 8-hour TWA sample results associated with use of this equipment were 50 μg/m^3 or below (the highest 8-hour TWA exposure level was 41 μg/m^3, and 95 percent of the 8-hour TWAs (20 of 21 sample results) were below 25 μg/m^3 (Document ID 4138; 2322, Attachment B [also 3998, Attachment 4a]; 3998, Attachment 4b; 3998, Attachment 4c). Table IV.5.6-C tabulates these results.

Table IV.5.6-C Personal Breathing Zone Respirable Crystalline Silica Exposures for Workers Cutting Fiber-Cement Board (NIOSH In-Depth Survey Reports)

Work Conditions	**Sample duration**	**Silica 8-hour TWA**	**Cutters-days sampled (% quartz [A])**	**Document ID**
Standard circular saw (68% of the cuts) and miter saw (32% of the cuts); no controls other than new specialty saw blade [B]	One sample 72 minutes, three samples 434 to 575 minutes	21, 45, 64 and 127 µg/m^3 (four samples)	Cutter #1, on four days (quartz average: 6.9%)	4138, pp. 4, 10, 12-Table 3 (EPHB 358-11a)
Dust collection circular saw, new specialty saw blade [B], and vacuum dust collector, with 6-second delay before turning off	219 to 413 minutes	3 to 18 µg/m^3’ (six samples)	Cutters #1 and #2, on three days (quartz average: 10.4%)	4139, pp. 10, 18, 19-20-Table 4, 22, (EPHB 358-12a)
	220 to 487 minutes	2 to 16 µg/m^3 (six samples)	Cutters #2 and #3, on three days (quartz average: 9.1%)	3998, Attachment 4a, p. 22-23-Table 4 (EPHB 358-13a)
	403 to 440 minutes	16, 23, and 41 µg/m^3 (three samples)	Cutter #1, on three days (quartz average: 13.3%)	3998, Attachment 4b, p. 15, 16-Table 4 (EPHB 358-14a)
	422 to 513 minutes	7 to 12 µg/m^3 (six samples)	Cutters #1 and #2, on three days (quartz average: 13.1%)	3998, Attachment 4c, pp. v, 5, 13, 14-Table 4 (EPHB 358-15a)

Notes:
[A] % quartz is the average measured in all personal samples collected at the site on sampling days.
[B] Specialty blade: Polycrystalline diamond-tipped blade with 4 to 8 teeth specifically designed to cut fiber-cement siding and minimize dust generation (Document ID 4138, p. 3).

The specially-configured circular saw consists of a “dust collecting” saw designed to guide the dust from the blade into a built-in hood covering about 69 percent of the saw blade. The saw is fitted with a new-each-day special-purpose 7.25-inch polycrystalline diamond blade with four to eight teeth, and is specifically designed for cutting fiber-cement board. The saw hood is connected to a dust collection system (a 12-gallon shop-vac or equivalent, in this case rated at 200 cfm air flow and with a 6-second delay in turning off the shop vacuum when the saw was turned off, so the vacuum removed dust following the cutting of the board) with dual filtration. The actual air flow when the saw was in use was estimated to be between 70 to 90 cfm. (Document ID 3998, Attachment 4c, p. 5; 4139, pp. 9-10, 16, 17).

OSHA received comments from James Hardie Building Products requesting that OSHA add an entry on Table 1 for cutting fiber cement board with a circular saw with a polycrystalline diamond-tipped blade equipped with a shroud and dust collection system (Document ID 2177, Attachments A-I, pp. 3-4, Attachment B, pp. 17-18; 2322). OSHA finds that the information presented in the NIOSH reports (as summarized in Table IV.5.6-C) demonstrates that silica exposures can be reduced to 50 μg/m^3 or less when sawyers cut fiber-cement board using a dust control-style circular saw connected to a vacuum dust collector and fitted with a specialty blade designed for cutting fiber-cement board. In the final rule, OSHA has added an entry to Table 1 for handheld power saws cutting fiber-cement board.

Table IV.5.6-B shows that 75 operators using any type of dust control for saws with special cutting blades designed for fiber-cement board had a mean 8-hour TWA exposure of 11 μg/m^3 (median 7 μg/m^3), although elevated exposures (high of 76 μg/m^3) still occurred with some saw/control configurations that proved less reliable (for example, miter saws and saws attached to a dust receptacle without the benefit of a vacuum dust collection device). By contrast, the sample results summarized in Table IV.5.6-B for 21 operators using uncontrolled saws (circular and miter) had a mean 8-hour TWA exposure of 63 μg/m^3 (median 21 μg/m^3), with the highest exposure reaching 605 μg/m^3. The industrial hygiene consultant that performed the industry air monitoring reported that “dust collection” circular saws “equipped with dust collection systems (HEPA vacuums) appear to generate the least amount of airborne particulate,” while other combinations of saws and less effective dust control methods did generate visible airborne particulates (Document ID 2322, Attachment F, pp. 13-14, caption Photos 12 and 19). Most of these workers cut siding for approximately half of their shifts (Document ID 2322, Attachment B-F; 4139 [a duplicate/final copy of 2322, Attachment B]). The variability associated with other configurations of saws and controls used to cut fiber-cement board leads OSHA to conclude that the combination of small diameter (less than 8 inches) blades designed for cutting fiber-cement board with an LEV dust collection system operating at the air flow recommended by the tool manufacturer or greater can reduce worker exposures to 50 μg/m^3 or below most of the time during cutting of fiber-cement board. Specifying the minimum rate airflow capacity of the dust collector as the rate recommended by the tool manufacturer will permit employers to use dust collectors that have been matched to the tool and will provide optimal dust control when using saws with blades smaller than the 7.25-inch blades used in the NIOSH investigations.

Availability of Other Cutting Methods for Cutting Fiber-Cement Board

Other cutting methods are also available for fiber-cement board with minimal dust. NIOSH briefly describes a scoring (with a knife) and snapping process, which "should be relatively dust-free"; however, this method is not applicable to siding (Document ID 2322, Attachment B, p. 7). NIOSH also mentions that commercially available handheld and foot-powered shears are also "relatively dust free"; however, a power saw cuts faster and is more precise than the shears (which can slow production rates) (Document ID 2322, Attachment B, p. 7).

Additional Controls for Rig-Mounted Core Saw or Drill Operators

As indicated in the discussion of baseline conditions and the exposure profile for these workers, most operators of core sawing machines (or core drills) already use wet methods. The four exposures summarized in the Table IV.5.6-B are for workers using rig-mounted, water-fed core saws, and all experienced exposure levels of 50 $\mu g/m^3$ or below. Additional controls are not required for core sawing or cutting machines already used with a water feed, in part because the slow speed of the core sawing operations, paired with water application, limits aerosol production. Flanagan et al. (2001), explained the utility of wet methods and the benefit of the low bit rotation speed for dust control during core cutting activities:

> Water appears to be effective for reducing concrete core drilling emissions. When the core bit is sunk into the concrete, dust particle velocity is slowed and [the particles are] mixed with water before exiting the borehole, emitting slurry with little velocity to produce an airborne aerosol (Document ID 0675, p. 1100).

Core sawing machines operate at lower speeds than many types of equipment more typically associated with silica dust emission. A typical core sawing machine producing 6- to 8- inch holes operates at speeds in the range of 250 to 350 rpm (Document ID 0679,

p. 21; 0222, p. 4). In contrast, other drilling, cutting, and grinding equipment operates at rpm several times greater. For example, a rig-mounted concrete wall saw evaluated by Flanagan et al. (2001) operated at 2,500 rpm; a circular saw and a miter saw evaluated by NIOSH with a tachometer (device to measure rotation speed) operated at 5,765 and 5,920 rpm; and a tuckpointing grinder blade operated in the range of 10,000 rpm (unloaded) (Document ID 0222, p. 4; 4138, p. 4; 0679, p. 25). As indicated by Flanagan et al. (2001), lower blade speeds make dust control less challenging because particles and slurry are released from the slower blade at a lower velocity, producing less airborne aerosol (Document ID 0675, p. 1100).

Cleaning up silica-containing slurry promptly can further reduce exposures. Flanagan et al. (2001) studied work practices for a wet process at a construction site that assigned a helper to each operator who used a water-fed tool (core boring machines, handheld saws, hand-guided rig-mounted wall saws and walk-behind slab saws). The helper's job was to vacuum water and slurry released from the water-fed tools, keeping it from spreading more than a few feet from the point of operation (Document ID 0675, p. 1098). The operator performing core drilling, however, performed his own water control (without a helper), suggesting that the core boring equipment required less attention or produced less wet slurry (or both) than the water-fed saws used at the same site, so a second person (helper) was not necessary.

If cleaning up slurry from water-fed core sawing equipment proves inconvenient in some locations, a tool with an integrated water collection ring (to capture water after it is provided to the coring blade) is commercially available to construction contractors (Document ID 0679, p. 19).

<u>*Additional Controls for Walk-Behind Saw Operators*</u>

Wet Methods

Wet methods are the primary dust control option for walk-behind saws, and most manufacturers offer water-fed models.[199] The available data for construction workers

[199] Water-fed walk-behind saws (manual and self-propelled) are widely available from many manufacturers and construction tool distributors (Document ID 0715; 1676; 1185; 0643; and 0615).

using walk-behind saws, summarized in Table IV.5.6-B, provide evidence that workers using wet methods experience lower silica exposure levels.

OSHA finds that wet methods are at least as effective for walk-behind saws as they are for handheld saws. The saw blade functions in the same manner, and some factors that can make it difficult to use a water-fed saw are less problematic for walk behind saws (e.g., the cutting direction of a walk-behind saw is down into the pavement, so water flow is more predictable – following gravity). Handheld and walk-behind saws are so similar that at least one model of commercially available water-fed saw (Hilti model DSH 700/900) is designed to be used as either a handheld saw or a walk-behind saw; the operator can convert a handheld saw to a walk-behind saw by attaching the saw body to a wheeled base, which is commercially available as a saw accessory (Document ID 3998, Attachment 12e, pp. 3, 7). Due to the functional similarities between handheld and walk-behind saws, the laboratory and field studies providing evidence that water fed to the saw blade reduces dust emissions apply equally to both walk-behind and handheld saws.

Table IV.5.6-B shows that none of the 12 respirable silica results associated with wet cutting concrete outdoors using walk-behind saws exceeds 50 $\mu g/m^3$. Furthermore, eight of the results obtained for this group of walk-behind saw operators were reported as less than or equal to the LOD of 12 $\mu g/m^3$ (Document ID 0784, pp. 216-217-Table V). These eight samples, tabulated by Linch (2002), were collected at outdoor road construction sites. On one site, water was provided to walk-behind saws via a hose from a water truck while expansion joints were being sawed in fresh concrete. No silica was detected in the saw operators' breathing zones at this site (Document ID 0784, pp. 216-217). At the other site, during demolition of an interstate highway (involving sawing through and lifting out blocks of concrete), water for the saws was provided by 725-gallon tanks mounted on trucks. The sample results at this site ranged from below the limit of detection to 20 $\mu g/m^3$ (Document ID 0784, pp. 216-217). These results suggest that, in the manner most typically used (i.e., outdoors), water-fed walk-behind saws are generally associated with 8-hour TWA silica exposures of 50 $\mu g/m^3$ or below.

These results were obtained using the saw's normal water feed system intended for cooling the blade. CISC inquired whether an additional water feed is needed for these saws. Based on the information presented by Linch (2002), OSHA concludes that the existing water feed system is sufficient to reduce exposures to 50 μg/m^3 or below during outdoor cutting, although the water feed system should be regularly inspected and adjusted to maximize dust suppression. CISC also questioned the feasibility of using wet methods in situations where there is no established water main on site (Document ID 2319, p. 112). OSHA recognizes that a municipal water hookup may not be available on all construction sites and that the availability of such a hookup may be out of the construction contractors' control; however, OSHA believes that water tanks, which were used to provide water to the walk-behind saws in Linch (2002), are already commonly available on many construction sites and can provide water for a walk-behind saw (Document ID 0784, pp. 216-217).

Although the data are limited, water-fed walk-behind saws used indoors may result in exposures that are considerably higher than those measured outdoors. Flanagan et al. (2001) reported higher 8-hour TWA respirable silica levels for operators and assistants who used water-fed walk-behind saws indoors for most of their shifts when compared with samples taken outdoors. The samples, obtained under what the authors described as worst-case work conditions, resulted in four 8-hour TWA values between 65 and 350 μg/m^3 (calculated from the reported silica concentrations of 130 to 710 μg/m^3 for the sampling period) (Document ID 0675, pp. 1097, 1098-1099-Tables I and II). As noted in the previous discussion of this study with respect to handheld saws, Flanagan et al. (2001) recommended evaluation of a commercially available vacuum attachment to collect slurry "to determine its effectiveness for controlling aerosol in the respirable size range. The test could also include an assessment of the vacuum exhaust air as it is emitted into the room" (Document ID 0675, p. 1100). Based on the similarity between silica concentrations measured for indoor slab saw operators, helpers, and general area samples, Flanagan et al. suggested that "the primary exposure may be due to a buildup of respirable aerosol within the enclosed space, rather than direct exposure to slurry spray" (Document ID 0675, p. 1099 and Figure 5). These authors mention that exposures may be reduced by checking vacuum filtration and taking steps to improve general (dilution) ventilation during indoor work (Document ID 0675, p. 1099). Based on the observations and recommendations from Flanagan et al., OSHA observes that the results for indoor sawing can be influenced by factors such as dust emitted from inefficient vacuum filters and dust that builds up in spaces where general dilution ventilation is poor.

The CSDA report submitted to the docket shows that all entries for outdoor slab sawing using a saw equipped with a water supply produced silica exposure levels at or below a TWA of 50 μg/m^3 (Document ID 3497, pp. 2-4). However, an indoor slab sawing result listed in the chart exceeded 50 μg/m^3, despite the use of equipment with a water supply (Document ID 3497, p. 2).

Flanagan et al. also demonstrated the importance of water flow rates in dust suppression (Document ID 0675). These investigators reported respirable quartz levels as high as 710 μg/m^3 for a worker and assistant who spent four hours cutting concrete in an enclosed space using a water-fed walk-behind saw and wet shop vacuum (to collect the slurry) at an indoor construction site (8-hour TWA of 350 μg/m^3) (Document ID 0675, pp. 1098-1099). Water was supplied to the cutting blade at 0.5 gallons per minute. When similar work was performed with a water-feed rate of 2 gallons per minute, the exposures dropped to 200 μg/m^3 (8-hour TWA of 110 μg/m^3), about one-third of the original value[200] (Document ID 0675, p. 1099).

Both the Masonry & Concrete Saw Manufacturers Institute and the MCAA (represented by Mr. Johnson) commented that most water-fed systems are designed to keep the blade cool, rather than to suppress dust, and that this topic has not been sufficiently researched (Document ID 2316, p. 3; 3585, Tr. 2885). As discussed previously, considerable evidence shows that water application reduces dust emissions and that several saw manufacturers do state that using wet cutting will suppress dust. Furthermore, the water delivery system described in Linch (2002) was for the purpose of cooling or protecting the blade, but was effective in suppressing respirable silica levels (Document ID 0784, p. 216). Although no specific information is available in CSDA's Silica Data Analysis

[200] The manufacturer of a walk-behind saw with an original-equipment water port also recommends connecting a hose providing 2 gallons per minute (Document ID 1676).

Chart, the concentrations listed for slab sawing may be associated with saws "equipped with water supply" for the purpose of cooling. These data includes 26 samples for outdoor work, 21 of which (80 percent) are less than 25 μg/m^3, and only one sample (65 μg/m^3) exceeds 50 μg/m^3 (Document ID 3497, pp. 2-4). OSHA concludes that water used as coolant can also control silica exposures.

OSHA concludes that an integrated water delivery system effectively reduces silica exposures to 50 μg/m^3 or below when work with walk-behind saws is performed outdoors. NIOSH noted the potential for elevated exposures when work is performed indoors (Document ID 4233, p. 10). Both effective wet dust suppression and minimizing the accumulation of airborne particulate near workers' breathing zones (e.g., when sawing indoors or within enclosed areas with limited ventilation) can reduce worker exposures to respirable dust and silica, and available data demonstrate that exposures to respirable crystalline silica typically exceed 50 μg/m^3 when walk-behind saws equipped with water delivery systems are used indoors or in enclosed areas (Document ID 0675, pp. 1097, 1098-1099; 3497, p. 2).

Dust Extraction (Vacuum Suction, Local Exhaust Ventilation)

Although some manufacturers offer an LEV option for walk-behind saws,[201] OSHA could not obtain exposure monitoring data on the effectiveness of LEV under either actual working conditions or experimental conditions (Document ID 1431, p. 3-71). These saws do exist, however, and are available as an alternative for reducing construction workers' silica exposure levels if a condition arises in which wet sawing is not possible. For example, a power tool manufacturer offers a walk-behind saw described as providing a "dust-less cutting environment" (Document ID 3998, Attachment 10, p. 57). This saw connects via a vacuum hose to a two-part 300 cfm dust collection system on a wheeled cart. This gas-powered dust collection system includes a primary cyclonic dust separator and secondary fine filter rated to remove 99.9 percent of dust 0.5 micron or

[201] Examples of walk-behind saws that have an LEV option are described in the following: CS-Unitec-CSR-150 (Document ID 0616), EDCO-accessories-walk-behind-saw (Document ID 0639), EDCO-E-C10-I-0209 (Document ID 0640), and EDCO-E-MPS-I-1007 (Document ID 1676). In some cases the saw is factory equipped with vacuum ports; in other cases the manufacturer offers an optional vacuum-compatible blade guard.

larger (which includes respirable size dust, defined as falling in the 1 to 10 micron size range) (Document ID 3998, Attachment 10, p. 57).

Based on the information OSHA has for handheld and drivable saws, OSHA believes that LEV systems should perform equally well for walk-behind saws, provided that a shroud or blade housing fits close to the pavement being cut and sufficient vacuum suction is provided. For most walk-behind saws, OSHA expects that adequate performance will require a relatively large vacuum cleaner. For example, the instruction manual for one relatively small walk-behind saw indicates that the vacuum hood over the blade is intended to be used with a high-volume vacuum that provides more than 200 cfm of suction (Document ID 0640, p. 5).[202] Larger walk-behind saws are likely to require even larger vacuums. Such vacuums (for example 500 cfm) are used with walk-behind milling machines (Document ID 0636, p. 7). Considering that the thin cutting area of a saw is smaller and removes (pulverizes) less volume of material than a milling machine blade or drum, the dust released by a saw blade will be easier to control than the dust from the milling machine. Therefore, OSHA anticipates that an LEV system with a powerful vacuum will work at least as well for a walk-behind saw as for a walk-behind milling machine. OIS contains records indicating that exposure levels were below the limit of detection (12 µg/m^3) for an operator using a walk-behind grinder and scarifier (types of walk-behind milling machines) while a helper vacuumed grinding debris left behind the equipment (Document ID 3958).

Although the extent of the reduction in silica exposures has not been confirmed, based on the evidence in the record, OSHA believes that LEV and a suitably sized dust collection system can reduce operator exposures to 50 µg/m^3 or below during the use of walk-behind saws outdoors. However, because there is more evidence available on the effectiveness of wet methods to reduce exposures when operating walk-behind saws, wet methods are the only control option specified on Table 1 (as discussed more fully later in this section).

[202] This walk-behind saw is a “crack-chaser” style for use with 7- to 10-inch blades and a blade housing (hood) that encloses the blade nearly to ground level, which provides more complete enclosure than the guards used on many walk-behind saws.

Additional Controls for Drivable Saw Operators

Wet Methods

Drivable saws are typically factory equipped with water-fed systems that apply water directly to the cutting blade. Two of the three samples in the exposure profile were collected for saw operators with low to moderate respirable silica exposures (suggesting dust suppression was occurring). One 8-hour TWA result was reported as less than or equal to the LOD of 12 μg/m^3 (actual sample duration 70 minutes, during which the respirable dust concentration was too low to collect a sufficient amount of dust to measure silica) (Document ID 1143, Company A), and the other 8-hour TWA result was reported as 33 μg/m^3 (Document ID 1143, Company R). These levels could potentially be reduced further by adjusting the water spray to optimize dust capture.

The highest result in the drivable saw group was obtained for a saw operator who cut pavement while the water nozzle at the saw blade was likely clogged (given the high respirable dust concentration of 9,630 μg/m^3 associated with this sample – a level more typical of uncontrolled releases) (Document ID 1143, Company R). The 8-hour TWA measurement of 88 μg/m^3 for this sample was based on an 80-minute sample with an actual respirable quartz reading of 530 μg/m^3 during the period monitored. This result demonstrates the importance of using sufficient amounts of water to reduce silica exposures and ensuring that water-fed equipment works properly. Based on the data in the record, OSHA concludes that, with respect to drivable saws, water-spray optimized for dust suppression can control worker silica exposures to 50 μg/m^3 or below provided that the system is regularly inspected to ensure proper functioning.

The Masonry & Concrete Saw Manufacturers Institute (SMI) commented that current saws use water to cool the cutting tool, rather than as a dust control (Document ID 2316, p. 3). As noted previously, however, water provided for cooling has a marked impact on dust release and optimizing the water application for dust suppression offers further benefit for silica control. This is as true for drivable saws as it is for other types of saws and construction equipment. The function and purpose of drivable saws (to produce a thin cut through partial or full depth of pavement) are similar in function and purpose to the blades of other portable pavement saws. As discussed with respect to handheld and walk-behind saws, considerable research has confirmed that water application to saw blades provides marked reduction of dust, including silica dust (Document ID 0846; 0868; 1181; 3610). The types of materials (concrete and asphalt pavement) cut by drivable saws is similar, if perhaps somewhat more limited in range, than the types of materials typically cut with handheld or walk-behind saws.

5.6.4 Feasibility Finding

Feasibility Finding—Handheld Power Saw Operators

Paragraph (c) of the construction standard gives employers the option of following Table 1, which includes specified engineering and work practice controls when operating handheld power saws (also referred to as cut-off, chop, or quickie saws); alternatively, the employer must assess and limit exposures in accordance with the more traditional regulatory approach contained in paragraph (d). When using handheld power saws to cut silica-containing materials, Table 1 requires employers to use an integrated water delivery system that continuously feeds water to the blade, and to operate and maintain the system in accordance with the manufacturer’s instructions to minimize dust emissions.

The exposure results summarized in Table IV.5.6-B and the studies described above demonstrate that water spray systems reduce respirable crystalline silica exposures substantially when the system is well designed, and properly implemented and maintained. Water-fed handheld saws are commercially available from a variety of sources (CS Unitec, Document ID 0615; Hilti, Document ID 0737 and 3998, Attachment 12e; Stihl, Document ID 3998, Attachment 12a; Husqvarna, Document ID 3998, Attachment 12f; Makita, Document ID 3998, Attachment 12g; Wacker group, Document ID 3998, Attachment 12h).

Use of an integrated water delivery system on cut-off, chop, quickie or masonry saws has been shown to produce exposure reductions of 78-96 percent (Document ID 3610, p. 162; 3777, p. 67; 0868, p. 10; 1181, pp. 443, 447-Table 2, 450-Table 4; 4073, Attachment 8a, p. 1). When used outdoors, this results in 8-hour TWA exposures of 50 $\mu g/m^3$ or below for 80 percent (four out of five) of the samples in the profile (Table IV.5.6-B). In addition, the CSDA data compiled from member jobsites and NIOSH showed that all outdoor hand sawing using a saw equipped with a water supply (seven samples) produced exposure levels below an 8-hour TWA of 50 µg/m^3 (Document ID 3497, p. 6). OSHA finds that Table 1's requirement to use integrated wet systems when operating these tools is effective and technologically feasible.

Workers typically use handheld power saws for brief, intermittent periods. The median duration for using handheld portable saws in the Flanagan database of silica exposures in construction tasks was 101 minutes, although the range of cutting times reported in studies is 9-447 minutes (Document ID 0677, Attachment 2; 3581, Tr. 1598; 3610, pp. 157, 162). Using data obtained during periods of outdoor intensive cutting (8-feet at a time) using handheld water-fed saws, Shepherd and Woskie (2013) determined that among workers who cut at this intensity level for 2 hours, 83 percent would have 8-hour TWAs of 50 µg/m^3 or below. They also concluded, however, that if the workers continued cutting (still at the same constant intensity, outdoors using wet methods) for 6 hours in the shift, only 61 percent of those saw operators would have 8-hour TWAs of 50 µg/m^3 or below. Based on these data, OSHA concludes that outdoor wet cutting for more than four hours (the midpoint between the two and six hours of continuous intensive sawing considered by Shepherd and Woskie in 2013) could result in exposures over 50 µg/m^3. Therefore, Table 1 requires respirators for periods of cutting outdoors that extend beyond four hours in a day.

The vast majority of samples for handheld saws summarized in Table IV.5.6-B involve work outdoors. However, workers may occasionally use handheld saws indoors. OSHA's exposure profile (Table IV.5.6.B) shows that TWA exposures to silica exceed 50 µg/m^3 half of the time when wet cutting with handheld saws indoors, and Flanagan et al. (2001) reported 8-hour TWA exposures of 65 µg/m^3 and 70 µg/m^3 for handheld slab saw operators who used wet methods at indoor sites (Document ID 0675, p. 1098-Table I). Thus, when an employee uses a water-based system indoors or within enclosed areas, exposures are likely to exceed 50 µg/m^3. For that reason, Table 1 requires the use of respiratory protection with an APF of 10 for this work. This finding is based on data summarized in Table IV.5.6-B, which shows that half of the exposure samples associated with using handheld saws indoors exceed 50 μg/m^3, even with wet methods. Also, CSDA's data show indoor handheld sawing results in exposure above an 8-hour TWA of 50 μg/m^3 (presented as a range of 240-260 μg/m^3 for 130-minute samples) using wet methods (Document ID 3497, p. 5). And Shepherd and Woskie's (2013) evaluation shows that 52 percent (89 out of 171) of the (largely indoors) saw operator 8-hour TWA exposures would exceed 50 μg/m^3 (Document ID 4073, Attachment 8a, p. 1). OSHA concludes that the use of a water-fed saw substantially reduces exposure levels during indoor cutting, such that a respirator with an APF of 10 will be adequate.

Additionally, based on testimony from the New Jersey Laborers' Health and Safety Fund, MCAA, and the International Union of Bricklayers and Allied Craftsworkers, OSHA finds that it is feasible to use stationary masonry saws equipped with wet methods instead of handheld saws, This may be particularly useful when cutting will last more than two hours (Document ID 3589, Tr. 4237; 3581, Tr. 2911; 3585, Tr. 3064). Using stationary masonry saws offers the benefits of wet sawing while simultaneously reducing the challenges of controlling slurry in the work area and addressing other safety concerns associated with handheld portable saws (e.g., cuts, increased risk of amputations, ergonomic stressors) (Document ID 0803, p. 109). As described more fully in Section IV-5.7 – Masonry Cutters Using Stationary Saws, masonry cutters using stationary saws can achieve exposures of 50 μg/m^3 or below most of the time by using a water-fed saw and work practice controls when used either indoors or outdoors.

In sum, OSHA concludes that 34 percent of workers using handheld power saws are currently exposed to silica levels below 50 μg/m^3. For the remaining 66 percent of workers who are currently exposed above 50 μg/m^3, the controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or below in most operations, most of the time, with exceptions in some cases for workers cutting outdoors for extended periods of time or workers cutting indoors. Therefore, OSHA finds that the standard is technologically feasible for workers using handheld saws. To achieve the PEL, however, supplemental respirator use may be necessary for workers cutting outdoors for extended periods of time and workers cutting indoors.

Feasibility Finding—Handheld Power Saw Operators Cutting Fiber-Cement Board

Paragraph (c) of the construction standard gives employers the option of following Table 1, which includes specified engineering and work practice controls when operating handheld power saws for cutting fiber-cement board (with blade diameter or 8 inches or less); alternatively, the employer must assess and limit exposures in accordance with the more traditional regulatory approach contained in paragraph (d). Table 1 requires the saw to be used outdoors and with a dust collection system operated and maintained in accordance with manufacturer's instructions to minimize dust emissions. The dust collector must provide the air flow rate recommended by the tool manufacturer, and the filter must have 99 percent or greater efficiency.

OSHA finds that the controls specified in Table 1 are technologically feasible, and that currently-available systems have demonstrated the ability of these controls to keep worker exposures to respirable silica at or below 50 μg/m^3 when used outdoors. This finding is based in part on the 21 sample results summarized in Table IV.5.6-C for operators using dust collecting circular saws with vacuum dust collectors on fiber-cement siding at siding installation sites evaluated by NIOSH. These samples show a maximum exposure of 41 μg/m^3, with 20 of the 21 sample results falling below 25 μg/m^3 (Document ID 4138; 2322, Attachment B [also 3998, Attachment 4a]; 3998, Attachment 4b; 3998, Attachment 4c). LEV systems for saws with larger blades are available, but evidence suggests this method is inconsistent when it comes to controlling silica exposures. OSHA has not included a requirement in Table 1 for larger handheld saws equipped with LEV systems.

OSHA concludes that most workers using handheld power saws to cut fiber-cement board outdoors are currently exposed to silica levels at or below 50 μg/m^3. For workers who are currently exposed above 50 μg/m^3, the controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or below in most operations, most of the time. Therefore, OSHA finds that the standard is technologically feasible for these workers.

Feasibility Finding—Rig Mounted Core Saw or Drill Operators

Paragraph (c) of the construction standard gives employers the option of following Table 1, which includes specified engineering and work practice controls when operating rig-mounted core cutting machines; alternatively, the employer must assess and limit exposures in accordance with the more traditional regulatory approach contained in paragraph (d). For rig-mounted core cutting machines, Table 1 requires employers to use an integrated water delivery system that supplies water to the cutting surface and to operate and maintain the system in accordance with the manufacturer's instructions to minimize dust emissions.

Core saws already use wet methods extensively, resulting in worker exposure levels of 50 $\mu g/m^3$ or below. Three of the four exposure results for core saws in Table IV.5.6-B are below 25 $\mu g/m^3$ and the fourth sample result is 29 $\mu g/m^3$ (Document ID 0675, pp. 1097, 1098-Table 1; 0898, p. 15). Therefore, additional controls are not required for rig-mounted core saws or core cutting machines used with a water feed, and the standard is technologically feasible for workers using rig mounted core saws or drills.

Feasibility Finding—Walk-Behind Saw Operators

Paragraph (c) of the construction standard gives employers the option of following Table 1, which includes specified engineering and work practice controls for operating walk-behind saws; alternatively, the employer must assess and limit exposures in accordance with the more traditional regulatory approach contained in paragraph (d). For walk-behind saws, Table 1 requires employers to use saws with integrated water delivery systems that continuously feed water to the blade and to operate and maintain those systems in accordance with the manufacturer's instructions to minimize dust emissions.

Water-fed walk-behind saws (manual and self-propelled) are widely available from many manufacturers and construction tool distributors (Grainger-cat-Husqvarna-concrete saw Document ID 0715; EDCO-E-MPS-I-1007, Document ID 1676; Toolfetch-MK-diamond-walk behind-saw, Document ID 1185; EDCO-self-propelled-saws, Document ID 0643; CS-Unitec-catalog, Document ID 0615). OSHA finds Table 1's requirement for walk-behind saws to be technologically feasible.

Although walk-behind saws are most commonly used outside, they are occasionally used indoors. When workers use walk-behind saws indoors, they can experience higher respirable silica concentrations. Flanagan et al. presented four results for water-fed walk-behind saws used indoors (ranging from 65 µg/m^3 to 350 µg/m^3) over 4 to 7 hours of indoor work (Document ID 0675, pp. 1098-1099). Both Flanagan et al. and CSDA suggest that respiratory protection may be needed under these circumstances (Document ID 0675, p. 1098-1099; 3497, p. 2). Therefore, Table 1 requires the use of respiratory protection with a minimum APF of 10 when walk-behind saws are used indoors or in enclosed areas. Because of the lack of data evaluating worker exposures to respirable crystalline silica when using walk-behind saws equipped with LEV systems, OSHA has not included a specification for such systems in Table 1 of the final rule.

As reflected in the exposure profile (Table IV.5.6-B), the silica exposures of all walk-behind saw operators who work outdoors using water-fed machines are already controlled to levels at or below 50 µg/m^3. Additionally, most silica sample results (25 of 26 rows) reported by CSDA for water-fed walk-behind (slab) saws used outdoors were at or below 50 µg/m^3 (Document ID 3497, pp. 2-4). OSHA believes that the small percentage of walk-behind saw operators who are exposed at levels above 50 µg/m^3 can reduce their exposures through proper maintenance of water-fed systems (e.g., ensuring nozzles are cleaned or replaced as often as necessary to keep them functioning as intended) and sufficient use of water (i.e., according to the saw manufacturer's directions). OSHA concludes that most workers using walk-behind saws are currently exposed to silica levels at or below 50 µg/m^3. For workers who are currently exposed above 50 µg/m^3, the controls described in this section can be implemented to reduce silica exposure levels to 50 µg/m^3 or below in most operations, most of the time, with exceptions in some cases for workers using walk-behind saws indoors. Therefore, OSHA finds that the standard is technologically feasible for workers using walk-behind saws.

Feasibility Finding—Drivable Saw Operators

Paragraph (c) of the construction standard gives employers the option of following Table 1, which includes specified engineering and work practice controls for operating drivable saws; alternatively, the employer must assess and limit exposures in accordance with the more traditional regulatory approach contained in paragraph (d). When using drivable or ride-on saws to cut silica-containing materials, Table 1 requires that the saw be equipped with an integrated water delivery system that continuously feeds water to the cutting surface, and that the system be operated and maintained in accordance with the manufacturer's instructions to minimize dust emissions. Due to their size, these saws these saws are used on roadways and parking lots, and OSHA's information covers their use in outdoor environments, thus Table 1 applies only to drivable saws used outdoors.

Based on the data summarized in the exposure profile (Table IV.5.6-B), OSHA finds exposure levels of 50 $\mu g/m^3$ or below have already been achieved for 67 percent of drivable saw operators. Drivable saws are typically equipped with water delivery systems (Document ID 4073, Attachment 4a), and OSHA finds that Table 1's requirements for drivable saws are technologically feasible.

OSHA concludes that most workers using drivable saws are currently exposed to silica levels below 50 $\mu g/m^3$. For workers who are currently exposed above 50 $\mu g/m^3$, the controls described in this section can be implemented to reduce silica exposure levels to 50 $\mu g/m^3$ or below in most operations, most of the time. Therefore, OSHA finds that the standard is technologically feasible for these workers.

5.7 MASONRY CUTTERS USING STATIONARY SAWS

5.7.1 Description

Workers in the construction industry use stationary saws to cut silica-containing masonry materials, such as bricks, concrete blocks, stone, and tile. These table-top or stand-mounted saws include a flat platform where the work piece (e.g., a brick) sits. To form a cut, the worker brings a rotating circular abrasive blade into contact with the work piece, either by pressing a swing arm-mounted blade down onto the piece, or by moving the piece on a sliding platform into contact with a fixed-position blade (depending on the saw design). In either configuration, the saw's orientation is fixed. The cutting surface is generally about waist-high and arm's length from the worker's breathing zone.

Stationary saws similar to those found on construction sites can be used to cut silica-containing material at manufacturing and nonmanufacturing general industry establishments. For these establishments, stationary saws may be used as part of a temporary construction activity or as part of the establishment's main business (e.g., granite countertop fabrication shops). At these locations, the baseline conditions, exposure profile, and additional controls presented here apply equally to construction as well as maintenance work.

5.7.2 Exposure Profile and Baseline Conditions

Record evidence indicates that most stationary masonry saws are designed for use with an integrated water application system that controls dust and improves blade longevity. However, comments and testimony received by OSHA suggest that workers often cut brick and block dry, particularly when working outdoors.

The Mason Contractors Association of America (MCAA) testified that most stationary masonry saws are equipped for wet cutting (Document ID 3585, Tr. 2885; 2286, p. 2). Mr. Wherry of the Unified Abrasives Manufacturers Association stated that water is applied to the blade for cooling and that "[i]f anything, dust control is a secondary benefit of water applied to the blade" (Document ID 2243, p. 1). This sentiment was echoed by Mr. Service of Saint Gobain Abrasives, on behalf of the Masonry and Concrete Saw Manufacturers Institute (SMI), and by Mr. Hammock, representing the Construction

Industry Safety Coalition (CISC) (Document ID 2316, pp. 1-2; 2319, p. 104). Mr. Johnson, representing MCAA, noted that "manufacturers of these saws are starting to explicitly state that the water used in this blade – in this system, is used for cooling the blade only and should not be used to suppress dust" (Document ID 3585, Tr. 2885).

However, Dr. Schulte of the National Institute for Occupational Safety and Health (NIOSH) observed that this statement by Mr. Johnson "overlooks manufacturers' literature stating the opposite" (Document ID 4233, pp. 5-6). NIOSH submitted examples of product literature for various types of saws from five major saw manufacturers; that literature highlights that the use of water application equipment suppresses dust (Document ID 3998, Attachment 12a, pp. 9, 15-16; 3998, Attachment 12e, p. 3; 3998, Attachment 12f; 3998, Attachment 12g; 3998, Attachment 12h). Mr. Walker, a World Floor Covering Association (WFCA) member, agreed that wall and floor tile and stone are almost always cut with water when using a stationary masonry saw, noting that "water not only keeps the temperature [of the blade] moderate, but it also suppresses the creation of any dust. The byproduct of the cutting is dirty water, not airborne particles of any sort" (Document ID 2359, Attachment 4, pp. 1-2).

At the public hearing, Mr. Cahill, a bricklayer from Arizona representing the International Union of Bricklayers and Allied Craftworkers (BAC), agreed that water systems have traditionally been for cooling saw blades; Mr. Cahill noted that the older style blades deteriorated rapidly if not constantly wetted, but he has observed that the wetting has the additional benefit of dust suppression. He stated that with the advent of modern wet/dry diamond blades, if "the water stops going, we keep right on cutting…. And the dust just gets worse and worse….I think the dusty, dirty conditions are mainly the result of development in [and] the rapid adoption of the wet/dry diamond blade" (Document ID 3585, Tr. 3042). Mr. Cahill further explained that the growing trend among workers is to cut masonry dry, rather than use the wet methods that used to be more universal. He stated that several decades ago (in the early days of his career, which started in 1959) his experience was that all masonry saws used water to protect the blade from overheating (Document ID 3585, Tr. 3041-3042).

Despite the mixed comments regarding the original intent of wetting the blade, OSHA received no comments disputing OSHA's understanding that workers sometimes perform dry cutting with stationary masonry saws. Nor did OSHA receive comments refuting that water has marked dust suppression properties when applied to masonry cutting blades. In fact, as OSHA describes later in this section, under the discussion of Additional Controls – Wet Methods, water-based cutting systems are the most effective means of suppressing dust emissions while cutting masonry.

The amount of time spent operating masonry saws during a work shift is a major determinant of a worker's 8-hour time-weighted-average (TWA) exposure to respirable crystalline silica. Many saw operators alternate cutting with laying masonry, mixing mortar, or pouring concrete, and thus cut for only a short portion of their shifts (Document ID 0231, p. 6; 0084, pp. 19, 33). At some worksites, however, saw operators cut masonry nearly continuously throughout their shifts; but even these workers typically pause between cuts to adjust the cut angle or pick up the next work piece (Document ID 1238, pp. 147-148).

NIOSH conducted a field study to evaluate exposures to silica among workers involved in the cutting of bricks and concrete masonry units. That study documented the amount of time workers spent cutting (Document ID 0231). NIOSH researchers collected eleven samples on five workers cutting masonry with stationary bench saws and portable chop saws at two construction sites (Document ID 0231, p. 5; 0223, p. 6). Only one (20 percent) of the five workers operated the saw for more than half the shift (that worker used the saw for 60 percent of the shift). The median percentage of shift time spent working with a stationary saw was 15 percent (i.e., 72 minutes of a 480-minute [8-hour] shift). All saw operators at these two NIOSH sites spent the remaining portion of their days laying brick, delivering mortar to other bricklayers, or preparing and making concrete pours, although one of the workers, who used a water-fed stationary saw for 25 percent of the shift, switched to a handheld masonry saw (operated dry) for an additional 10 percent of his shift (Document ID 0223, p. 7).

To further estimate the amount of time construction workers typically spend operating stationary masonry saws, OSHA reviewed information presented in a construction exposure database assembled by Flanagan (Document ID 0677, Attachments 1 and 2).[203] In the database, 17 of the 53 personal silica exposure samples for workers using “table mounted saws” (i.e., stationary masonry saws) contain information on the amount of time the worker spent on specific tasks. For this group, the percentage of work time spent using stationary masonry saws ranged from 7 percent to 60 percent. Using the information in the database, OSHA determined that the 17 workers spent 4 to 282 minutes using the saw during the period sampled. The median time spent using the saw was 69 minutes and the mean time was 81 minutes, indicating that most observed workers spent less than 1.5 hours per work shift operating a stationary masonry saw (Document ID 0677, Attachment 2).[204]

Mr. Humphrey, representing WFCA, explained that masonry cutters routinely spend little time on cutting and sawing activities during masonry or stone installation jobs because the overwhelming majority of the tile and stone comes pre-cut (Document ID 2359, Attachment 1, pp. 3-4). Mr. Humphrey stated that, based on information from WFCA members, tile and stone flooring are cut only intermittently and for short periods of time (often a minute or two) (Document ID 2359, Attachment 1, pp. 3-4).

Mr. Humphrey reported that, based on his organization’s members’ experience, even if an entire floor installation is performed by one worker, that worker would still spend less than one to two hours cutting or sanding stone, tile, or concrete for the job (Document ID

[203] The Flanagan dataset may contain a few masonry cutter results that are included in OSHA’s exposure profile, but individual data points in the Flanagan dataset are not attributed to specific sources. All 53 silica results recorded in the Flanagan dataset for workers using stationary saws were obtained between 1997 and 2002 by researchers, government regulatory agencies (primarily Oregon and Illinois), and private organizations (Document ID 0677, Attachment 2). For comparison, OSHA’s exposure profile contains 30 results, obtained mainly by OSHA and NIOSH, between 1990 and 2014.

[204] To calculate minutes spent on the task, OSHA multiplied the reported sample time (in minutes) by the percent of time the worker performed the task (as provided in the Flanagan dataset) to obtain the number of minutes spent on the task during the period sampled (Document ID 0677, Attachment 2). For example, if a worker spends 10 percent of a 480-minute sampling period using a table-mounted saw, OSHA calculated that the worker spent 0.10 x 480 minutes = 48 minutes using the saw. The sampling reported in the Flanagan dataset was conducted over periods ranging from 37 to 505 minutes (Document ID 0677, Attachment 2).

2359, Attachment 1, pp. 3-4). These comments are supported by written testimonials from several WFCA members (e.g., Document ID 2359, Attachment 2; 2359, Attachment 3, p. 1; Attachment 4, pp. 1-2). Additionally, the Bay Area Roofers and Waterproofers Training Center reported that workers in the roofing industry usually cut concrete roofing tiles or concrete roofing pavers for only about 30 to 45 minutes per day (Document ID 3581, Tr. 1598).[205]

Table IV.5.7-A summarizes the major activities and primary sources of silica exposure among workers in this job category.

Table IV.5.7-A Job Categories, Major Activities, and Sources of Exposure of Masonry Cutters Using Stationary Saws	
Job Category*	**Major Activities and Sources of Exposure**
Masonry Cutter Using Stationary Saw	Cutting block, brick, or stone. • Dust generated by abrasive cutting wheel during dry cutting. • Re-suspended dust particles released when dust-laden water or slurry from wet cutting dries and becomes airborne (particularly under extremely hot or dry conditions).
*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site. Source: Document ID 1720, p. IV-443.	

OSHA's exposure profile presents the best exposure monitoring data available to OSHA; it includes 30 sample results for stationary masonry cutting, including 28 samples described in the PEA and two exposure monitoring results from OSHA's Information System (OIS) (Document ID 1720, p. IV-445; 3958, Rows 1041, 1042). The 28 samples previously summarized in the PEA were drawn from eight OSHA special emphasis program inspections (SEP), and two NIOSH reports (Document ID 0040; 0084; 0092; 0102; 0103; 0144; 0158; 0181; 0223; 0231).

Table IV.5.7-B presents the exposure profile for masonry cutters using stationary saws under various conditions. Overall, the exposure profile in Table IV.5.7-B includes 30 samples of respirable crystalline silica for masonry cutters using stationary saws. The

[205] Although workers in this industry typically use handheld saws for cutting roofing materials, Mr. Smith did not specify what tools are used for cutting tile and pavers (Document ID 3581, Tr. 1598).

median is 50 μg/m^3, the mean is 217 μg/m^3, and the range is 11 to 2,005 μg/m^3. Of the 30 samples, 15 (50 percent) exceed 50 μg/m^3. The exposure profile values described in this section were obtained under both wet and dry working conditions and represent baseline exposures for workers using stationary saws.

Of the 30 total measurements summarized in Table IV.5.7-B, 13 sample results are for workers dry cutting outdoors with no controls. For these 13 sample results, the mean 8-hour time-weighted average (TWA) silica exposure is 329 μg/m^3, although the median is notably lower (45 μg/m^3). The two lowest results, 21 μg/m^3 and 12 μg/m^3 (limit of detection (LOD)), were obtained for a worker dry-cutting concrete block for approximately 45 minutes (10 percent of the shift) during each of two 8-hour sampling periods (Document ID 0231, pp. 6-7).[206] The concrete block being cut during these sampling periods contained four percent or less silica. The maximum silica exposure reported in this 13-sample subset was 2,005 μg/m^3 (an 8-hour TWA obtained over a 350-minute work period), and was associated with a sawyer dry-cutting concrete blocks containing 15 percent silica (Document ID 0114, pp. 119-120).

Exposure levels are considerably lower when workers use wet methods. For these workers, the profile shows exposures ranging from 11 μg/m^3 to 94 μg/m^3, with a median exposure of 34 μg/m^3 and a mean exposure of 41 μg/m^3 (based on eight sample results for workers using water-fed masonry saws to cut brick and block outdoors) (Document ID 1143, Row 7). In these eight samples, the median percentage of silica in the materials being cut was 9 percent.

The profile includes an additional nine samples for workers working under various other conditions. These results show a mean exposure of 211 μg/m^3, with a median exposure of 91 μg/m^3, and overall exposures ranging from 12 μg/m^3 to 824 μg/m^3. Mr. Hammock, for CISC, took exception to this category in the exposure profile, as it contains results from some samples that were not described in sufficient detail in source documents to be

[206] Results reported as "none detected" are assigned a value equal to the LOD. The LOD is determined individually for each sample based on the volume of air sampled and the method used to analyze the sample; therefore, the limit of detection varies between samples. See Section IV.2 – Methodology for additional information on LODs.

classified as wet or dry sawing samples (Document ID 2319, p. 53). Even though the detailed characteristics of the construction sites from which the samples were taken may not be known, OSHA retained this data in the exposure profile because the results represent exposures for workers who cut masonry using stationary saws in the United States.

The exposure profile values stem from samples that were obtained over varying lengths of time. In OSHA's judgment, the exposure profile reflects workers' full daily exposures because the vast majority of the samples covered most, if not all, of the workers' shifts. Although some shorter samples were included because they are relevant to baseline exposures, the median sampling duration among the samples included in the exposure profile was 450 minutes, indicating that half the samples were taken over periods of more than 7.5 hours. Two-thirds of the samples were taken over periods exceeding 6 hours. Thus, a majority of the samples in the profile were taken over a full shift and provided full-shift exposure values. These samples captured all silica in the workers' breathing zones during the sampling period, regardless of the source(s) of exposure.

CISC commented that OSHA should exclude one sample from the profile because it was taken over a period of only 16 minutes (Document ID 2319, p. 53). Because the OSHA compliance safety and health officer (CSHO) who obtained the 16-minute sample spent nearly seven hours at the construction site, and noted that the worker made only two or three cuts per day, OSHA believes that the 16-minute sample captured all, or nearly all, of that worker's exposures attributable to masonry cutting during that work shift (Document ID 0092, pp. 2, 15, 18). Therefore, OSHA concluded that the 16-minute sample reflects the observed duration of cutting tasks on the day the worker was sampled, and OSHA retained the sample in the FEA exposure profile.

Masonry saw cuts on brick typically take 1 to 2 minutes each (including the time it takes to pick up and position the brick), as confirmed in an iQ Power Tools air monitoring report indicating that a saw operator can, at the maximum work rate, cut 400 bricks per 8-hour day (i.e., one every 72 seconds) (Document ID 3501, p. 2).

CISC also asserted that OSHA's analysis of stationary saws did not take into account differences in the silica content of materials being cut (Document ID 2319, p. 53). OSHA acknowledges that the silica content of brick and block can vary greatly and has taken this into consideration. Among the data used for the exposure profile (Table IV.5.7-B), the respirable dust samples contained proportions of silica ranging from 3 to 22 percent, encompassing the range of materials used in brick and block masonry (Document ID 0084, p. 36; 0092, p. 17; 0102, p. 6; 0144, p. 10; 0159, pp. 50, 56, 62, 68; 0181, p. 21). Likewise, standard construction brick and block were used in every study upon which OSHA relied (some with moderate silica content, some with higher silica content).

In addition to the exposure data in the exposure profile, OSHA also reviewed extensive exposure data from other sources. These data, discussed below, were compiled in part from published studies and therefore included some of the same samples OSHA used to develop the exposure profile. The overall exposure results from these data for workers using stationary saws are consistent with the values in OSHA's exposure profile.

OSHA reviewed the Flanagan data, mentioned earlier in this section, which includes 53 personal silica sample results for workers using "table-mounted saws" to cut brick, concrete block and stone (Document ID 0677, Attachments 1 and 2). Location and control method information are not available for most of the samples in this dataset. Exposures ranged from 6 μg/m^3 to 2,750 μg/m^3, with a mean exposure of 210 μg/m^3 and a median exposure of 58 μg/m^3. Although these results represent exposure concentrations during the period monitored (rather than 8-hour time-weighted averages), these data are consistent with the exposure profile presented in Table IV.5.7-B. Sixteen of the samples from the Flanagan data were collected while the worker used wet-cutting methods and are associated with markedly lower exposure levels than were reported for all workers using table-mounted saws. Silica exposures among workers wet-cutting ranged from 6 μg/m^3 to 316 μg/m^3, with a mean exposure of 73 μg/m^3 and a median exposure of 46 μg/m^3. Although these results are higher than those in OSHA's exposure profile for wet cutting methods, this is likely because the results in the Flanagan data represent the concentrations during the periods sampled rather than 8-hour time weighted averages. Although most of the samples for workers using stationary saws in the Flanagan data were collected for periods of 3.5 hours to 8 or more hours (median 209 minutes), the highest of the wet-cutting exposure levels was obtained during one of the shortest sample times (just 12 minutes, suggesting a period of intense cutting, although no details are provided). The Flanagan data identify four wet-cutting samples collected during work indoors or in otherwise enclosed areas; these sample results were 18, 34, 61, and 139 μg/m^3 (with a mean exposure of 63 μg/m^3, and a median exposure of 48 μg/m^3).

Where available, Flanagan captured information on the percent of the sampled time that a worker spent on a specific task. For stationary saws, this information is available for 17 of the 53 samples and suggests that the workers most typically operated the saws for 15 percent of the period sampled (with a range of 7 to 60 percent of the sampled period) (Document ID 0677, Attachment 2). As noted above, the median sample period was 3.5 hours. OSHA notes that similar results (workers using stationary saws for approximately 15 percent of their shifts) were observed at the two NIOSH sites discussed previously (Document ID 0231, p. 6; 0223, p. 7).

In addition to the Flanagan study, OSHA also reviewed published summaries of an international database of silica construction exposure data assembled by Sauvé et al. (2013) and Beaudry et al. (2013a, 2013b) (Document ID 3778; 3797; 3803).[207] The underlying data in these studies were not made available to OSHA. The literature describing this dataset did not specifically separate exposure values for workers using stationary and handheld masonry saws, but OSHA judges the task described by Beaudry (2013b) as "sawing pieces of masonry" to apply most closely to masonry cutters using stationary saws. The investigators identified 74 samples, drawn from eight studies in which workers sawed pieces of masonry, then calculated a geometric mean exposure of 70 μg/m^3 for the samples presented as individual values (24 of the 74 results were individual values, the remainder were available as summarized rather than individual data) (Document ID 3797, pp. 83-84). Reviewing the data by type of tool (rather than

[207] This Canadian dataset includes references that OSHA consulted when developing the exposure profile and evaluating technologically feasible control methods. Individual data points are not attributed, but OSHA considers the similarity in source documents to suggest substantial overlap between this data set and the data that OSHA relied upon. Beaudry et al. also note a significant (20 percent) contribution from the Flanagan dataset (Document ID 3797, p. i; 0677, Attachment 2).

worker activity), the investigators found that five individual exposure results for workers (at any type of construction site) using bench-based masonry saws had a geometric mean exposure of 50 μg/m^3, similar to the overall median exposure of 50 μg/m^3 in OSHA's exposure profile (Table IV.5.7-B) (Document ID 3797, pp. 89-90).[208] These data provide corroborative evidence of worker exposure levels during the operation of stationary saws, although the effects of control methods and work environment (indoors/outdoors) on exposure levels were not reported for individual samples.

On the basis of the information in the record, OSHA has determined that baseline conditions for masonry cutters using stationary saws vary widely, with common conditions including wet cutting methods (indoors and outdoors) and dry cutting outdoors with no engineering controls. Although most masonry saws can be operated using wet methods, the number of stationary saw samples from dry cutting in Table IV.5.7-B indicates that saws are, at times, operated without active water flow.

Overall, the exposure profile in Table IV.5.7-B indicates that 50 percent of masonry cutters using stationary saws currently experience exposure levels of 50 μg/m^3 or below.

[208] The geometric mean of lognormally distributed data is equivalent to the median.

Table IV.5.7-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Construction Workers: Masonry Cutters Using Stationary Saws

	Exposure Summary			Exposure Range			Exposure Profile				
Masonry Cutters Using Stationary Saws	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**		**<25 (μg/m³)**	**≥25 and ≤50 (μg/m³)**	**>50 and ≤100 (μg/m³)**	**>100 and ≤250 (μg/m³)**	**>250 (μg/m³)**

5.7.3 Additional Controls

The exposure profile in Table IV.5.7-B shows that 50 percent (15 out of 30 samples) of masonry cutters using stationary saws have exposures above the final PEL of 50 µg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Based on the evidence in the record, OSHA has determined that the use of water suppression methods is both a feasible and highly effective means of dust control that can reduce workers' exposures to respirable crystalline silica during the use of stationary masonry saws. Where the use of such wet systems is not feasible for particular applications, employers can reduce worker exposures to a lesser extent using LEV-equipped saws (e.g., vacuum dust collection systems) or ventilated booths.

Wet Methods

The most reliable data showing substantial reductions in silica exposures involve the use of water when cutting (wet sawing method). As noted previously, OSHA identified eight respirable quartz samples for masonry sawyers using wet methods (Document ID 1720, p. IV-445; 3958, Row 1042). The mean exposure of 41 µg/m^3 associated with wet cutting is substantially lower than the mean exposure of 329 µg/m^3 for dry cutting operations with no engineering controls. Moreover, 75 percent of the samples taken for work done using wet methods show exposures less than 50 µg/m^3. When fully and properly implemented, wet cutting methods provide effective dust suppression. NIOSH found that use of wet methods can result in barely detectable levels of airborne respirable dust, even during the instant a mason starts the cut with a stationary saw. NIOSH found that the average airborne respirable dust concentration during wet cutting, as shown by area samples, is 154 times lower than the average concentration during dry cutting – a reduction of 99.3 percent (Document ID 1252, pp. 6, 7, 10).

When wet dust suppression is used properly, evidence in the record indicates that the reduction in worker exposure levels is substantial. A study to evaluate the effectiveness of dust controls was conducted under controlled conditions so that investigators could confirm that the control in use was fully and properly implemented. Meeker et al. (2009) ran trials to evaluate exposures during intensive masonry cutting done without controls compared to exposures while using saws with integrated water delivery systems and maximum flow rates of 2.3 and 2.4 liters per minute (0.6 and 0.63 gallons per minute).[209] The investigators reported that the stationary wet saws were associated with a 91-percent reduction in exposures (Document ID 2177, Reference 11, pp. 104, 107-108). They also separated results associated with stationary wet sawing into data obtained while a worker cut block (mean exposure of 260 μg/m^3 for the duration sampled) and data obtained while a worker cut brick (mean exposure of 90 μg/m^3 for the duration sampled). If these workers cut block or brick at this same intensity for the amount of time that a typical worker uses a stationary masonry saw (i.e., 15 percent of an 8-hour shift, or 72 minutes per day, as explained earlier), OSHA estimates that these workers would experience 8-hour TWA mean exposure levels of 13 to 38 μg/m^3.[210] Furthermore, applying a 91-percent reduction factor to the 13 dry cutting (outdoor) samples in the exposure profile (Table IV.5.7-B) would result in 9 sample results below 25 μg/m^3, 1 sample result between 25 and 50 μg/m^3, 2 sample results between 50 and 100 μg/m^3, and only one sample result between 100 and 250 μg/m^3.[211]

Differences in effectiveness have been observed among various wet cutting methods. Beamer et al. (2005) conducted experiments using a stationary saw to cut bricks in order to compare respirable dust suppression through free-flowing water (typical of stationary saws fitted with a water basin and pump) and water misting (Document ID 1555, p. 509). The highest dust suppression occurred with freely flowing water applied at a rate of 48 gallons per hour (0.8 gallons per minute), resulting in dust reduction of about 93 percent and confirming the benefits of water flowing over the stationary saw cutting blade. This is the most common configuration used for these saws. While not as effective in suppressing dust when compared to freely flowing water, the authors saw an important

[209] Because the samples were obtained under experimental conditions, with repeating trials, and did not capture the workers' total exposures for the day, these results are not included in OSHA's exposure profile.

[210] The 8-hour TWA is determined using OSHA's instructions for calculating an 8-hour TWA published in 29 CFR 1910.1000(d)(1)(ii). For example, the 8-hour TWA resulting from a 69-minute exposure at a concentration of 260 μg/m^3 would be (260 μg/m^3 x 69 minutes)/480 minutes = 37.4 μg/m^3.

[211] The impact of a 91-percent exposure reduction on an exposure level of 250 μg/m^3 is calculated (1-0.91) x 250 μg/m^3 = 22.5 μg/m^3.

benefit to misting, noting that as an aerosol, mist tends to dry much more quickly than freely flowing water (Document ID 1555, p. 509).[212] Among construction teams, rapid drying is considered a benefit because sawyers using brick or block often prefer to work with dry surfaces; however, OSHA notes that rapid drying can contribute to increased exposure from re-suspension of previously wetted dust. Rigorous housekeeping with a high-efficiency-particulate-filtered vacuum can limit exposures from re-suspended dust.

The value of wet cutting methods was also demonstrated in a laboratory study designed to compare, under otherwise identical conditions, the amount of respirable dust released during each of three different cutting conditions: wet masonry cutting, cutting with LEV, and cutting without controls (Document ID 3612, pp. 246-247, 249). This study used the same wet/dry 14-inch electric masonry table saw to test all three conditions. Dust samples were collected only during the 30-second cuts. Compared with no controls, operation of the saw at the manufacturer-recommended water flow rate (0.13 liters per second, equal to 2 gallons per minute) reduced respirable dust concentrations in the chamber from 49,700 $\mu g/m^3$ to 570 $\mu g/m^3$ when cutting flat roofing tiles, and from 39,200 $\mu g/m^3$ to 360 $\mu g/m^3$ when cutting curved tiles.[213] This represents a 99-percent reduction in respirable dust exposure. Additional trials were conducted at lower flow rates, down to less than one-quarter of the manufacturer-recommended water flow rate, which reduced respirable dust by 98 percent compared to dry cutting with no controls. The saw was also set up to test LEV dust controls (in separate, but similar trials), as described later in this section. Carlo et al. (2010) demonstrates how water application can effectively reduce respirable dust released during masonry cutting when the saw is equipped with a manufacturer's

[212] In the study by Beamer et al. (2005), water misting was tested at three water application rates: 4.8, 8.6, or 17.3 gallons per hour (equivalent to 0.08, 0.14, or 0.29 gallons per minute) (Document ID 1555, p. 503).

[213] Through all trials (involving eight repetitions at each water flow rate), the saw cut concrete roof tile (two shapes, all from the same two batches) at the steady rate of 0.013 meters per second (0.51 inch per second) in a chamber with a constant air flow through the chamber. The relative amount of respirable dust generated during actual cutting was measured in the air flowing out of the chamber through a single exhaust duct. In addition to trials at 0.13 L/sec (2 gal/min), the investigators also tested lower flow rates of 0.06 (0.95 gal/min), 0.03 (0.5 gal/min) or 0.02 L/sec (0.3 gal/min) (Document ID 3612, pp. 246-247).

standard water application equipment, even at flow rates much lower than the recommended flow rate (Document ID 3612, p. 245).

These findings are supported by a NIOSH study that found that wet masonry saw operators' silica exposures were routinely below 100 μg/m^3, and usually below 50 μg/m^3, even though some of the sampled workers also used a portable, dry cut, chop saw during the sampling period (Document ID 0223, pp. 5-7).

Even when wet methods are used, silica exposures can exceed 50 μg/m^3 if the wet methods are not fully or properly implemented or if other sources of exposure are present. Table IV.5.7-B shows that 2 of the 8 silica sample results from workers using stationary saws with wet methods exceeded 50 μg/m^3. However, both samples suffered from possible exposure bias. In the NIOSH study sample, researchers observed that the wet-cut saw dispersed a significant cloud about 20 feet in the air during cutting. The operator was also working in an area where a dry cut chop saw was being used (Document ID 0231, pp. 4, 6). The other sample was from the Shields dataset, which provides only limited information on the control method (wet saw) and was collected where tuck point grinding was also being performed (Document ID 1143, Rows 7, 8).

Some commenters expressed concern about saw operating parameters for wet dust control. Mr. Wherry, Unified Abrasives Manufacturers Association (UAMA), and Mr. Service of Saint Gobain Abrasives, representing the Masonry & Concrete Saw Manufacturers Institute (SMI), both stated that existing research has not determined the "specific requirement for applied water volume, velocity, and location" (Document ID 2243, p. 1; 2316, pp. 1-2). OSHA believes that there is no single optimum operating parameter for wet methods. Saw designs vary between manufacturers, and, as with other operating parameters, recommendations for optimizing wet methods are likely to vary somewhat with the size and design of the saw.

The rulemaking record contains several studies reporting water flow rates that effectively suppressed dust for stationary masonry saws. Three examples include the studies by Carlo et al. (2009), Meeker et al. (2009), and Beamer et al. (2005). As discussed previously, Carlo et al. (2009) reported that for a 14-inch (35.6 centimeter) stand-mounted masonry saw, dramatic dust suppression was accomplished using the 0.13 liters per second (2 gallons per minute) water flow recommended by the saw manufacturer. Although other saws were not tested in this study, other flow rates were, and flow rates below one-quarter of the recommended level (i.e., 0.03 liters per second, equivalent to 0.5 gallons per minute) were similarly effective for suppressing dust under the experimental conditions (Document ID 3612, pp. 245, 247). In Meeker et al. (2009), two other brands of 14-inch stationary masonry saws were tested using the manufacturers' maximum water flow settings of 2.3 and 2.4 liters per minute (0.6 and 0.63 gallons per minute); these settings suppressed 91 percent of the dust released by these saws. These investigators also tested a lower flow rate (0.73 liters per minute, equal to 0.12 gallons per minute) for one of these saws and found dust control somewhat diminished compared to the higher flow rate (Document ID 2177, pp. 107-108). A free-flowing water application rate of 0.8 gallons per minute (48 gallons per hour) was also reported by Beamer et al. (2005) to be an effective dust suppressant for a stationary saw, providing 93 percent reduction in respirable dust (Document ID 1555, p. 503). OSHA observes that all three of these studies found that flow rates of 0.5 to 0.8 gallons per minute provided notable dust reduction (greater than 90 percent), but the water application was more effective in some cases than in others. Under the final rule, OSHA has not specified a minimum flow rate, but rather anticipates that the water flow rates specified by the saw manufacturers will optimize dust reduction.

Commenters raised a number of issues related to the use of wet methods. Several commenters were concerned about how to deal with the potential for slurry in re-circulating water used to wet saw blades. OSHA's proposed entry on Table 1 provided that employers "prevent wet slurry from accumulating and drying" when using stationary saws (78 FR 56496). UAMA and CISC expressed concern over the lack of comprehensive research into the water change frequency (in the saw's water basin) necessary to prevent slurry accumulation, the definition of "accumulation", and whether minimizing slurry has a beneficial impact on worker exposure (Document ID 2243, p. 1; 2319, p. 6; 3580, Tr. 1360). While optimal water change frequency has not been researched, OSHA believes that the evidence in the record shows that preventing slurry containing silica from drying (and potentially becoming airborne) reduces employee exposure. As a practical matter, dried slurry is nothing more than dry masonry dust, which can be suspended in air if disturbed; therefore, slurry should be kept to the minimum amount that is practically achievable. Additionally, given that most masonry saws are already equipped with wet methods, OSHA believes that most employers know what "accumulation" is and have experience in preventing slurry accumulation. OSHA anticipates that the appropriate water change frequency will vary depending on the circumstances of the job, as the rate of slurry buildup depends on the amount the saw is used (specifically, the amount of material cut). As a practical matter, the control and cleanup of wet slurry is necessary when cutting concrete indoors (regardless of whether it contributes to silica exposure). Additionally, the Concrete Sawing and Drilling Association has published a Best Practice Guide for Management of Slurry, which may be useful for some employers (Document ID 3998, Attachment 12d). The Best Practice Guide provides practical advice on how to prevent the accumulation of slurry when using wet saws to cut concrete. OSHA notes that it has removed the requirement to prevent wet slurry from accumulating and drying from final Table 1, although the Agency anticipates that most employers will incorporate these preventive measures into their exposure control plans.

Several commenters were concerned about slurry disposal, including UAMA and the National Association of Home Builders (NAHB) (Document ID 2243, p. 1; 2296, p. 28). NAHB asked whether employers are supposed to dispose of the slurry in a wet or dry form (Document ID 2296, p. 28). OSHA believes that collecting and allowing slurry to dry is acceptable if the slurry is held during the drying process in a way that will prevent the resulting dust from being released into workers’ breathing zones once the slurry is dry. One example of an unacceptable practice would be to allow thick slurry to be spread as droplets from the saw (or to be intentionally poured) on the ground to dry, since the dry dust that will result might later be disturbed by passing foot traffic, releasing dust into the air.

Other commenters raised questions about the environmental implications of using wet methods. SMI, for example, commented that the rule does not recognize the existence of regulations regarding water/silt runoff imposed by other government agencies (Document

ID 2316, p. 2). OSHA has addressed the environmental implications of the standard in Chapter X – Environmental Impacts.

A number of commenters (e.g., CISC, NAHB, and Edison Electric Institute (EEI)) questioned the feasibility of using wet methods in freezing weather (Document ID 2319, pp. 53-54; 2296, p. 30; 4220, pp. 5-6; 2357, pp. 7, 24, 28). Although wet methods may not always be available in freezing temperatures, evidence in the record shows that in many situations, employers are able to use wet methods despite freezing temperatures. For example, Mr. Hoffner of the New Jersey Laborers' Health and Safety Fund described how construction contractors cope with freezing weather in his state, where there are restrictions on the dry-cutting of brick, block, and other silica-containing building materials: "Many contractors have dealt with the usual concerns about what to do in the winter by wrapping gutter heat tape around 55 gallon drums to make sure the water stays liquid in freezing temperatures" (Document ID 3589, Tr. 4214). OSHA believes that this is a feasible option for most employers. In response to a question about a scenario where electrical power is not available, Mr. Hoffner described how one contractor on a road construction project used an environmentally friendly antifreeze additive to prevent the water from freezing (Document ID 3589, Tr. 4230).

Additionally, some commenters explained that wet methods cannot always be used due to customer specifications or because of other hazards. The National Roofing Contractors Association noted that water can stain or discolor some building materials (Document ID 2319, p. 94; 2320; 3587, Tr. 3609-3610). Ms. Trahan, representing the BCTD/AFL-CIO, indicated that it is common for an employer to choose which set of tools offer the best opportunity to control a hazard while effectively completing the job to the customer's specifications. She said, "It is common for workers' assignments, and tools and control strategies they utilize, to vary. For example, an employer on one project could assign a worker to use a stationary masonry saw equipped with a water attachment to cut products containing silica, and on another project that same worker could be assigned to use a handheld masonry saw with a vacuum attachment to perform the same task" (Document ID 2371, p. 6). OSHA acknowledges that there are some situations where the use of water systems is contraindicated and that employers need to determine the silica control method that will offer the best protection for workers using masonry saws, while still being compatible with the work product and environment. OSHA concludes that in situations in which the use of wet methods is disfavored, employers will be able to use alternative tools with alternative controls, such as a saw fitted with LEV, as a feasible alternative for reducing silica exposure; the employer should be aware that LEV might not reduce exposures to the same extent as wet methods that are well implemented.

Construction managers representing NAHB and EEI commented that construction sites do not always have a water source (Document ID 2296; 4220; 2334; 2357; 3587, Tr. 3525). NAHB stated that it often takes two to three months after construction begins for a water meter to be hooked up on a residential construction site, and noted that it is the local municipality that controls when water service is provided (Document ID 3587, Tr. 3525).

OSHA recognizes that a residential contractor may not be able to control when a water meter is hooked up on a construction site, but does not view this as a major impediment to the use of wet methods on construction sites. Water tanks are already commonly available on many construction sites and could provide water for a stationary masonry saw. Additionally, stationary saws need not be connected to a continuous water supply because the saws are commercially available with a water basin and water recycling pump. Recirculating water-fed saws require just a few gallons of water per shift (Document ID 1431, p. 1-8); OSHA does not believe employers would need to bring large tanks of water to a jobsite, as asserted by one commenter (Document ID 2319, p. 94).

CISC also questioned whether the water delivery system on the stationary saw needed to be integrated. OSHA's proposed entry on Table 1 for masonry cutters using stationary saws required the use of an integrated water delivery system, and OSHA has retained this requirement in the final rule. CISC asked why a separate wet method (e.g., a hand operated hose or spray, not integrated into the tool) would not be acceptable (Document ID 2319, p. 104). The Power Tool Institute commented that the use of a water delivery system that is not specified by the tool manufacturer could result in a shock hazard with electrically operated tools (Document ID 1973, p. 2). And OSHA has determined that a separate wet method is unnecessary, because, as noted earlier in this section, and as observed by commenters from MCAA and BAC, nearly all models of stationary saws already are available from the manufacturers with integrated water delivery systems (Document ID 3585, Tr. 3041-3042; 2885; 2286, p. 2).

The comments in the record do not dispute that wet methods on stationary masonry saws can substantially reduce silica dust emissions; rather, the comments focus on describing difficulties that could be potentially encountered during implementation of wet methods at construction sites. OSHA believes that these concerns can be addressed through careful job planning to fully implement wet dust suppression methods, choosing appropriate equipment, and ensuring that the tool is used properly. Mr. Ward, a bricklayer from Detroit, Michigan, representing the International Union of Bricklayers and Allied Craftworkers, strongly supported this conclusion. In his experience, dry-cutting is not necessary, and, with advance planning, a construction firm can replace dry saws with water-fed stationary saws as a practical and economical option. He described working as a supervisor for his most recent construction contractor employer; he explained that they cut with wet saws equipped with a garden hose connection that prevents slurry and flow rate issues (Document ID 3585, Tr. 3018-3019).

The available evidence shows that wet cutting is a highly effective dust control option for stationary masonry saws. Table IV.5.7-B shows a median respirable silica dust value of 34 μg/m^3 when wet methods are used when cutting with stationary saws. Based on this evidence, OSHA concludes that the use of fully and properly implemented wet methods can reduce silica exposures to levels of 50 μg/m^3 or below for most workers using these saws to cut masonry, most of the time.

Local Exhaust Ventilation

Stationary saws equipped with local exhaust ventilation (LEV) are engineered to capture dust generated by the cut at the source (cutting blade), preventing dust from becoming airborne. ERG-C (2008) reviewed literature suggesting that additional controls for workers in some settings could include the use of LEV-equipped stationary masonry saws or stationary saws set into ventilated enclosures (e.g., a ventilation booth that permits the operator to stand outside the enclosure). There is evidence that workers who cut blocks using saws located in site-built ventilation booths throughout their shifts can experience silica exposures at levels below 100 μg/m^3 (Document ID 0165, pp. 47, 132). For example, OSHA observed 80-percent lower exposures to respirable quartz when workers used a site-built ventilated booth outdoors (mean exposure of 66 μg/m^3) compared with cutting outdoors with no booth (mean exposure of 329 μg/m^3 included on Table IV.5.7-B) (Document ID 0165, pp. 47-58; 0181, pp. 20, 26).

CISC questioned the effectiveness of ventilated enclosures, noting that the study OSHA relied upon showed a median exposure of 78 μg/m^3 when ventilated booths are used (Document ID 2319, p. 54). However, OSHA compliance inspection data from a construction site (such as that for the site-built ventilated booth described above) is a prime example of the type of exposure information that captures the worker’s silica exposures from all sources.

CISC also questioned OSHA’s reliance on laboratory data in evaluating the effectiveness of ventilated booths for stationary saws, noting that laboratory studies do not capture exposures from secondary or adjacent sources (Document ID 2319, p. 30). Certain types of experimental data are not intended to replicate workplace conditions, but OSHA believes these data are still relevant in evaluating the effectiveness of controls. Studies may be intentionally designed to eliminate extraneous factors that would interfere with a correct interpretation of a control method’s capacity to reduce silica emissions and associated exposure levels. Far from being a drawback, these experimental studies, under controlled conditions, typically are designed by the investigators to answer specific questions (hypotheses). The resulting data may be obtained under isolated conditions that ensure no additional sources of exposure are present. This exposure information can objectively show how well a control method works in an environment where other sources of silica are also controlled (e.g., as might occur on a well-controlled work site, or a site where only one source of silica exposure is active at a time). Sample results from the controlled condition are also routinely compared by investigators to the sample results for the uncontrolled condition. The resulting ratio shows the exposure reduction efficiency for the control method, independent of work rate variability, variations in construction materials, or other factors that do not relate to the individual control's functional performance. When available, this type of information is valuable for comparing the benefits of one control method to another. OSHA acknowledges that there are limitations to experimental data, but believes such data can also provide useful information. The following discussions of LEV controls fitted to stationary saws draw on data from a demonstration project and experimental conditions.

Although OSHA believes that controlling silica exposure during the use of stationary saws is best achieved by cutting brick and block with water suppression, NIOSH has noted that some construction methods specify dry cutting to avoid discoloration (staining) or because dry brick is desirable for subsequent processes (Document ID 0861, p. iv). OSHA received evidence during the rulemaking suggesting that the LEV technology for stationary masonry saws is advancing. For example, iQ Power Tools provided information on masonry saws fitted with LEV systems, including a saw table that adds an LEV option to a conventional stationary masonry saw mounted to the table. Mr. Joel Guth, president of iQ Power Tools, stated that these systems incorporate "dust collection and filter system on it to collect up to 90 percent of the dust" (Document ID 3585, Tr. 2972-2974).

Mr. Guth also submitted a personal exposure monitoring report for a worker using a stationary masonry saw fitted to the LEV table system just described. The report shows that during the 4-hour (241-minute) sampling period, a worker used the saw outdoors to dry-cut 100 units of concrete block (an average rate of approximately two blocks every five minutes), sawing through both parallel faces of each hollow 8 by 8 by 16-inch block. These blocks were of the size and shape typically used in constructing walls (Document ID 3501, p. 2). Although the sampling was conducted as a demonstration project at the saw manufacturer's site (not an active construction site), the work activity, work materials, cutting tool, and cutting frequency was consistent with heavy sawing by one masonry cutter on a construction site.[214] Air monitoring results show that the silica exposure level for this worker was 75 µg/m^3 during the period monitored, the equivalent of 38 µg/m^3 as an 8-hour time weighted average, assuming that the worker experienced no additional exposure during the unsampled portion of the shift (i.e., the worker did not cut additional blocks or have other sources of silica exposure outside the 4-hour sampling period). The air sample contained 16 percent silica in the respirable dust. In a corresponding area sample obtained during the same period of cutting, but 20 feet "down wind" from the saw, no silica was detected (in this case the limit of detection was 10 µg/m^3) (Document ID 3501, p. 3).[215] This result indicates that with active dust control in place, workers 20 feet down wind would have experienced no detectable silica exposures, even if they had worked in that position over the entire cutting period (4 hours).

The record also contains several studies that evaluated stationary saws fitted with vacuum suction. In one study, NIOSH used a test chamber to evaluate dry-cutting methods, with and without the use of LEV, using a commercially available 10-inch masonry saw factory-equipped with two exhaust take-offs (one below the blade and one surrounding the blade guard, with a different air mover attached to each exhaust take-off).[216] With the saw LEV turned off, the respirable dust concentration in air drawn from the test chamber was 13,000 µg/m^3 (13 mg/m^3). However, when the saw's LEV was activated, the measured respirable dust concentration was notably lower, at 50 µg/m^3 (0.05 mg/m^3) (Document ID 0861, p. iv). Although these concentrations do not relate directly to worker silica exposure levels, they do indicate that the LEV system captured respirable dust effectively during the tests. NIOSH concluded that exhaust ventilation can be used to reduce respirable dust emissions by at least 99 percent when LEV air flow rates are

[214] The sampling report lists the "typical" frequency for a tool operator performing masonry cutting as 25 to 400 cuts per 8-hour day. The worker who was the subject of this air monitoring report cut 100 blocks over 4 hours. There is no indication that the worker cut additional blocks during the unsampled portion of the day (Air Sampling Report - Document ID 3501, p. 2).

[215] The personal sample result was reported as "0.075 mg/m^3" silica as quartz (equal to 75 µg/m^3) and the area sample limit of detection was reported as " <0.0096 mg/m^3" silica (rounded to <10 µg/m^3) (Document ID 3501, pp. 2-3). Document ID 3501 also contains additional air monitoring results, but those relate to other types of masonry saws (not stationary saws).

[216] As standard features, this EDCO GMS-10 masonry saw is designed for use with both LEV and wet dust control methods (Document ID 0641).

sufficient (the total airflow was 206 cfm in this case).[217] However, NIOSH also recommended several improvements to prevent captured dust from settling where it could block air flow (Document ID 0861, p. iv).[218]

Carlo et al. (2010) also used a ventilated test chamber when they evaluated a wet/dry 14-inch electric table-mounted masonry saw used to cut concrete roofing tiles (50 to 60 percent sand and aggregate of varying silica content) at a constant cutting rate. This was the same saw and test chamber arrangement described earlier in the discussion of Carlo et al.'s (2010) evaluation of wet dust control methods. For this test of LEV, the water supply was disconnected and the saw manufacturer's LEV dust control system was installed on the saw. The LEV consisted of a dust hood and curtain assemblies, installed directly behind the saw and connected to an air filtration system. Dust emissions were recorded with the saw LEV system operating at 0.24 cubic meters per second (m^3/second) (509 cubic feet per minute [CFM], which is the rate recommended by the manufacturer), at a lower airflow rate of 0.13 m^3/second (approximately half of the manufacturer's recommended air flow), and with the saw LEV system turned off (no controls). Compared to uncontrolled cutting, the LEV system used at the manufacturer's recommended exhaust air flow rate (0.24 m^3/s) reduced the mean respirable dust levels in the test chamber from 49,700 µg/m^3 to 4,320 µg/m^3 for flat roofing tile, and from 39,200 µg/m^3 to 5,420 µg/m^3 for s-shaped tile, for an overall reduction in dust levels of 91 and 86 percent, respectively. When the LEV air flow was reduced to almost half the manufacturer's recommended rate (0.13 m^3/s), the respirable dust mean concentration was reduced by 87 percent for the flat tile and 79 percent for the s-shape tile (when compared to uncontrolled cutting) (Document ID 3612, pp. 247-250). These results demonstrate substantial respirable dust capture by the LEV system, although in comparison, the water application system reduced the dust to a greater extent (reducing respirable dust levels by a factor of 10 more than the LEV systems tested).

[217] In this case, the vacuums were equipped with "high efficiency filters (99.9 percent at 0.3 µm)" (Document ID 0861, p. iv).

[218] Improvements involved increasing the exhaust air channel air transport velocity to 4,500 feet per minute and enlarging the channel to reduce the pressure loss (Document ID 0861, p. iv).

OSHA also reviewed a brick-cutting experiment conducted by Croteau (2000), in which LEV used during concrete paver block cutting reduced respirable quartz in workers' breathing zones by 69 to 83 percent (depending on the air flow rate), and reduced the concentration 85 to 95 percent (Document ID 0613, p. 4). In a follow-up report, Croteau et al. (2002) elaborated on this study, testing LEV dust control methods for a stand-mounted stationary saw in an experimental indoor area (an enclosed ventilated tent with constant air flow velocity through the area equivalent to 40-60 feet per minute, comparable to a barely-detectable breeze) (Document ID 0611, pp. 459, 463).[219] Breathing zone air samples of 15 minutes duration were collected while apprentice brick and cement masons cut block and brick at a work rate of approximately three 12-inch square pavers or four to five 7-inch bricks every two minutes – a rapid sequential cutting rate.[220] In a series of trials cutting concrete block, the saw-based LEV reduced personal breathing zone silica sample results by up to 96 percent at the high ventilation rate, from a geometric mean silica exposure level of 22,520 μg/m^3 under uncontrolled conditions to a mean silica exposure level of 950 μg/m^3 with LEV (Document ID 0611, p. 463). Although silica levels remained extremely high in this simulated indoor environment during the period of intense cutting, OSHA notes that for a worker cutting block at this rate for half the shift, the use of LEV would bring the airborne silica concentration down to a level for which a respirator with an APF of 10 would provide adequate protection.[221]

[219] The tent enclosure was fitted with a fan providing a constant airflow through the area averaging 50 feet/minute air velocity. The gasoline-powered masonry saw's LEV system consisted of a tube running the length of the saw immediately below the blade. Dust was captured through a slot in the tube near the point of contact between the blade and the material being cut. The LEV performed as a push/pull system, with air currents generated by the blade pushing dust into the slot and the exhaust system pulling the dust away (Document ID 0611, p. 460).

[220] The investigators tracked the apprentices' work rate and determined it averaged 79 to 86 linear feet per hour for block and brick respectively (Document ID 0611, p. 462).

[221] If an intense cutting task with an airborne exposure concentration of 950 μg/m^3 were performed for half a shift (4 hours), the worker would experience an 8-hour TWA exposure of half the concentration measured during the task, for a total daily exposure of 475 μg/m^3 (assuming no additional exposure during the other 4 hours of the shift). Under the proposed PEL, the maximum use level for a respirator with an APF of 10 would be 500 μg/m^3. A half mask respirator would provide sufficient protection.

Work Practice Controls

OSHA's review of the literature also finds that worker exposures to airborne silica can be reduced by employing specific work practice controls. For example, integrated dust controls on saws work best when the equipment is maintained in good working condition (according to manufacturers' specifications), construction managers ensure workers know how to use the equipment to its best advantage (e.g., how to adjust water flow to minimize dust, when to empty vacuums and clean filters), and the equipment chosen is appropriate for the need (e.g., appropriately sized vacuums that will consistently provide sufficient suction) (Document ID 0933, pp. 7-12). Additionally, ERG-C (2008) noted that saws with either water filtration or LEV systems require regular maintenance and servicing to limit the clogging of hoses and filters (Document ID 0231, p. 5). Yereb (2003) noted that worn saw blades should be replaced to minimize the amount of fine particles produced (Document ID 1238, p. 150). Finally, when wet methods are used, housekeeping is needed to remove and dispose of dust-laden water before it dries to prevent possible re-entrainment of dust into the air. OSHA expects that these work practice controls will be used to supplement whichever engineering controls the employer selects to suppress dust.

Comments were received regarding replacing worn blades as an exposure management practice. CISC commented that OSHA's proposed requirement in Table 1 for masonry cutters using stationary saws to "ensure [that the] saw blade is not excessively worn" (78 FR 56496) was vague (Document ID 2319, p. 104; 3580, Tr. 1359). OSHA expects that any employer conscious of jobsite efficiency is already adept at recognizing worn blades, which cut more slowly and slow the work process. The Building and Construction Trades Division (BCTD) of the American Federation of Labor-Congress of Industrial Organizations (AFL-CIO) recommended that OSHA require replacing worn blades as a silica exposure management practice in the text of Table 1 (Document ID 4223, Appendix 1, p. 1). Ms. Vasquez, of Holes, Incorporated (a concrete coring contractor) indicated that it is her company's standard procedure (independent of silica exposure reduction) for the diamond blades used for concrete coring to be checked, and often replaced, during the day, as the particularly hard concrete used in Houston, Texas, causes blades to deteriorate quickly. Although related to a different piece of equipment, Ms. Vasquez's testimony indicates that employers are capable of recognizing when a blade is worn and already make this determination in order to cut more effectively and efficiently (Document ID 3580, Tr. 1440-1441). OSHA expects that employers will be able to determine when a blade becomes worn to the point of being less effective, and finds that changing the blade when it gets to that point is an effective work practice control that will reduce masonry cutters' exposures to silica during the use of stationary saws.

As mentioned previously in this section under the heading for Wet Methods, it is necessary to control and cleanup wet slurry when workers are using wet methods to cut silica-containing materials, particularly when the work is done indoors, as the slurry may be a source of silica exposure after drying. The Concrete Sawing and Drilling Association has published a Best Practice Guide for Management of Slurry, which may be useful for some employers (Document ID 3998, Attachment 12d).

5.7.4 Feasibility Finding

Paragraph (c) of the construction standard gives employers the option of following Table 1, which includes specified engineering and work practice controls for operating stationary masonry saws; alternatively, the employer must assess and limit exposures in accordance with the more traditional regulatory approach contained in paragraph (d). Table 1 requires employers to ensure the saw is operated using an integrated water delivery system that continuously feeds water to the blade. It also requires employers to ensure the tool is operated and maintained in accordance with the manufacturer's instructions to minimize dust emissions.

Based on the exposure profile in Table IV.5.7-B and other record evidence discussed previously, OSHA finds that the standard is technologically feasible for masonry cutters using stationary saws when baseline and additional controls previously discussed are used.

Stationary masonry saws equipped with integrated water delivery systems are the best available technology for controlling respirable crystalline silica. The effectiveness of wet cutting methods in controlling exposures is demonstrated in the exposure profile (Table

IV.5.7-B) by a median 8-hour TWA reading of 34 µg/m^3 for workers using wet methods to cut masonry with stationary saws. Thus, based on the information in the record, when wet sawing methods are fully and properly implemented, OSHA expects most respirable quartz exposures to be reduced to 50 µg/m^3 or below.

Stationary masonry saws with integrated water systems are readily available from several manufacturers including EDCO, Andreas Stihl, Hilte, Makita USA, Husqvarna, Wacker Group, MK Diamond, and Borsch (for tile cutting) (Document ID 4073, Attachment 4a; 4073, Attachment 4b; 3998, Attachment 12a; 3998, Attachment 12e; 3998, Attachment 12f; 3998, Attachment 12g; 3998, Attachment 12h). For those workers who are already using wet methods, but are not consistently using the controls effectively, further training is needed to fully and properly implement these methods in order to achieve optimal dust control (e.g., what level of water flow to use, how water flow should be directed on the blade, when to change dust-laden water in the basin, and how to recognize signs that exposure controls need to be checked). The final rule's Table 1 entry for using stationary masonry saws equipped with integrated water systems includes additional specifications that ensure that these dust control systems are fully and properly implemented (operating and maintaining the system in accordance with the manufacturer's instructions to minimize dust emissions).

OSHA is not requiring the use of respiratory protection when employers are using wet stationary saws in accordance with the Table 1. For stationary masonry saws used indoors or in otherwise enclosed areas, Flanagan 2009 reported a mean respirable crystalline silica exposure of 63 µg/m^3 and a median exposure of 48 µg/m^3 (range 18-139 µg/m^3) from four samples where water use was not described in any detail. There is no other evidence in the record that would suggest that using good water-based systems on saws, even when used indoors, will consistently result in exposures sufficiently high to warrant the use of respirators for all such situations.

Although most masonry cutters can use wet methods with good results, wet methods might not always be feasible (Document ID 1431, pp. 1-6 – 1-9). In the limited cases where wet methods, as prescribed in Table 1, cannot be applied, the use of LEV can substantially reduce silica exposure levels. Saws equipped with LEV systems are commercially available from iQ and EDCO (Document ID 4073, Attachment 4a). While the effectiveness of LEV systems for stationary masonry saws has not been widely evaluated, there is some evidence that LEV can reduce exposures to 50 μg/m^3 or below when used for typical cutting periods of 15 to 30 percent of a work shift (i.e., 72 to 144 minutes) (Document ID 3612).

OSHA concludes that half of masonry cutters using stationary saws are currently exposed to silica levels at or below 50 μg/m^3. For workers who are currently exposed above 50 μg/m^3, the controls described in this section can be implemented to reduce silica exposures to or below 50 μg/m^3 in most operations, most of the time. Therefore, OSHA finds that the standard is technologically feasible for masonry cutters using stationary saws. If an employer decides to comply with paragraph (d) and meet the PEL using methods other than the wet method prescribed by Table 1, OSHA finds that the use of LEV systems is technologically feasible, with the caveat that supplemental respiratory protection may be necessary in some cases to achieve personal exposures at or below the PEL.

5.8 MILLERS USING PORTABLE OR MOBILE MACHINES

5.8.1 Description

Millers are workers who use milling equipment to grate or grind solid surfaces, such as concrete floors, masonry walls, sidewalks, and asphalt roads. OSHA has divided this job category into two major subcategories:

- Workers who drive, tend, or help with drivable milling machines, including -
  - Workers who drive or operate large drivable (road) milling machines, half-lane or larger, from seats on top of the equipment;
  - Workers ("tenders") who tend the large milling machines while walking beside the equipment; and
  - Workers who operate small (less than half-lane) drivable milling machines from a position on the equipment, or who help with this equipment while walking nearby.
- Workers who operate or help with walk-behind milling machines.

Milling machinery often uses a rapidly rotating drum or a bit covered with nibs to abrade surfaces, although other mechanisms (including systems based on impact, shot-blast, or rotating abrasive cups) are common. An operator can drive larger models (half-lane-size and larger) from above; these models include road milling equipment used in recycling/resurfacing operations. An operator controls small, purpose-built road milling machines or small utility tractors, like a skid steer fitted with a milling tool, from a seat or platform on the machine. Still smaller milling equipment, such as walk-behind machines used for small pavement areas and floor work, is guided by hand. Laborers or construction workers operate the smaller machines during specialty tasks such as resurfacing floors, repairing pavement, or creating grooves for electrical cables (Document ID 0036, p. 15; 3958; 3959, p. 39).

Tenders and helpers can work at close range, assisting the operators of drivable and walk-behind machines. Mr. Zimmer of the International Union of Operating Engineers (IUOE), Local 478 in Connecticut, explained that crews supporting drivable milling machines generally include several laborers in addition to the operator, with the number of laborers depending on the size of the milling machine (one or two laborers for a small drivable milling machine, up to three or four for a large machine) (Document ID 3583, Tr. 2441). Walk-behind milling machine operators can also have helpers working in close association with the task. For example, helpers may vacuum debris behind the grinder (Document ID 3958).

In the Preliminary Economic Analysis (PEA), OSHA divided milling machine operators and tenders into three categories: 1) workers who operate large drivable milling machines; 2) workers who tend the large milling machines; and 3) workers who operate walk behind milling machines (Document ID 1720, p. IV-454).

The job categories associated with drivable milling machines have been slightly reorganized in the Final Economic Analysis (FEA) in response to commenters' recommendations. Commenters urged OSHA to divide the group of drivable milling machine operators into subgroups of operators of large milling machines and operators of small milling machines. Mr. Fore and Mr. Richmond, representing the National Asphalt Pavement Association (NAPA), asked OSHA to consider operators of larger road milling machines (with cutting drums of half-lane width and wider) separately from operators of smaller drivable milling machines (with cutting drums that are less than a half-lane wide) (Document ID 3583, Tr. 2171, Tr. 2212-2213).[222] Mr. Bodway of Payne & Dolan, an asphalt paving contractor, who also represented NAPA, made the same point in his written comments (Document ID 2181, pp. 4, 7, 9). Both Mr. Zimmer, representing the IUOE, and a road milling machine manufacturer categorized drivable milling machines as either small or large (half-lane or larger, with cutting drum about 79 inches or wider) (Document ID 3583, Tr. 2441; 1229). After considering the evidence, OSHA agrees with NAPA and has created an additional subgroup for workers (operators and helpers) using small drivable milling machines (with cutting tools that are less than a half-lane wide). This subgroup is added to the umbrella group for all workers using drivable milling machines. The preexisting category for workers who operate walk-behind milling

[222] "Half-lane" and larger road milling machines typically have cutting blades that are at least 79 inches (approximately six and one-half feet) wide. For example, NIOSH evaluated a milling machine with an 86-inch wide cutter drum and described it as a half-lane machine, and most large milling machines in one road milling machine manufacturer's online catalog are 79 inches wide or wider (Document ID 1229, pp. 3-5; 4149, p. 2).

machines is unchanged, except that OSHA has clarified that helpers closely associated with the machine are also included in this group.

Some smaller milling equipment is operated dry, creating dust. Almost all road milling machines, however, are designed with a water tank and water feed at the milling drum to cool the cutting blades (Document ID 3583, Tr. 2200; 3959, p. 39).

Regardless of the size of the equipment, operators may be assisted by helpers. Operators and helpers are often responsible for sweeping and disposing of debris after milling is complete, potentially exposing them to dust. For example, a NIOSH report described a worker who walked beside a large road mill to operate the lower (rear) controls on this machine (Document ID 0866, p. 8). On road milling sites, a vehicular street sweeper is often present and can create additional dust. The OIS dataset describes an indoor worksite where a helper with a vacuum assisted a walk-behind saw operator (Document ID 3958).

As with other construction tasks, the duration of milling activities might vary substantially from shift to shift. For example, at a site evaluated by NIOSH, workers milled a road for more than 8 hours the first day but only 3.5 hours the next (and final) day of the project (NIOSH-Swank, 1995, Document ID 1386, pp. 5-6). Time spent on milling activities varies even more (from less than 1 hour to more than 8 hours a day) for smaller milling equipment (both small drivable and walk-behind machines).[223]

[223] Small milling machines (both drivable and walk-behind) are used for short tasks, such as milling around a manhole. This task was described by Mr. Fore, representing NAPA, as requiring only “a very short duration” (Document ID 3583, Tr. 2213). Small walk-behind milling machines capable of removing up to 800 linear feet of striping per hour can be used to remove road paint stripes. As an example of the amount of time it takes to complete a stripe removal task, OSHA estimates that a 4-way intersection would have four stripes indicating where drivers should stop, each 30 feet wide and requiring two passes to remove. The operator of a small milling machine would need to push the machine for 20 minutes to remove all four stripes (4 stripes x 30 feet x 2 passes)/800 feet/hour = 0.3 hours) (Document ID 0642). The small machines can also be used for jobs that will take longer, such as removing road striping from a mile of roadway. It may take one hour to shallow (1/8-inch deep) mill the floor of a single small 300 square-foot room, and the worker or team could pack up the equipment and drive to another location to do another similar project or two in the same day. Some jobs done with small milling machines may take an entire work shift, such as when a worker (or worker and helper) mills a series of large rooms at one location using, for example, an 8-inch scarifier-type walk-behind machine capable of working 350 square feet per hour (Document ID 0642).

5.8) Millers Using Portable or Mobile Machines

Uncontrolled road milling releases a notable amount of dust and can become a source of exposure for other trades or bystanders in the immediate area. In written comments, NIOSH noted this potential for exposures among bystanders and other trades, including flagmen, in the immediate areas where dusty operations occur. NIOSH also noted (citing the Health and Safety Executive [2011]) that airborne concentrations tend to be lower (rarely exceeding 10 µg/m^3) outdoors where dust can disburse, including at the boundaries of construction sites (Document ID 3951, p. 2; 4233, pp. 12-13).

Table IV.5.8-A summarizes the job categories, major activities, and primary sources of silica exposure for millers.

Table IV.5.8-A
Job Categories, Major Activities, and Sources of Exposure of Millers Using Portable or Mobile Machines

Job Category	Major Activities and Sources of Exposure
Workers Using Drivable Milling Machines	Operating large drivable road milling equipment (half-lane or larger) for grating or grinding solid surfaces (such as pavement); operator is often seated on the machine. • Dust from action of cutting blades and conveyor. Tending/assisting with the operation of large milling machines while walking beside the equipment. • Dust from action of cutting blades. • Dust from related activities, such as sweeping or shoveling debris. Operating or helping with small drivable milling machines (less than a half-lane wide) for grating or grinding solid surfaces (such as pavement). • Dust from action of cutting blades. • Dust from related activities, such as sweeping or shoveling debris,
Workers Using Walk-Behind Milling Machines	Grating or grinding solid surfaces (such as concrete floors, masonry walls, and sidewalks); operator often guides from behind; helper works in close association with the machine and operator. • Dust from action of cutting blades. • Dust from related activities, such as sweeping or shoveling debris,

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.

5.8.2 Exposure Profile and Baseline Conditions

Data and Studies Used

The following section describes baseline conditions for each affected job category based on reports from OSHA, NIOSH, and Eastern Research Group (ERG). OSHA used the best available exposure information to develop the exposure profile for workers using milling machines and helpers performing associated tasks. These include personal breathing zone (PBZ) silica sample results reported in an OSHA Special Emphasis Program (SEP) Inspection Report, a 1995 NIOSH health hazard evaluation, five NIOSH dust control technology studies in the EPHB 282 series, and an ERG site visit report.[224,225] OSHA added eight sample results from the OSHA Information System (OIS) 2011 to April 2014 dataset (Document ID 3958). Of these eight OIS samples, two are for small drivable milling machine operators and six are for walk-behind milling machine operators and their helpers ("laborers"). Table IV.5.8-C presents the exposure profile and summarizes exposure results for workers in each job category.[226]

OSHA received comments from NAPA suggesting that exposure results from one NIOSH road milling machine study were improperly included in the exposure profile. Mr. Bodway cited the experimental nature of the wet methods applied for drum cooling during the two days of road milling to suggest this was not a good example of optimal dust controls. He also noted the possibility that multiple layers of different road materials

[224] References for these reports are as follows: OSHA Special Emphasis Program (SEP) Inspection Report 300442977 (Document ID 0036, pp. 34-37, 99); NIOSH-Swank, 1995 (Document ID 1386, p. 3); NIOSH studies (NIOSH EPHB 282-11b, 2004, Document ID 0866 [duplicate 3798], p. 8; NIOSH EPHB 282-12a, 2007, 1362, p. 23; NIOSH EPHB 282-14a, 2009, 1251, p. 17, Table 1; NIOSH EPHB 282-15a, 2009, 0869, p. 16, Table 1; NIOSH EPHB 282-16a, 2009, 0870, p. 16, Table 1); ERG site visit report (Document ID 0200, pp. 11-12, Tables 1 and 2). For purposes of the exposure profile, OSHA calculated the 8-hour TWA from the gravimetric concentrations when NIOSH presented personal exposure results for discrete segments of the worker's shift. In these cases, OSHA used the equation presented in 29 CFR 1910.1000(d)(1)(i) to calculate the 8 hour TWA.

[225] There are gaps in the numbering system for the NIOSH reports. While the EPHB 282 series, starting with EPHB 282-11b, is largely devoted to road milling machines, a few numbers in the series were used for other topics.

[226] As noted in Section IV.2 – Methodology, all results included in the exposure profile are 8-hour time-weighted averages (8-hour TWAs) calculated assuming no additional exposure during any unsampled portion of the shift. Unless explicitly stated otherwise, all results discussed in the additional controls section are also 8-hour TWAs calculated the same way. Assumptions made in calculating 8-hour TWAs are discussed in Section IV.2 – Methodology.

had been milled (rather than just asphalt) and the percentage of silica in the road material (12 to 28 percent silica, which, according to NAPA, is higher than is usually found in asphalt samples) (Document ID 2181, p. 15; 3798, pp. 1-2, 4-7, 10). Upon reviewing the study protocol and site descriptions provided in the NIOSH report in question, OSHA again concludes that these full-shift exposure data for milling machine operators and tenders, using an older 8-foot drum milling machine during contract roadwork, represent realistic exposure conditions for some milling machine operators who do not always have the advantage of newer equipment and may occasionally mill deeply and encounter multiple layers of varying road materials (including concrete). This test machine was fitted with the manufacturer's original-equipment water delivery system for wetting the cutting drum (which operated at lower pressure than some later models), and, during the testing, the operator intermittently switched between the manufacturer's original water spray nozzles and an alternate nozzle type (at varying water spray rates, always with the modest water pressure that this older machine could generate) (Document ID 3798, pp. 1-2, 4-7).

The hearing testimony of two other commenters supports OSHA's view. Mr. Zimmer, representing IUOE, noted that "it is expected that [asphalt] millers will occasionally come across concrete sub-base" within the depth of material being milled (Document ID 3583, Tr. 2352). And Mr. Turek, of Local 150 in Chicago, also representing IUOE, stated that grinding away unwanted pavement with a milling machine in order to re-route or realign a road is one option for this demolition task, signaling that he concurs that millers sometimes grind away concrete (although other methods exist for complete road removal) (Document ID 3583, Tr. 2364-2365).

The NIOSH report containing the data questioned by NAPA mentions that the road milling and removal contract allowed for the contractor to choose the removal method for the section of road to be realigned and the contractor "chose to mill the pavement because it was of value as a recycled product" (Document ID 3798, p. 2). This consideration suggests that other roadway construction companies likely make the same decision when it is economically advantageous. Furthermore, a road milling machine manufacturer actively advertises large milling machines with "deep cutting" capability, that is, 12 to 14 inches cutting depth (Document ID 1229, p. 4, see also, pp. 1-5). This reference suggests that road milling contractors may consider deep cutting capability when purchasing new machines.

OSHA agrees with NAPA that the milling conditions in this study were not ideal for evaluating the effectiveness of dust controls for steady, shallow milling of asphalt, and that the milling depth and frequent stops likely were not typical of day-to-day operations. OSHA finds, however, that the work performed indicates the range of non-routine conditions under which operators and tenders perform, particularly where they may encounter concrete or aggregate within the depth milled. The silica exposure results from this two-day study were 14 and 100 μg/m^3 (8-hour time weighted average (TWA)) for the operator, and 27, 42, and 66 μg/m^3 (8-hour TWA) for the tenders (one tender on one sampling date, two on the other), calculated from the silica concentrations reported for each of the personal sampling periods (Document ID 3798, pp. 8, 14, Table 2).[227] These exposures were slightly higher than other exposure levels obtained during the more controlled (strictly asphalt) milling conditions represented by the majority of the sample results in the exposure profile. Nevertheless, the samples from this study are well within the range reported in the exposure profile for other operators and tenders of large road milling machines under various conditions (Table IV.5.8-C). Therefore, OSHA has retained the sample results from this study in the exposure profile.

In addition to the sources previously described, two reports by Flanagan et al. (2003, 2006) provide summary, rather than individual, exposure data (Document ID 0676, p.

[227] On Day 1, the skid steer operator and foreman traded jobs mid-day, with each operating the rear controls on the milling machine (in the "tender" role) for part of the shift. For Day 1, the 8-hour TWA silica results for the workers appear in the text of Document ID 3798, p. 8 (3rd paragraph). For Day 2 , OSHA calculated the silica exposures by determining the time-weighted average of the four cumulative sampling sessions obtained for each worker (one session per use of each of the four nozzle types). On Day 2, the period monitored was 495 minutes for the operator and 457 minutes for the tender at the rear controls, demonstrating that the sampling periods on Day 2 represented most of (and in one case 15 minutes more than) an 8-hour shift. To calculate the workers' silica exposures for Day 2, OSHA used the equation for an 8-hour time-weighted average: 8-hr TWA= (C1*T1 + C2*T2+C3*T3+C4*T4)/480, where C1 is the silica concentration in μg/m^3 measured in the breathing zone of the worker during the time when the first nozzle type was in use and T1 is the cumulative amount of time over which C1 was sampled. C2 and T2 are the concentration and time that worker was sampled during use of the second nozzle type, and so on. As an example, for the tender (rear controls) on Day 2, TWA = ([23*105]+[65*111]+[18*134]+[76*107])/480=42 μg/m^3.

322, Table III; 0677, p. 149, Table IV). Further information comes from two other studies on pavement milling machine dust controls used in the Netherlands (Document ID 1184; 1216). Although these studies do not provide individual sample results suitable for inclusion in the exposure profile, as discussed in the following paragraphs, these reports offer additional insight into silica exposures among construction workers working with milling equipment. To avoid duplication, a large summary review of North American and international workplace silica exposure data compiled in Quebec by Beaudry et al. (2013) is not further addressed here because the included milling equipment operator studies are already described individually in this FEA (Document ID 2287, pp. 16, 30).

Substantial additional information on control technology for road milling machines has become available since the PEA was developed. NIOSH has published nine additional studies in the series on large asphalt milling machines, which contribute valuable information on control technology.[228] These nine studies are more experimental than the earlier reports in this series, and most of the tested concepts for equipment are not commercially available on milling machines. Four of the reports involve laboratory evaluations of idle machines (not actual milling), while the rest are highly randomized tests in the field (while road milling is conducted) or tests of control packages that are only just beginning to enter commerce. While the manufacturers of road milling equipment have committed to producing large milling machines with effective dust control features by the year 2017, OSHA understands that few such machines are currently in use; thus, exposure information for these machines does not represent typical exposures among workers using large road milling machines in the United States. As such, OSHA felt it inappropriate to include the exposure results from these studies in the exposure profile (Table IV.5.8-C) (Document ID 3583, Tr. 2222; 2181, pp. 20-29). However, the sample results for these NIOSH studies are discussed extensively under the heading Additional Controls (Section IV.5.8.3).

[228] The nine reports are: NIOSH EPHB 282-17a, EPHB 282-18a, EPHB 282-19a, EPHB 282-20a, EPHB 282-21a, EPHB 282-22a, EPHB 282-23a, EPHB 282-024a, EPHB 282-25a, which appear in the docket as Document ID 4141, 4142, 4143, 4144, 4145, 4146, 4147, 4148, and 4149.

Baseline Conditions and Exposure Profile for Workers Using Drivable Milling Machines

This group includes all machines operated by a worker from a position on the machine and tenders/helpers who assist the operator in close proximity to the machine. The exposure profile in Table IV.5.8-C includes 31 samples of respirable crystalline silica for workers using drivable milling machines (broken down into the following categories: large drivable milling machine operators; tenders associated with those large machines; and small drivable milling machine operators and helpers). The median exposure level for this group is 21 μg/m^3, the mean is 48 μg/m^3, and the range is 5 to 340 μg/m^3. Of the 31 samples, 9 (29 percent) exceed 50 μg/m^3, and 2 (6 percent) exceed 100 μg/m^3. Details of these exposures are presented below.

Baseline Conditions and Exposure Profile for Large Drivable Milling Machine Operators

The exposure profile in Table IV.5.8-C includes 14 samples of respirable crystalline silica for large drivable milling machine operators. The median exposure level is 17 μg/m^3, the mean is 39 μg/m^3, and the range is 5 μg/m^3 to 181 μg/m^3. Of the 14 sample results, 3 (21 percent) exceed 50 μg/m^3, and only one result (7 percent) exceeds 100 μg/m^3. Construction workers operating large drivable milling machines most commonly perform their duties from the tops of the machines. A typical asphalt milling machine has a built-in reservoir from which water is applied to the cutting drum (Document ID 0912, p. 1). The operators use the same water-fed equipment (with different cutting tools on the drum) for concrete milling, but as the vast majority of U.S. roadways are paved with asphalt, concrete milling is performed less frequently (Document ID 1231). The machines are available with or without cabs, although sources suggest that cabs are uncommon because of concerns about visibility and safety (Document ID 1353, pp. 717, 720; 1231). Various commenters supported OSHA's view that asphalt milling represents the majority of road milling jobs; Mr. Rice, of Fann Contracting, a heavy equipment contractor that also performs milling and road construction, described his asphalt road milling and paving operations at length, but did not mention concrete milling or paving. Mr. Richmond of Roadtec, representing NAPA, noted that while the machines his company manufactures can be used for milling concrete, that work constitutes "a relatively minor percentage of the work that we would see on a typical machine." (Document ID 3583, Tr. 2213-2214). Commenters such as Mr. Rice and Mr. Callahan, representing the IUOE, also agreed that cabs are not standard equipment for large milling machines (Document ID 2116, Attachment 1, pp. 6-7, 30; 2262, p. 25).

Exposures can be variable among operators of large drivable milling machines (with water designed primarily for cooling the drum). The contractor report used in developing the PEA (ERG-C, 2008) identified two sample results, both less than or equal to the limit of detection (LOD) (12 μg/m^3), for asphalt milling machine drivers performing wet milling (Document ID 1386, p. 3).[229]

The additional data in the current exposure profile come from five NIOSH reports on investigations performed during asphalt milling using adjustments to drum cooling water sprays (summarized in Table IV.5.8-B, below). All of these studies had an experimental component in which some aspect of the water spray was systematically varied. Eight-hour TWAs were calculated from consecutive samples, the majority of which were two hours or shorter, during which various water treatments were applied (e.g., high- and low-flow). The cumulative total duration of sampling for each operator was at least four hours for the majority of workers, that is, the consecutive short sampling times added up to at least four hours and the concentrations for the consecutive samples were used to calculate the eight-hour TWA. The calculations therefore only incorporated exposure levels during periods of active milling. In accordance with the study design, zero exposure was assumed for the unsampled portion of the shift. The exposure results from these studies were included in the exposure profile because working conditions reflect those actually experienced by milling operators on the job (contracted road work was performed during these studies), although on some dates the amount of time spent milling might have been on the low end of the normal range for milling machine operators.

[229] Results reported as "none detected" are assigned a value equal to the LOD. The LOD is determined individually for each sample based on the volume of air sampled and the method used to analyze the sample. See Section IV.2 – Methodology for additional information on LODs.

OSHA received no general comments on the exposure profile presented in the PEA for large milling machines, although, as mentioned earlier, NAPA objected to inclusion of exposure data from one of the NIOSH reports (NIOSH EPHB 282-11b) in the profile (Document ID 2181, p. 15; 3798, pp. 1-2, 4-7, 10). As previously discussed, OSHA reviewed the study conditions described in the report in question and determined that the conditions fall in the range of activities performed by operators of large milling machines. Therefore, OSHA has decided that the exposure data from that report should remain in the profile.

Table IV.5.8-B
Overview of Five NIOSH Asphalt Milling Machine Studies Conducted 2003 Through 2006

Study Date	Type of Milling	Average Water Spray	8-hour TWA PBZ Silica Sample Results[A]	Percent Silica	Important Findings and Conclusions	Report No. (Year)
Oct 2003	Road demolition (averages of 6 to 11-inch removals, and up to 12-inches)	Cutter drum: 6 to 9 gpm Conveyor:[B] 4 to 3.7 gpm	Operator: 14 to 100 µg/m^3 Tender: 27 to 66 µg/m^3	4 to 9 percent silica on filters 12 to 28 percent quartz in bulk samples	The deep cut created more dust than typical jobs because of the large gap it created between the bottom of the machine and the milled surface (allowing more dust to escape) and the greater quantity of material removed. This is not a typical asphalt “mill and fill” job.	Document ID 0555; NIOSH EPHB 282-11b (2004), 0866 (pp. 6-7, 8, 14 – Table 2)
Jul 2004	Typical “mill and fill” (1 to 4-inch removal)	Cutter drum: 5 to 9 gpm Conveyor: 2 to 3 gpm	Operator: 22 to 91 µg/m^3 Tender (foreman):: 15 to 25 µg/m^3	10 percent silica on filters	Increased water application rate resulted in 50 percent overall reductions in dust emissions.	Document ID 0555; NIOSH EPHB 282-12a (2007), 1362 (pp. 6, 8-11, 23 – Table 1).
Jun 2006	Typical “mill and fill” (1 to 4-inch removal; 1.5 inches most of the time)	Cutter drum: 16 to 18.5 gpm Conveyor: Not available	Operator 5 to 8 µg/m^3 Tender : 13 to 28 µg/m^3	4 to 6 percent silica on the filters 25 to 43 percent silica in bulk samples	No substantial difference in dust control was found between the two relatively similar flow rates.	Document ID 0555; NIOSH EPHB 282-15a (2009), 0869 (pp. iv, 7, 13, 16-Table 1).
Aug 2006	Typical “mill and fill” (1 to 4-inch removal (1 to 2 inches most of the time)	Cutter drum: 7 to 12 gpm Conveyor: 5 to 6.5 gpm	Operator: 15 to 20 µg/m^3 Tender: 15 to 20 µg/m^3	ND to 4 percent silica on filters 13 to 15 percent silica in bulk samples	Dust levels were reduced when water flow rate increased. The hot weather caused the asphalt to become sticky, which might have helped suppress dust.	Document ID 0555; NIOSH EPHB 282-14a (2009), 1251 (pp. 1, 7-8, 13-14, 17-Table 1).

Table IV.5.8-B
Overview of Five NIOSH Asphalt Milling Machine Studies Conducted 2003 Through 2006

Sep 2006	Typical "mill and fill" (1 to 4-inch removal)	Cutter drum and Conveyor (total):[C] 12.5 to 20 gpm	Operator: 39 to 181 µg/m³ Tender: 60 to 82 µg/m³	10 to 19 percent silica on filters	There was no correlation between water flow rates and dust levels. Pressure spray at higher flow rate might have stirred dust into the air. The cold weather might have caused the asphalt to become brittle, contributing to particularly high levels of dust.	Document ID 0555; NIOSH EPHB 282-16a (2009), 0870, pp. iv, 1, 8, 16 - Table1).

Notes: gpm = gallons per minute; ND = none detected.

[A] Daily 8-hour TWAs were calculated from two to four consecutive samples (the majority being 2 hours or shorter) obtained on the same shift, during which various water treatments were applied (e.g., high- and low-flow). The cumulative total duration of sampling on each day for each operator was at least 4 hours for the majority of workers, and only incorporated periods of active milling. Zero exposure was assumed for the unsampled portion of the shift.

[B] When water flow to the cutter drum increased, water flow to the conveyor decreased.

[C] Separate values for cutter drum and conveyor are not available.

In the first study (October 2003), NIOSH investigators collected air samples while evaluating an asphalt-milling machine water spray dust suppression system using two different types of nozzles, high-flow and low-flow (Document ID 0866). NIOSH obtained an exposure result of 14 µg/m^3 for the milling machine operator on the first day, which was a typical day of wet-milling (although water flow rate was not evaluated). A higher result of 100 µg/m^3 was obtained for the operator on the day that investigators evaluated nozzle types (average flow rates between 10 and 12.7 gpm). NIOSH noted that the effect of wind speed and direction is uncertain. At this site, workers removed 12 inches of pavement all at once. In this study, the removal of excess pavement during milling machine demolition-type work created a large gap between the road and the milling machine drum enclosure, allowing more dust to escape than during typical milling conditions (Document ID 0555, p. 1). Milling operators will rarely encounter these “worst case” conditions (Document ID 0555, p. 1).

Subsequently (in July 2004), NIOSH completed a similar study to determine if the engineering controls supplied with new asphalt milling machines, when operated according to the manufacturer’s recommendations, were adequate to control worker exposures. Two sample results of 91 µg/m^3 and 22 µg/m^3 were obtained for the milling machine operator during this typical “mill and fill” job, while water spray flow rate averages ranged from 5 gpm to 9 gpm at the cutting drum (Document ID 1362, p. 1). The system tested provided additional spray at the conveyor. The next study in this series (June 2006) compared several new milling machines manufactured with spray systems, which were tested at 80 percent and 100 percent of their respective maximum flow rates. All three operator quartz exposure levels were below the LOD (less than or equal to 10 µg/m^3 as 8-hour TWAs) (Document ID 0869, calculated from p. 16 – Table 1). Similarly low exposures were observed in the fourth study (August 2006), which tested a late-model mill retrofitted with the newest manufacturer spray system with average total (cutter drum and conveyor) water spray flow rates between 12 gpm and 19 gpm. The three operator quartz exposures were below the LOD (two sample results of less than or equal to 20 µg/m^3 and one result less than or equal to 15 µg/m^3) (Document ID 1251, calculated from p. 17 – Table 1). Although the percent of silica in the asphalt was relatively low (containing an average of 14 percent quartz), respirable dust also was well controlled (Document ID 1251, p. 13). NIOSH suggested that the high summer temperatures (85° to 100° Fahrenheit [F]) caused the asphalt to become sticky, which helped limit respirable dust emissions (Document ID 0555).

The final study in this series (September 2006) again tested a late-model milling machine retrofitted with the newest manufacturer spray system; average total water spray flow rates ranged between 12 gpm and 20 gpm. Quartz exposures among operators at this site, 39 μg/m^3 and 181 μg/m^3, were higher than those at the previous site (Document ID 0870, p. 8, calculated from p. 16 – Table 1). As previously noted, the PBZ exposure levels are composites of samples taken during both high- and low-flow trials, so they do not correlate with specific flow rates. Milling was conducted at nighttime when temperatures were very cool (in the 40s° F). NIOSH noted that it is unclear whether this influenced the silica sample results, although it is possible that the tendency of asphalt to fracture when cold contributed to the difference in results between this study and the warm weather trial of August 2006.

In a separate review of construction data from a variety of sources, Flanagan et al. (2006) summarized 48 respirable quartz samples associated with the use of road milling machines in construction and found a geometric mean of 110 μg/m^3 (Document ID 0677, p. 149, Table II – see Road mill). Flanagan's dataset was drawn from a variety of published and private data, not all of which are available to OSHA, but which likely overlap somewhat with OSHA's dataset. The Flanagan dataset is therefore not included in Table IV.5.8-C. The exposure levels in the larger, but earlier, Flanagan dataset (with sample results obtained from 1992 through 2002) are somewhat higher than the sample results in OSHA's exposure profile, for which most samples were obtained in 2002 or later and which shows that most milling machine operator exposures are currently below 50 μg/m^3 (Document ID 0677, p. 149, Table II – see Road mill).

OSHA also examined differences between asphalt and concrete milling and determined that exposures among operators milling concrete roads might be somewhat higher than exposures during the milling of asphalt, but not necessarily to the extent shown by the concrete milling data available to OSHA. In an extreme case, the New Jersey Department of Health and Senior Services (NJDHSS) reported that, while none of the eight asphalt road millers it evaluated were exposed to silica above the preceding permissible exposure level (PEL) for general industry, the average of the sample results for two concrete road millers was roughly 12 times the relevant PEL.[230, 231] In these cases, the asphalt milling was performed as a wet process while the concrete milling was a dry operation (Document ID 0912, pp. 1-5, 8; 1699). A milling machine manufacturer explained that its recommended operating procedures include wet processes for all road milling to protect the equipment. Because dry milling quickly results in costly equipment damage, it is not an accepted normal practice for asphalt or concrete (Wirtgen, 2010) (Document ID 1231).

Wirtgen (2010) also indicated that there are no practical contraindications to using water sprays during concrete milling, although, even with equivalent water spray, silica emissions could still be higher during concrete milling than they are during asphalt milling. This difference is due to the potential for the silica content to be higher in some concrete compared with some asphalts, and also due to the softness and "stickiness" of asphalt milled warm, which likely helps reduce separation of the pavement components and perhaps limits dust release in hot weather (Document ID 1251, p. 14; 1231). Because the same milling machines (fitted with different models of interchangeable teeth on the

[230] NJDHSS (2000) calculated the PEL using OSHA's general industry silica PEL equation based on the percent of quartz in a respirable dust sample (Document ID 0912, see footnote 3 on each page of the reference). The percent silica in the respirable dust samples varied, so the value of the PEL (as a concentration of respirable dust) ranged from 630 μg/m^3 to 5,000 μg/m^3 (0.63 mg/m^3 to 5.00 mg/m^3) for samples obtained during asphalt milling using wet methods. The value of the silica PEL (again as a concentration of respirable dust) was 670 μg/m^3 (0.67 mg/m^3) during dry concrete milling, while the measured 8-hour TWA respirable dust level was 7,620 μg/m^3 (7.62 mg/m^3), approaching 12 times the calculated PEL (Document ID 1699).

[231] In this case, although evaluating a construction industry activity, the investigator elected to compare silica exposure results using OSHA's gravimetric general industry PEL for silica (Document ID 0912, see footnote 3 on each page of the reference). This might be due to the fact that the construction industry PEL for silica is based on the unit "millions of particles per cubic foot" (mppcf), requiring an obsolete analytical method not available through most analytical laboratories. Instead, laboratories typically report silica air sampling results as mass-based gravimetric values (e.g., mg/m^3) for respirable dust, along with the percent silica. An alternative has been available since 2008, when OSHA published a compliance directive, National Emphasis Program (NEP)–Crystalline Silica CPL 03-00-007 (Appendix E), which provides a conversion factor to convert air sampling results between mppcf and mg/m^3 or μg/m^3. However, some investigators have continued to use the more familiar gravimetric units and compare construction industry air monitoring results with the gravimetric general industry PEL for silica.

milling drum) can be used to mill asphalt and concrete roads (Document ID 1230), OSHA expects that operators use these machines on both materials.

Based on information described above, OSHA concludes that the baseline conditions for large road milling machine operators consist of no cabs or open awnings (which would not provide substantial isolation from the outdoor environment) and the use of wet milling methods primarily intended for drum cooling (with varying degrees of attention to water flow). Furthermore, baseline conditions include primarily “mill and fill” asphalt replacement, with only occasional road demolition jobs (i.e., deeper milling action). Because the sample results included in the exposure profile represent a similar range of conditions, OSHA concludes that the exposure profile for large drivable milling machine operators represents normal baseline exposures for these workers (median exposure of 17 μg/m^3, mean exposure of 39 μg/m^3, range of 5 μg/m^3 to 181 μg/m^3). Operators of road milling machines typically experience silica exposure levels less than 50 μg/m^3, but airborne concentrations can be higher, depending on environmental conditions, the status and design of the water feed system, the depth milled, and whether workers mill concrete road surfaces.

Baseline Conditions and Exposure Profile for Large Drivable Milling Machine Tenders

The exposure profile in Table IV.5.8-C includes 15 samples of respirable crystalline silica for tenders of large milling machines. The median silica exposure is 27 μg/m^3, the mean is 57 μg/m^3, and the range is 11 μg/m^3 to 340 μg/m^3. Of the 15 samples, 5 (33 percent) exceed 50 μg/m^3, and one result (7 percent) exceeds 100 μg/m^3. Construction workers tending large milling machines most commonly perform their duties while walking beside the machines. Their duties can include operating the ground-based rear controls of the milling machine, which requires the worker to walk beside the equipment.

The two highest exposure results in this job category, 340 μg/m^3 and 97 μg/m^3 (from 504-minute and 202-minute samples, respectively), were obtained at a site where minimal water spray was used to cool the equipment. This was the job site where the highest milling machine operator exposures also were obtained, and where NIOSH had strongly suggested that the water spray volume and position needed to be improved (Document ID 1386, p. 4, Table 1 p. 5, and Table 2, p. 6).

The five initial EPHB 282 series of NIOSH studies investigating water spray dust suppression, described above, also measured exposures among milling machine tenders. In order to include personal sampling data from these studies, OSHA calculated 8-hour TWAs for tenders using all the available personal sampling results presented for a given worker during the trials of different water application rates. During the first study, two 8-hour TWA exposure results (66 $\mu g/m^3$ and 27 $\mu g/m^3$) were obtained for the foreman and a skid steer loader operator, respectively. NIOSH noted that both of these workers spent half of the first (most typical) day working at ground level while operating the rear controls of the milling machine, which were located on the side of the machine. They spent the remainder of their shifts on tasks elsewhere at the construction site. A sample result of 44 $\mu g/m^3$ was obtained on the second day of sampling for another crewmember; that worker operated the rear controls for the entire day (Document ID 0866, pp. 8, 14-Table 2). At another construction site, NIOSH investigators obtained two exposure results of less than or equal to 15 $\mu g/m^3$ and 25 $\mu g/m^3$ for a foreman (performing tender duties) who operated the ground-based rear controls of a milling machine (Document ID 1362, p. 23). A ground man performing these same duties during the third study had exposures of 28 $\mu g/m^3$, 18 $\mu g/m^3$, and 13 $\mu g/m^3$ on three consecutive days (Document ID 0869, p. 16, Table 1). At the fourth site, the foreman divided his time between operating the controls alongside the mill and driving the water truck. The exposures for this worker were below the LOD (two sample results of less than or equal to 20 $\mu g/m^3$ and one result of less than or equal to 15 $\mu g/m^3$) (Document ID 1251, pp. 8-9, 17, Table 1). Finally, the ground man at the last study site, who operated controls alongside the mills, had elevated exposures of 82 $\mu g/m^3$ and 60 $\mu g/m^3$ (Document ID 0870, p. 16- Table 1). As previously noted, during this study, water pressure sprays were operated at a higher flow rate, which might have stirred dust into the air, contributing to the higher exposures.

These reports from NIOSH suggest that water spray design, environmental conditions, and the depth of the milling can affect the exposures of ground-based construction workers near asphalt milling machines (just as they can affect exposures among operators).

Based on information described in this section, OSHA concludes that the baseline conditions for large road milling machine tenders consist of operating controls and performing other duties (such as sweeping or shoveling debris) alongside the milling machine where wet milling methods are in use (with varying degrees of attention to water flow). Furthermore, baseline conditions include primarily "mill and fill" asphalt replacement, with only occasional road demolition jobs (i.e., deeper milling action). OSHA concludes that the exposure profile for milling machine tenders represents baseline exposures among these workers. Tenders of road milling machines typically experience silica exposure levels less than 50 μg/m^3. However, exposures can be higher, depending on environmental conditions, the status and design of the water feed system, the depth of the milling, and whether the surface milled includes concrete.

Baseline Conditions and Exposure Profile for Small Drivable Milling Machine Operators and Helpers

The exposure profile in Table IV.5.8-C summarizes the available exposure information for small drivable milling machine operators and helpers. These workers use equipment with a cutting tool less than a half-lane wide, either purpose-built or created by attaching a milling tool (like a "planer") to a small utility tractor, skid-steer, or other similar equipment. Based on two sample results from one OSHA inspection site (21 and 63 μg/m^3), the median exposure level is 42 μg/m^3 and the mean exposure is 42 μg/m^3. OSHA believes this very small sample set does not represent the full range of exposures that these workers currently experience. Over the course of a shift, an uncontrolled small drivable milling machine produces less dust than an uncontrolled large drivable milling machine (small machines are used intermittently and have smaller cutting tools) (Document ID 1229, pp. 1-3; 3583, Tr. 2213). However, some small machines are more likely to be operated with no water application (even for drum cooling) and operators of the smaller machines can be positioned closer to the grinding tool (where dust is more concentrated). As a result, most workers using small drivable milling machines experience modest exposures, but the upper boundary of exposures from small milling machines is potentially similar to the highest exposure levels for large milling machines. OSHA finds that a surrogate exposure profile comprised of all sample results for drivable milling machine operators and helpers best represents the potential for a wide range of current exposures among workers using small drivable milling machines.

Construction workers using small drivable milling machines most commonly operate the equipment from an elevated position on the machine (like a seat or standing platform), although they are never elevated to the same extent as large road milling machine operators (Document ID 1229, pp. 1-3).

The smaller drivable milling machines are used for smaller jobs and detail work, e.g., milling around a manhole, adding rumble strips at the side of a highway, or grinding off unwanted road markings/paint (Document ID 1229, pp. 1-3). The work performed using small drivable milling machines is intermittent; these workers also perform a variety of other tasks during the same shift (Document ID 1229; 3958). Industry representatives agreed that small milling machines used for intermittent tasks (such as milling around a manhole) are typically used only for a “very short duration” during the shift, which would result in lower daily exposures when compared to the operators of large road milling equipment (typically used for 85 percent of the shift) (Document ID 3583, Tr. 2213-2215, 2217-2218). An industry representative agreed that small milling machines are capable of achieving low exposure levels (although this has not yet been demonstrated) (Document ID 3583, Tr. 2213-2215).

Workers operating small drivable milling machines perform a variety of tasks at construction sites. For example, two 2013 exposure results for this job category are for workers who milled a narrow trench in an asphalt highway using a small utility tractor with a milling attachment. They also operated a utility tractor with a sweeper attachment, and worked as flagmen to direct traffic at the site (Document ID 3958).

The smaller drivable machines mill a narrower strip of pavement than large milling machines (median of 20 inches compared to a minimum of 79 inches for large machines), and typically are capable of milling less depth (median 8 inches) than a large machine (median 13 inches) (Document ID 1229; 3958). The samples in OIS were obtained while workers milled a 1-foot wide strip of pavement (Document ID 3958). While the shallower cutting depth could limit the chance a small milling machine would inadvertently cut into a concrete layer below asphalt, OSHA finds that small drivable milling machines are actually more likely to be used (intentionally) to mill on or very near concrete because they are operated in specialty situations where concrete could be more prevalent (for example, the road edge where there might be a concrete curb). In any event, concrete milling occurs only occasionally (Document ID 1231).

Purpose-built equipment, essentially a smaller version of large road milling machines, includes a water tank and application system for drum cooling (Document ID 1229, pp. 1-3 [water weight is included in total weight of the machines]). Use of water likely suppresses dust to some extent. Table IV.5.8-B shows that with only drum cooling water (with minor adjustments), asphalt milling often results in exposures at or below 50 $\mu g/m^3$, although exposures as high as 181 $\mu g/m^3$ were reported. OSHA considers it unlikely that all workers routinely install a supplemental water kit when using smaller drivable milling machines with temporary milling attachments (water dust controls are not standard on that equipment). On small jobs, where the machine moves only in a very limited area, a helper may use a hose to apply water spray, as documented for other utility vehicles with demolition attachments (Document ID 0858, p. 3). See Section IV-5.3 – Heavy Equipment Operators and Ground Crew Laborers. OIS records for workers using small drivable milling machines at one site inspected by OSHA do not indicate that the operators used wet cutting methods, but do show that the workers were protected by an enclosed cab (although the cab likely was not ventilated with filtered air) (Document ID 3958). Therefore, OSHA finds that with respect to small drivable milling machines, the purposeful use of wet methods specifically for dust control is inconsistent.

While OSHA cannot rule out the use of small drivable milling machines indoors (since they can be used wherever small utility tractors might be used), OSHA finds that indoor work is rare if it occurs at all. The more portable walk-behind milling machines are the preferred tool for indoor milling work; both the PEA and OIS described indoor work performed by workers using walk-behind milling machines, but these sources contain no examples of drivable machines operated indoors (Document ID 1720, pp. IV-451 – IV-469; 3958).

Based on the information previously described, OSHA finds that small drivable milling machines are frequently operated without intentional dust controls, although supplemental water application kits are sometimes added. On small jobs, a helper with a hose may apply water spray to the grinding tool (as has been reported for other attachments to utility equipment) (Document ID 0858, p. 3). Additionally, purpose-built small drivable machines apply cooling water to the milling drum, which offers a recognized, but inconsistent, benefit (as shown in IV.5.8-B) (Document ID 0912, pp. 1-5, 8; 1386, p. 5; 1699). The fact that there is a lack of consistency when it comes to the intentional use of dust controls can increase the higher-end of the current exposures for operators and helpers, particularly those who use the equipment for extended periods of time. At the same time, most milling accomplished with the small drivable machines is intermittent, usually characterized by short bursts of activity (e.g., a few minutes spent milling around a man hole) followed by periods during which the operators and helpers perform other activities (sweeping, flagman) (Document ID 3958). The intermittent nature of the work greatly reduces silica exposures among these workers. As a result, OSHA has determined that the potential range of exposures associated with small drivable milling machine operators and helpers is substantially broader (at both the low and high ends) than indicated by the two samples available to OSHA and contained in the exposure profile.

OSHA has also determined that small milling machines are used primarily to mill asphalt, but, like the large machines, do encounter concrete occasionally. Furthermore, the workers operating small drivable milling machines can sit on top of the machine (but not at the same elevation as the operators of large road milling machines) or they can work sitting or standing at or near ground level (Document ID 1229, pp. 1-3). OSHA observes that when an operator is close to ground level, his or her position is similar to that of a machine tender.

OSHA concludes that, rather than relying on the very limited (two) existing data points for workers using small drivable milling machines, the exposure profile for this group is better represented by a surrogate data set comprising the more comprehensive and wide ranging profile for the entire group of workers using drivable milling machines (including operators and tenders/helpers of both large and small drivable milling machines). Thus, the exposure profile for small drivable milling machines shows a median exposure of 21 μg/m^3 and a mean exposure of 48 μg/m^3, with overall exposures ranging from 5 μg/m^3 to 340 μg/m^3.

The baseline conditions for workers using small drivable milling machines consist of either no dust controls, unpressurized cabs, or the use of wet milling methods (with varying degrees of attention to water flow; generally associated with drum cooling systems on purpose-built equipment, or occasionally applied with a hose by a helper or via a supplemental water kit for utility vehicles fitted with milling attachments).

Baseline Conditions and Exposure Profile for Walk-Behind Machine Operators and Helpers

The exposure profile in Table IV.5.8-C includes 12 samples of respirable crystalline silica for walk-behind milling machine operators and their helpers. The median exposure is 12 μg/m^3, the mean is 63 μg/m^3, and the range is 12 μg/m^3 to 504 μg/m^3. Of the 12 samples, 2 (17 percent) exceed 50 μg/m^3. The 504 μg/m^3 exposure reading, and another of 80 μg/m^3, are the only exposures exceeding 50 μg/m^3.

Millers in this second major division of workers using milling machines operate walk-behind machines or work closely assisting workers who operate such machines. Surface preparation jobs can be performed either outdoors or indoors. Workers using these machines are positioned more than arm’s length from the grinding action.

A related surface preparation activity, floor sanding, is described as a concrete finishing process using a sandpaper disk attached to equipment that is operated from a standing position (Document ID 0676, p. 328 [Figure 8]). OSHA has grouped floor sanding activities with walk-behind milling machine operations for the purpose of this analysis.

Sanding is similar to the final smoothing actions of other milling machines that have changeable abrasive units (Document ID 0676).

OSHA originally reviewed six sample results for walk-behind milling equipment operators as part of the PEA. Two of these sample results (both below the LOD of 12 μg/m^3) were obtained by ERG for workers using water-fed walk-behind milling machines indoors while producing a terrazzo floor (Document ID 0200, pp. 6-7, 10-12, Tables 1 & 2). OSHA collected two more sample results (14 μg/m^3 and 80 μg/m^3) while visiting a worksite at which workers used a gas-powered walk-behind router-style milling machine as part of asphalt road pavement repair.[232] Two additional follow-up monitoring sample results of 26 μg/m^3 and 48 μg/m^3 were obtained while workers of the same company used similar equipment on pavement at an airport. Average silica content in the respirable dust samples was 6 and 15 percent (the latter a time-weighted average from two shorter samples of 9 and 18 percent silica), while a bulk sample of the asphalt pavement contained 20 percent quartz. During the sampling period, another worker also used compressed air to clean the dust from the grooves. Dust controls were not mentioned on either occasion (Document ID 0036, pp. 15-16, 34-37, 42, 82, 99).

OSHA added to the original exposure profile six additional exposure results from two sites, as reported in OIS. The 504 μg/m^3 result (the highest in the exposure profile) was obtained in 2014 during an inspection of a worksite where an employee of a structural concrete contractor used a large electric floor grinding machine (with multiple grinding cups) to remove the top layer of concrete from an indoor floor. Notes associated with the sample indicate that local exhaust ventilation (LEV) was used and that a second worker used a small grinding tool (single grinding cup) to grind the corners and edges of the floor "at the same time 10-20 [feet] away" (Document ID 3958, Row 74).

At the second construction site, operators (three samples) and helpers (two samples) from a company that specializes in coating concrete floors used two types of walk-behind

[232] A variety of equipment is available for "chasing cracks," which was the type of road repair being performed at this worksite. Some walk-behind equipment models are similar to masonry saws. In this case, the OSHA representative called the machine a router, suggesting it was more closely related to milling equipment (Document ID 0036, p. 15).

milling machines (a scarifier and a floor grinder) to prepare the surface for repainting. The operators first used the scarifier to remove paint and roughen the floor. Then they leveled the freshly exposed material with a floor grinder. The operators used a series of grinding pads on the grinder (from coarse “chipping” pads to a fine “diamond” pad) to smooth the grooves made by the scarifier. Meanwhile, a helper moved hoses around to keep them away from the milling equipment and vacuumed the floor behind the milling machines. The OSHA inspector who visited the site reported that the milling equipment was operated with LEV. No silica exposures were recorded for either the operator or helper (Document ID 3958, Rows 209-211, 214-215).

OSHA reviewed an additional study designed to evaluate exposures to silica during common dust-producing construction activities. Flanagan et al. (2003) summarized nine sample results for concrete floor sanding activities and reported a geometric mean of 70 μg/m^3 (Document ID 0676, p. 322, Table II). However, as previously noted, the study did not provide individual sample results, so OSHA was unable to include them in the exposure profile for this job category.

In a separate experimental study, short-term exposures to silica for an operator using a walk-behind scabbler on a covered[233] (semi-enclosed) concrete parking garage floor were as high as 2,100 μg/m^3 over an 8-minute test period evaluating dry milling. During other test periods, exposures were controlled by an intense use of wet methods (involving water application at a rate of 15 gallons per minute).[234] This study showed that workers using certain types of particularly aggressive equipment indoors can encounter higher airborne silica concentrations during short periods of intensive milling without dust controls (Document ID 0633, p. 211, Table 1; also reported in 0860, p. 9, Table 1).

Vacuums can be connected to walk-behind milling machines to capture dust generated during milling. Although most walk-behind milling machines are currently manufactured

[233] The semi-enclosed configuration of the parking garage is inferred from photos of the milling trials that show support columns in the area being milled (Document ID 0860, p. 6, Figure 1).

[234] Samples from this study represent exposure concentrations during specific experimental test periods of 5 to 16-minutes in duration, alternating with and without controls; results are not 8-hour TWA values and do not cover the worker’s entire time milling on the test dates (Document ID 0633, p. 211, Table 1). Therefore, the samples are not included in the exposure profile.

with vacuum ports (to which a vacuum can be connected), older equipment might not include this feature (Document ID 1431, p. 3-82). Six of the sample results (for walk-behind equipment operators and their helpers) in the exposure profile (including the highest and lowest values) were collected with LEV in use; thus OSHA concludes that baseline conditions for walk-behind milling machine operators can include the use of LEV to control dust, but the vacuum systems are not always performing effectively (whether due to a mismatched vacuum or poor maintenance and cleaning).

In the PEA, OSHA preliminarily concluded that wet methods appeared to be used more commonly with certain types of walk-behind milling equipment, including terrazzo-milling equipment (Document ID 1720, p. IV-459). OSHA received comments on walk-behind milling machine operator exposures during floor sanding from Mr. Barrett, representing the International Union of Bricklayers and Carpenters (BAC). Mr. Barrett explained that within the past eight years, changes in the terrazzo industry have led to a switch from using lower-power wet methods of polishing to using higher-powered dry grinders with vacuum dust control. The higher-powered equipment can process twice as much floor area per day (1,000 to 1,100 [square] feet per day, compared to 500 [square] feet per day with the lower-powered equipment). The new system creates less of a mess to clean up, “assuming the machines and vacuum controls are properly maintained and used,” but in Mr. Barrett’s experience, “the vacuum systems were not always properly maintained, and/or the filters were not changed when necessary, leading to more dust exposure than with the prior system” (Document ID 4053, Attachment 5). OSHA notes that although the floor type is different (concrete rather than terrazzo), Mr. Barrett’s description is consistent with the operation involving a large floor grinder with LEV described in OIS, which resulted in an exposure of 504 $\mu g/m^3$ (Document ID 3958).

Based on the available information, OSHA concludes that the sample results in Table IV.5.8-C represent the baseline exposure levels for walk-behind milling machine operators and other workers engaged in this activity. However, OSHA acknowledges that this may underestimate exposures for workers using certain types of particularly aggressive equipment indoors.

OSHA finds that the use of either LEV or wet methods is in the range of normal baseline conditions for this diverse group of equipment, but that these methods are not used consistently (e.g., LEV was associated with half of the exposure results summarized in Table IV.5.8-C, while wet methods were associated with one-sixth of the exposure results). Nor do these methods appear to be fully implemented when they are used (the highest exposure level for this group, 504 $\mu g/m^3$, was associated with an LEV system (not described)).

Table IV.5.8-C
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Construction Workers: Millers Using Portable or Mobile Machines

	Exposure Summary			**Exposure Range**			**Exposure Profile**				
Millers Using Portable or Mobile Machines	**N**	**Mean (µg/m³)**	**Median (µg/m³)**	**Min (µg/m³)**	**Max (µg/m³)**		**< 25 (µg/m³)**	**≥ 25 and ≤ 50 (µg/m³)**	**> 50 and ≤ 100 (µg/m³)**	**> 100 and ≤ 250 (µg/m³)**	**> 250 (µg/m³)**
Operator - Large Drivable Milling Machine (half lane or wider)	14	39	17	5	181		10 (71.4%)	1 (7.1%)	2 (14.3%)	1 (7.1%)	0 (0%)
Tender - Large Drivable Milling Machine (half lane or wider)	15	57	27	11	340		6 (40%)	4 (26.7%)	4 (26.7%)	0 (0%)	1 (6.7%)
Operator/Helper - Small Drivable Milling Machine (less than half lane)	2	42	42	21	63		1 (50%)	0 (0%)	1 (50%)	0 (0%)	0 (0%)
Workers Using Drivable Milling Machines Subtotal	*31*	*48*	*21*	*5*	*340*		*17 (54.8%)*	*5 (16.1%)*	*7 (22.6%)*	*1 (3.2%)*	*1 (3.2%)*
Workers Using Walk-Behind Milling Machine	*12*	*63*	*12*	*12*	*504*		*8 (66.7%)*	*2 (16.7%)*	*1 (8.3%)*	*0 (0%)*	*1 (8.3%)*
Millers Using Portable or Mobile Machines Total	**43**	**52**	**20**	**5**	**504**		**25 (58.1%)**	**7 (16.3%)**	**8 (18.6%)**	**1 (2.3%)**	**2 (4.7%)**

Notes: All samples are personal breathing zone (PBZ) results and represent 8-hour time-weighted average exposures.
Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.
Percentages may not add to 100 percent due to rounding.

5.8.3 Additional Controls

The exposure profile in Table IV.5.8-C shows that approximately 26 percent (11 out of 43 samples) of millers using portable or mobile machines have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

Additional Controls for Workers Using Drivable Milling Machines

Water spray and LEV are the primary dust controls for this job category. Because much of the research on dust controls for road milling machines was conducted by the Silica Milling Machine Partnership, the first subsection below describes this organization and its investigative process. After describing the Partnership, this section addresses wet dust control methods and then LEV as exposure controls for the operators of large drivable asphalt milling machines. Subsequent subsections relate the discussion of controls to tenders of large drivable milling machines, small drivable milling machines, and drivable milling machines used on concrete.

Additional controls for walk-behind milling machines are discussed separately below.

Overview of the Silica Milling Machines Partnership – a Silica Dust Control Effort Focused on Road Milling Machines

NIOSH publications document the extensive work of the Silica/Asphalt Milling Machine Partnership. Public comments submitted to the rulemaking record contain extensive information on the Silica Partnership and its accomplishments. The unique nature and success of this partnership warrants further attention here:

In his hearing testimony, Mr. Acott (president of NAPA), described the partnership's mission as an effort to develop innovative engineering controls "that all but eliminate dust and potential silica exposure," and methods "to retrofit existing milling machines to ensure a safe workplace" (Document ID 3583, Tr. 2153). Representatives of NAPA, including Mr. Acott, Mr. Bodway (of Payne & Dolan, an asphalt paving contractor), and Mr. Richmond (of Roadtec, a milling machine manufacturer) indicate that the Silica Partnership includes representatives from the road construction contractors industry, labor, academia, and government: NAPA, the Association of Equipment Manufacturers (AEM), the International Union of Operating Engineers (IUOE), the Laborer's International Union of North America (LIUNA), and major road milling machine manufacturers. In cooperation with another Silica Partnership member, NIOSH, this group has been studying dust controls for milling machines since 2003 (Document ID 2181, pp. 1-2; 3583, Tr. 2152, 2160).

Partnership members described their visit to a NIOSH research facility in Pittsburgh, Pennsylvania, in 2007 as the turning point in this effort. During that visit they "learned the similarity of mining dust suppressing and milling machines" and that if they could capture the dust, they would capture the silica contained in the dust (Document ID 3583, Tr. 2157). This partnership developed an effective control technology for milling machines. The technology captures 97 percent or more of the respirable dust and maintains worker exposure levels at less than 25 μg/m^3 respirable silica. With NIOSH's help, the partnership members tested multiple designs, evaluated the best-performing designs with several manufacturers' equipment, coordinated extensive laboratory and field testing on 10 road construction sites, collected 42 full-shift exposure samples, and published the testing and dust control design information to benefit the industry as a whole (Document ID 3583, Tr. 2156-2166). Many reports in the resulting series of NIOSH publications provide convincing evidence of the effectiveness of these large asphalt road milling machine dust controls in managing silica exposures among operators and tenders.[235]

Wet Dust Control Methods

Cooling water applied to the cutting drum helps reduce dust exposures among milling machine operators. All of the sample results in Table IV.5.8-C for road milling machine

[235] References that represent steady progress toward managing silica exposures are: Document ID 0866 [duplicate 3798]; 0869; 0870; 1362; 1251; 4143; 4144; 4145; 4146; 4147; and 4149. As with most research endeavors, not every avenue explored by the partnership showed great promise; some represent setbacks or described works in progress that had not yet achieved positive dust reduction results (Document ID 4141, 4142; and 4148). In addition, because the Partnership set a goal to reduce all dust, not all the reports contain worker exposure data, even when they show great efficiency for dust capture. Some of the reports contain only highly experimental field or lab data (area samples, dust analysis rather than silica results), which show the effectiveness of controls for dust capture, which in turn results in silica capture.

operators are associated with the use of wet dust suppression, and 71 percent of the results were 50 μg/m^3 or less. Purpose-built systems for wet dust suppression can be even more effective at reducing silica exposures.

In a study conducted in the Netherlands, a novel wet dust emission suppression system reduced the PBZ respirable quartz exposures of asphalt milling machine drivers to a mean of 20 μg/m^3 (n = 4), with a range of 9 μg/m^3 to 30 μg/m^3 (Document ID 1216, p. 4, Table 1). The system consists of 24 spray nozzles (located at the picks drum, collection conveyor, and loading conveyor), which spray aerosolized water containing an additive (likely a foam, based on the product name) onto the milled asphalt material (Document ID 1216, p. 3; 1217, Slide 4). The additive foam causes the dust to become tacky and aggregate, and expands rapidly to encompass small particles generated by the tool's aggressive action (Document ID 1216, p. 3). This technology can offer more effective dust suppression than plain water.[236] Milling machine tenders benefitted equally from the system, having a mean PBZ respirable quartz exposure of 8 μg/m^3 (n = 4) with a range of 4 μg/m^3 to 12 μg/m^3. Compared with a standard milling machine, which uses only cooling water (not aerosolized) on the blade, the use of the aerosolized water and foam system reduced the mean exposure for drivers and tenders combined by 97 percent.[237] Without the added controls (i.e., cooling water only), the mean exposure for drivers was 418 μg/m^3 (n = 2) and the mean exposure for tenders was 509 μg/m^3 (n = 1) (Document ID 1216, p. 4, Table 1).

Investigators Van Rooij and Klaasse (2007) also reported results for the use of aerosolized water without the additive foam. Aerosolized water alone provided a substantial benefit, giving PBZ respirable quartz exposures of 42 μg/m^3 and 57 μg/m^3 for

[236] Although more costly than a simple water spray, foams are more effective (by volume applied) than water spray. Foam can be adapted to control dust from most tasks, including applications that require a rugged design (Document ID 1360).

[237] OSHA calculated an average exposure of 448 μg/m^3 from three samples for the driver and tender beside the machine (range 39 to 509 μg/m^3) using "only cooling water," and an average exposure of 14 μg/m^3 from eight samples (range 4 to 30 μg/m^3) for the same workers in the same job titles using water aerosol with additive, for a 97 percent reduction in the average personal breathing zone concentration. Samples were obtained at four different road construction sites between September 2002 and December 2003 (Document ID 1216, pp. 3-5, Tables 1 and II).

drivers, and 56 µg/m^3 and 104 µg/m^3 for tenders. Aerosolized water reduced the mean exposure for drivers and tenders combined by 86 percent when compared with cooling water only; however, three of four exposures remained above 50 µg/m^3. The authors did not report individual sample durations, but the average sampling time for all 15 samples was 254 minutes (range: 60 to 388 minutes). The investigators concluded that exposure results were lower when the additive was used in the spray water (Document ID 1216, pp. 4-5, Table 1 and Appendix Table II).

Mr. Bodway, of Payne & Dolan (a road milling contractor), representing NAPA and the Silica/Asphalt Milling Partnership, agreed with OSHA that worker exposures from asphalt road milling machines will be reduced to levels at or below 50 µg/m^3 when milling machines are fitted with effectively designed water spray systems paired with surfactants (a type of water additive) and routine inspections (to be sure the system components are working properly). He noted that all six major road milling machine manufacturers have recently begun, or will soon be, offering dust control optimized water spray systems as standard equipment and/or retrofit kits (Document ID 2181, pp. 21-29). In support of these systems, Mr. Bodway stated:

> The [Silica/Asphalt Milling Machine] partnership is convinced that the water spray systems being provided by milling machine manufacturers for retrofitting older machines are effective at controlling worker exposures to below the proposed PEL, particularly when the water is amended [altered] using surfactants as described by Van Rooij and Klaasse (2007). The Rooij and Klaasse study demonstrated that amending the water used in an aerosol dust-suppression system with a foaming agent reduced worker exposures by 4–5 times when compared to water aerosol alone. ***A further level of protection is provided by the Partnership's recommendation that these control systems be inspected daily by a competent person and inspected annually by a qualified person with training from the appropriate milling machine manufacturer. Such inspections will ensure that the control systems are operating as designed and remain effective (Document ID 2181, p. 11).

Mr. Bodway also testified that, while calcium chloride, a typical additive used in other industries, is not a suitable additive for road milling water spray systems, milling machine operators have available for use an additive “that most people are familiar with as [trade name] dish soap that helps encapsulate [dust]” and helps prevent water from freezing in cold weather (Document ID 3583, Tr. 2187-2188).

The initial series of five NIOSH studies (described previously and summarized in IV.5.8-B) focused on water spray controls (without added dust suppressants) using the standard cooling water system available in milling machines at the time. Taken as a body of work, the results of these studies were inconclusive regarding the extent and reliability of this control in all situations encountered by road milling equipment. More recent studies offer more support for the efficacy and reliability of wet dust control methods.

NIOSH tested alternate designs involving equipment specially added to optimize water spray for dust suppression (Document ID 4148, p. v-vi; 4141, pp. vi-vii). One design, (sometimes referred to as test configuration “B2”) showed more promise than others, reducing dust release by 38 to 46 percent (an average of 43 percent) (Document ID 4141, p. 26). As described in NAPA’s post-hearing comments, the Silica/Asphalt Milling Machine Partnership has adopted this “B2” dust-control optimized water spray design as an industry standard and has placed detailed engineering designs for it in the public record for all milling machine manufacturers to use (Document ID 3749, PDF pp. 3, 5-8 Exhibit 1). During typical “mill and fill” type operations using this method of dust control, ERG’s study of supplemental engineering controls found that with this type of control (B2), the operator and tender experienced exposure levels of less than the limit of detection (12 $\mu g/m^3$ in this case) to 14 $\mu g/m^3$ (Document ID 2181, Appendix II, pp. 30, 45). Including a surfactant additive in the water is a practical way to reduce worker exposures to the lowest level achievable with this wet method (Document ID 1216, p. 3; 1217, Slide 4).

Water spray systems that optimize dust control have other benefits. One milling machine manufacturer indicated that its improved dust control system reduces machine maintenance requirements and improves visibility (by reducing emitted dust) on and around the milling machine (Document ID 1231). In his testimony, Mr. Richmond (of Roadtec, Inc., a road milling machine manufacturer), representing NAPA, confirmed that equipment manufacturers anticipate that spray systems that reduce dust will increase productivity by decreasing equipment down-time (Document ID 3583, Tr. 2204). Mr. Bodway (of Payne and Dolan, a paving contractor), representing NAPA, agreed that "if anything, we are a little more productive" as a result of using wet dust control methods (Document ID 3583, Tr. 2205). The same commenters (Mr. Richmond and Mr. Bodway) also agreed that water spray on milling machines does not create water runoff at road construction sites; rather, the water remains with the milled material, which is trucked to a recycling site (Document ID 3583, Tr. 2203-2204).

Milling concrete can pose additional challenges for controlling silica exposure compared with milling asphalt.[238] For example, one investigator suggested that the smaller teeth on concrete milling drums produce more fine dust (Document ID 1699). Despite these differences, some of the same milling machines (high-power equipment) can readily be adapted to mill either asphalt or concrete (Document ID 1230). Thus, OSHA expects that water spray nozzles applied to asphalt milling machines will function similarly when the same machine is used for concrete. Although the available data are not sufficient for OSHA to conclude with certainty that workers milling concrete roads would achieve the same exposure levels seen for asphalt millers, there is evidence suggesting wet methods work well for managing concrete dust. For example, in a study of tunnel construction workers, Blute et al. (1999) reported respirable silica exposures of 10 $\mu g/m^3$, 59 $\mu g/m^3$ (estimated), and 79 $\mu g/m^3$ for workers removing concrete with heavy equipment (forklifts, backhoes) having grinder or scabbler attachments (analogous action and worker positioning to milling machines). The authors posited that these relatively low exposures (not exceeding 100 $\mu g/m^3$)[239] resulted from the use of hoses to wet down the concrete and the distance between the source of the silica dust and the worker (Document

[238] In one evaluation, the percentage of silica on respirable dust sample filters was higher with concrete milling (16 percent) than with asphalt milling (7 percent) (Document ID 0912, pp. 5, 8). Wirtgen (2010) reported the silica content of concrete is generally higher than asphalt (Document ID 1231, p. 1). The silica exposure results from one NIOSH study where concrete and aggregate were also encountered along with asphalt within the depth milled were slightly higher than other exposure levels obtained during the more controlled (strictly asphalt) milling conditions represented by the majority of the sample results in the exposure profile (Document ID 3798, pp. 8, 14, Table 2).

[239] Blute et al. (1999) used the general industry equation to calculate the PEL for respirable dust containing silica (Document ID 0562).

ID 0562, pp. 636-637, Table III).[240] Therefore, OSHA concludes that wet methods are effective when milling concrete roadways, and that exposure levels will typically be at or below the PEL. The use of dust suppressants (e.g., foams that offer binding and surfactant properties, such as used in studies by Van Rooij and Klaasse [2007]) should further reduce exposures (Document ID 1217, p. 5).

Based on the information reviewed here, OSHA concludes that purpose-designed dust control water spray systems for large milling machines are commercially available (or soon will be available) for most models of large road milling machines in operation, either as original equipment or as a retrofit kit. For typical road milling operations, the water spray will maintain most operators' exposures to 50 μg/m^3 or less most of the time if a surfactant (soap) water additive is used.

TNO Bouw (2002), which evaluated dust controls for milling machines in the Netherlands, noted that blowback of dust released from an LEV-based dust control (specifically, from discharged dust introduced onto the long conveyor belt exiting the machine) can become a source of silica exposures if a breeze carries the dust back over the milling machine into the operator's breathing zone (Document ID 1184, p. 27). Based on their experience with limestone milling machines, the authors recommended that judicious use of water spray in the discharge pipe (for example, at a rate of 2.5 liters of water per hour) could control blowback, where it is a problem (Document ID 1184, p. 30).

Local Exhaust Ventilation

A particularly effective control option for drivable milling machine operators involves the use of LEV to minimize the release of dust from the machine. Since OSHA developed the PEA, NIOSH has completed additional studies in the EPHB 282 series on dust controls for road milling equipment, this time focusing primarily on LEV. The results of these studies, conducted with the Silica/Asphalt Milling Machine Partnership, consistently demonstrate silica exposure levels below 25 μg/m^3 during typical shallow

[240] Tunnel ventilation made this environment similar to working in open air (see Section IV-5.12, Underground Construction Workers).

("mill and fill") asphalt road milling operations. Additionally, the studies indicate that silica exposure levels can be effectively controlled to 25 $\mu g/m^3$ and below when making deeper cuts during asphalt milling. The LEV control (in addition to drum wetting for cooling) also results in consistently low respirable dust levels. This is an important point; it means that when used according to the manufacturers' recommendations during typical road milling jobs, this dust control equipment will keep workers' silica exposures below 50 $\mu g/m^3$ (and usually below 25 $\mu g/m^3$), even when there are higher levels of silica in the respirable dust sample.

Samples obtained while LEV was being used to control dust (with the highest percent silica measured by NIOSH) at a road milling site demonstrate the value of effective dust capture. Samples were taken during the milling of a parking lot where the pavement contained 23 percent silica. The respirable dust samples contained 14 percent silica, yet the lowest operator and ground man (tender) exposure levels were 9 and 8 $\mu g/m^3$ respectively and the highest exposures were only slightly higher. On this occasion, the respirable dust concentrations for the operator and ground man were 70 and 50 $\mu g/m^3$ (reported as 0.07 and 0.05 mg/m^3) (Document ID 4147, p. 13-14, Tables 1 and 2).[241] If the silica content of the pavement had been double the actual level (46 percent, with 28 percent silica in the respirable dust sample), the operator and ground man would have experienced silica exposure levels of 18 and 16 $\mu g/m^3$, respectively (calculated, for example, as 70 $\mu g/m^3$ respirable dust concentration multiplied by the portion that is silica (0.28) = 18 $\mu g/m^3$), instead of 9 and 8 $\mu g/m^3$. The silica content of the pavement in both the original scenario and the hypothetical is in the range of what workers typically encounter. Mr. Fore, representing the Silica/Asphalt Milling Machine Partnership, stated that the silica content of the material being milled varies from region to region and from site to site. "Typically, it would be in the range of say 10 to 30 percent, but it is as low as

[241] OSHA notes that respirable dust levels of 100 to 200 $\mu g/m^3$ were more typical in this LEV study, but the lower values most clearly demonstrate the value of effective respirable dust capture as a method of achieving good silica dust control (Document ID 4147, pp. 13-14, Tables 1 and 2). When respirable dust can be controlled to such low levels, silica values cannot exceed the PEL regardless of the silica content of the material.

0 and maybe as high as 50," depending on the nature of the aggregate used in the asphalt (Document ID 3583, Tr. 2177-2178).

Evidence of the effectiveness of LEV dust controls for road milling machines comes from both laboratory studies and tests performed on milling machines at construction sites. Under laboratory conditions, NIOSH tested the capture efficiency of LEV applied to the milling drum housing on large road milling machines provided by four different manufacturers. In these studies, machines were tested in a stationary position, with the drum spinning and belts moving, but without any reclaimed asphalt pavement moving through the system. The milling machines were set up to simulate the amount of open area around the drum that would be present during a typical milling job. Smoke and tracer gas were used as surrogates for silica dust, allowing NIOSH to evaluate capture efficiencies of the dust emission-control systems in a controlled setting, without exposing NIOSH investigators to silica dust. These studies allowed the Silica/Asphalt Milling Machine Partnership to confirm that the LEV system was effective on each brand of machine tested and to evaluate the effect of varying airflow rates on how well the system captured dust. Table IV.5.8-D presents an overview of the laboratory studies. For all machines, the LEV system captured at least 93.5 percent of the simulated dust particles released in the milling drum housing (at one or more of the tested air flow rates), with capture efficiency of 97 to 99 percent in three of the four machines.[242]

Table IV.5.8-D
NIOSH Laboratory Tests of Capture Efficiency for LEV on Asphalt Milling Machines

Study Date (Machine)	Type of Study	Control Tested	Test Conditions	Important Findings and Conclusions	Report No. (Year)
Aug 2011 (Machine 1)	Laboratory test	Local exhaust ventilation in milling drum housing	Tested at one air flow rate	Average dust capture efficiency: 93.5%	NIOSH EPHB 282-19a (2011), Document ID 4143, p. v.
Aug 2011 (Machine 2)	Laboratory test	Local exhaust ventilation in milling drum housing	Tested at three air flow rates	Average dust capture efficiency:	NIOSH EPHB 282-20a (2011), Document ID 4144, p. v.
			600 CFM	97.4 to 98.2%	
			900 CFM	99.9%	
			1300 CFM	100%	
Apr 2012 (Machine 3)	Laboratory test	Local exhaust ventilation in milling drum housing	Tested at one air flow rate	Average dust capture efficiency: 99%	NIOSH EPHB 282-21a (2013), Document ID 4145, p. v.
Aug 2012 (Machine 4)	Laboratory test	Local exhaust ventilation in milling drum housing	Tested at four air flow rates:	Average dust capture efficiency:	NIOSH EPHB 282-22a (2013), Document ID 4146, p. v.
			980 CFM	88.6%	
			1250 CFM	94.7%	
			1450 CFM	97.5%	
			1675 CFM	98.1%	

Notes: Machines were tested in a stationary (laboratory) setting, with the drum spinning and belts moving, but without any reclaimed asphalt pavement moving through the system. Machines were set up to simulate the amount of open area around the drum that would be present during a typical milling job. Smoke and tracer gas (analyzed by Miran infrared spectrophotometer) were used as surrogates for silica dust to evaluate capture efficiencies of the dust emission-control systems.

CFM = cubic feet per minute

The Silica/Asphalt Milling Machine Partnership subsequently conducted field trials for large road milling machine LEV systems on machines produced by two different manufacturers. NIOSH evaluated exposures among workers associated with each machine on four to six road construction jobs, for a combined total of 11 construction sites and 21 days of steady asphalt milling (11 days for one machine, 10 for the other) (Document ID 4147, pp. v, 5-7, 13, Table 1; 4149, pp. v, 5-7, 13, Table 1). NIOSH deemed one sampling date and location (Site 3) atypical because little time was spent actually milling and discarded the sample results from that day (Document ID 4149, pp. 6, 13, Table 1). Therefore, the analysis considered 10 construction sites and 20 days of sampling. On those days NIOSH monitored silica exposures for operators and tenders (40 samples over the 20 days) who worked long days, up to almost 11 hours. Silica content ranged from 5 to 23 percent in the road material, which resulted in 2 to 14 percent respirable silica in the breathing zone samples. All 40 samples, for operators and tenders combined, showed that exposure levels never exceeded 25 $\mu g/m^3$ when workers used machines fitted with the LEV system, even when making cuts up to 11 inches deep in asphalt (Document ID 4147, pp. v, 6-7, 13, Table 1; 4149, pp. v, 5-7, 13, Table 1). In fact, the highest sample result (24 $\mu g/m^3$ for a "ground man" walking beside a milling machine removing 11 inches of pavement on each pass) was the only sample result to exceed 13 $\mu g/m^3$ during the two sampling dates (Document ID 4147, pp. v, 5-7, 13, Table 1; 4149, pp. v, 5-7, 13, Table 1). Table IV.5.8-E presents a summary of NIOSH's sample results.

Table IV.5.8-E NIOSH Asphalt Milling with LEV (water spray for drum cooling only)						
Study Date	**Type of Milling**	**Control type(s)**	**8-hour TWA PBZ Silica Sample Results**	**Percent Silica**	**Important Findings and Conclusions**	**Report No. (Year)**
Jun-Aug 2012	11 days at 4 road construction sites; activities ranging from typical “mill and fill” (1.5 to 4 inches removal) to total removal (5 to 7 inches)	Local exhaust ventilation in milling drum housing [Water spray system at cutting drum]	Operator: A <2 to 13 µg/m^3 (N=11) Tender: A <2 to 10 µg/m^3 (N=11) 279 to 700 minutes	In bulk: 7 to 23% In samples: 4 to 14%	This configuration of local exhaust ventilation maintained all sample results below 25 µg/m^3 for both the operator and the tender	NIOSH EPHB 282-23a (2013), Document ID 4147, pp. v, 5-7, 13 Table 1
Sep-Oct 2012	9 days at 6 road construction sites milling depths up to 11 inches (NIOSH excluded Site 3 as atypical; it is also excluded here)	Local exhaust ventilation in milling drum housing [Water spray system at cutting drum]	Operator: 2 to 11 µg/m^3 (N=9) Tender: 4 to 24 µg/m^3 (N=9) 482 to 685 minutes	In bulk: 5 to 12% In samples: 2 to 9%	This configuration of local exhaust ventilation maintained all sample results below 25 µg/m^3 for both the operator and the tender	NIOSH EPHB 282-25a (2013), Document ID 4149, pp. v, 5-7, 13 Table 1

Notes:
[A]All results are from personal breathing zone samples. A ground man has the same duties as a tender. For both the operator and tender, the lowest sample result was below the limit of detection (LOD), reported by NIOSH as 2 µg/m^3 (large sample volumes made low LOD possible).

The findings presented by NIOSH are generally consistent with earlier international studies of LEV designed for dust control on large drivable milling machines. The European Agency for Safety and Health at Work reported on a cooperative effort between a road construction company, a road milling machine manufacturer, labor organizations, and a governmental group in the Netherlands. This effort resulted in a prototype LEV system for road milling machines, after attempts at using wet methods did not provide the desired results (Document ID 0945, pp. 17-20). A preliminary study by TNO Bouw (2002), also in the Netherlands, measured TWA exposure levels for a milling machine operator (Bovenmachinist) over a 5-day period. With the exhaust system fitted on the machine, exposures ranged from less than 4 μg/m^3 to 28 μg/m^3.[243] The study found similar results for workers on the ground (rear control operator) (Ondermachinist), with exposures ranging from less than 3 μg/m^3 to 29 μg/m^3 (Document ID 1184, pp. 5, 25, Table 11). A street sweeper cleaned up loose debris behind the milling machine when milling involved less than the full road surface depth (Document ID 1184, pp. 9, 16). This housekeeping step can improve the effectiveness of controls during milling operations. Echt et al. (2002) reported that airborne dust increased when a walk-behind milling machine (in this case a scabbler) passed over previously milled areas. Milling debris should be cleaned up prior to making a second pass over an area. This step prevents the milling debris from interfering with the seal between the machine and the pavement and minimizes the gap (equally important for drivable milling machines as for the walk-behind machine that Echt et al. evaluated in this study). Additionally, it prevents debris from being re-suspended and acting as another source of contamination (Document ID 0633, pp. 812-813).

Initially, the construction company in the Netherlands started with an asphalt milling machine with a 2-meter (approximately 79-inch) drum. Modifications to the milling machine included improvements to make the milling drum compartment airtight and to add an air exhaust system that kept the drum compartment under negative pressure. Ductwork carried the dusty exhaust air from the milling drum to the long conveyor extending out from the front of the milling machine (used to transfer milled material to a dump truck or reprocessing equipment). The conveyor was covered, so dusty air followed the path of the conveyor to its terminal transfer point, adding distance and elevation between the point of road milling and the point where dusty air was released to the environment. The TNO Bouw (2002) report suggests that certain wind conditions could blow dusty air back to the milling machine, increasing operator exposures to respirable

[243] The multi-day test period covered by this report encompassed work on wet and dry pavement (due to rainy and clear weather); still and breezy days; highway, residential, and bicycle path pavements; and asphalt road grinding to several depths, ranging from 2 centimeters (top layer of about three-quarters of an inch removed) to 25 centimeters (nearly 10 inches, involving total demolition/removal of the road surface and some of the supporting layers). Actual road milling occurred over 35 to 67 percent of each monitoring session. Monitoring took place for 3 to 4 hours per morning session, and 2 to 3 hours per afternoon session (8-hour TWA calculated based on both sessions for the day, typically a total of 6 to 7 hours). In most samples, 6 to 13 percent of respirable dust on the sample filter was quartz, although values as low as 2 percent and as high as 28 percent quartz were recorded.

dust and silica. Nevertheless, OSHA notes that all sample results obtained were well below 50 μg/m^3.

The European Agency for Safety and Health at Work's follow-up article reported on the same construction company in the Netherlands and indicated that the firm subsequently retrofit all of its front-loader milling machines (various models) with LEV to improve dust control company-wide. The article states: "Using unmodified machines, exposure measurements were between 0.02 and 0.290 mg/m^3 [20 and 290 μg/m^3]. This has been reduced to between 0.0019 and 0.017 mg/m^3 [1.9 and 17 μg/m^3] for machines fitted with the exhaust system" (Document ID 0945, p. 19).[244] The exhaust system resulted in a 94 percent reduction in the highest reported exposure levels, and OSHA concludes that comparable results could be achieved by using a similar dust extraction system on milling machines in the United States. The uncontrolled exposure levels are comparable to the values reported in the United States. As of 2010, LEV, like the system used in the Netherlands, is coming into production on several models of front-loading milling machines in the United States (Document ID 1231). Furthermore, the model of road milling machine that the construction company in the Netherlands initially retrofit with LEV is commercially available in the United States, and the company is able to similarly modify other models of milling machines (Document ID 0945, p. 19; 1184, p. 5; 2181, p. 24).

TNO Bouw (2002) suggested that other improvements could further reduce exposures by minimizing airborne dust blow-back. These improvements include: 1) redesigning the exhaust duct outlet over the conveyor so released exhaust air does not create turbulence that kicks up more dust from material on the conveyor; and 2) adding water spray nozzles to the exhaust discharge to suppress dust (Document ID 1184, p. 30).[245] Additionally, the construction company was reportedly testing filtration systems to capture dust in exhaust air to minimize blow-back on operators even in a head-on wind (Document ID 0945, p.

[244] Low value of 0.0019 [1.9 μg/m^3] is as reported by the authors (Document ID 4072, p. 19). The article does not specify whether these exposure levels are time weighted for 8-hour shifts.

[245] Based on previous experience with a modified sandstone milling machine, the report suggests a water application rate of 5 liters per 2 hours, equal to a little more than one half-gallon per hour (Document ID 1184, p. 30).

20). Although the LEV system tested more recently by NIOSH in the United States did not incorporate a filtration system, Table IV.5.8-E shows that NIOSH and the Silica/Asphalt Milling Machine Partnership were able to build on the earlier research to further reduce worker exposure levels (maximum exposure result was 24 µg/m^3) (Document ID 4147, pp. v, 5-7, 13, Table 1; 4149, pp. v, 5-7, 13, Table 1).

When needed, a greater depth of milling can be accomplished by making additional passes, each pass removing successive shallow layers. The study conducted by TNO Bouw (2002) included sites where the road was completely removed by repeatedly milling over the same area in a series of passes. For example, during Monitoring Day 2, TNO Bouw reported on two half-day milling sessions in which sequential passes each removed 1.5 to 5 inches (4 to 12 centimeters) of material. Quartz exposure concentrations ranged from 3 to 28 µg/m^3 (respirable dust concentrations were usually around 100 µg/m^3, ranging up to an LOD of 180 µg/m^3) (Document ID 1184, pp. 12-13). Although the milling machine operated only about half the time (47 and 53 percent of the monitoring sessions), these exposure results indicate that even if the machine had been operated for 80 to 85 percent of the time (as NAPA comments indicate is usual in the U.S., Document ID 3583, Tr. 2216-2217), exposure levels would still have been below 50 µg/m^3. To make this determination, OSHA calculated the ratio of 85 percent operating time to (average) 50 percent operating time (a factor of 1.7) multiplied by the highest exposure measured at this site (28) for a maximum result of 48 µg/m^3 for the road demolition job. This exposure calculation does not take into consideration the possibility that a milling machine operating 85 percent of the session could have completed the job in less time.

The NIOSH studies of LEV for drivable milling machines were conducted using large asphalt road milling machines (half-lane or wider) during a variety of conditions and cutting depths. OSHA finds that these studies offer compelling evidence that exposure levels at or below 50 µg/m^3 (and even below 25 µg/m^3) can be achieved for workers operating this type of equipment during typical shallow “mill and fill” type road milling. In addition, the NIOSH data indicates that deeper cuts can be effectively controlled to exposure levels below 25 µg/m^3 provided that the material being milled is asphalt alone.

Work Practices

In addition to milling, other pavement removal methods are available for road demolition work. As noted previously, Mr. Turek, representing the IUOE, noted that milling is just one way to accomplish roadway removal. Construction companies can choose other methods, such as cutting the roadway into manageable size pieces or squares with a drivable masonry saw and lifting the pieces out intact, creating "substantially less dust than other forms of road demolition, including grinding" (Document ID 3583, Tr. 2364-2365).

OSHA observes that removing asphalt roadways in large pieces can involve heavy equipment operations. See Section IV-5.3 – Heavy Equipment Operators and Ground Crew Laborers. Where the roadway is constructed of concrete, the demolition can also involve concrete drilling with a dowel pack. See Section IV-5.9 – Rock and Concrete Drillers.

Applicability of Additional Controls to Large Milling Machine Tenders

OSHA finds, and breathing zone samples show, that drum-level dust control methods can reduce airborne silica concentrations for milling machine tenders to a similar extent as they can for machine operators. Of the twenty samples summarized in Table IV.5.8-E for tenders working alongside large milling machines fitted with LEV, all but one are 13 μg/m^3 or below. The exception, the highest exposure for a tender (24 μg/m^3), is still below 25 μg/m^3.[246] In these studies, "ground men" managed the lower controls while walking alongside the road milling machines (duties within the scope of milling machine tenders).

When milling machines are fitted with LEV or appropriate wet dust suppression systems at the grinding drum, dust release is controlled at the source, i.e., at ground level. The IUOE urged OSHA to consider whether operators (on top of machines) and tenders (on the ground alongside machines) should receive separate consideration, as tender exposures can be higher (Document ID 2262, p. 24). OSHA agrees that during the

[246] References include Document ID 4147, pp. v, 5-7, 13 Table 1; 4149, p. 13, Table 1.

intermittent periods when tenders work immediately adjacent to the drum, they can experience greater exposures during uncontrolled milling than do operators seated on top of the machine. This means that controls on the milling drum that reduce exposures from that source can particularly benefit tenders, by reducing these peak exposures. Effective control measures of this type benefit workers in both job categories, but operators on top of the machines might continue to experience exposures from more diffuse sources, while the primary source of exposure for tenders can be minimized by drum-level controls. The studies by Van Rooij and Klaasse (2007) and TNO Bouw (2002) in the Netherlands, described previously, reported that tender exposures were reduced at least as much as operator exposures when effective controls were used (exposures for both were well below 50 $\mu g/m^3$). Van Rooij and Klaasse (2007) used a water spray system and foam additive to reduce mean exposure levels for asphalt milling machine operators to 20 $\mu g/m^3$ (range 9 to 30 $\mu g/m^3$) and for tenders to 8 $\mu g/m^3$ (range 4 to 12 $\mu g/m^3$) (Document ID 1216, p. 4, Table 1). Additionally, TNO Bouw (2002) measured TWA exposure levels for workers using a milling machine fitted with LEV and found operator exposure levels ranging from less than 4 $\mu g/m^3$ to 28 $\mu g/m^3$ and exposures among tenders (operating rear controls) ranging from less than 3 $\mu g/m^3$ to 29 $\mu g/m^3$ (Document ID 1184, p. 25, Table 11). OSHA finds that the additional controls that are effective for milling machine operators are at least as effective for the tenders of large drivable milling machines and that these two groups of workers (operators and tenders) do not require separate treatment during controlled milling. Furthermore, in response to comments presented by NAPA and IUOE, OSHA finds that during typical asphalt road milling, available control methods can manage silica exposures sufficiently that respiratory protection is not required for either operators or tenders (Document ID 3583, Tr. 2170; 4234, Attachment 1, p. 30).

Applicability of Additional Controls to Small Drivable Milling Machines (Cutting Tool Less than a Half-Lane Wide)

Both wet methods and LEV have potential to suppress or collect dust generated by small machines equally as well as they suppress or collect dust generated by large road milling machines. Differences in how the large and small machines are used, however, can influence how effective the controls can be on the smaller machines.

The cutting tools on large and small milling machines are generally similar in function (high-energy abrading tools), but, by definition, the tools are narrower and mill to shallower depths on the smaller machines. Many small road milling machines have the same form/shape as large machines, but are smaller, lower, narrower, and more maneuverable (Document ID 1229, pp. 1-3). In other cases the cutting tool is attached to an articulated arm on construction equipment that is better known for being used for other purposes, such as when a grinding attachment is fitted to the movable arm of an excavator, front-end loader, or small utility tractor (Document ID 0562, p. 633; 3958).

Water spray can suppress dust during a wide variety of high energy operations (see related sections of this FEA on additional controls in Section IV-5.5 – Jackhammers and Other Powered Handheld Chipping Tools; Section IV-5.6 – Masonry and Concrete Cutters Using Portable Saws; and Section IV-5.7 – Masonry Cutters Using Stationary Saws. Because small drivable milling machines remove the same material using similar grinding/grating/abrading actions as the large machines, OSHA finds that dust generated by both the small and large machines is similar and water dust suppression will be equally effective on both types of machines. Use of a surfactant additive will increase the effectiveness of wet dust control methods equally well for large and small drivable milling machines. A wet dust emission suppression system with surfactant additive reduced the PBZ respirable quartz exposures among asphalt milling machine drivers to a mean of 20 μg/m^3 (n = 4), with a range of 9 μg/m^3 to 30 μg/m^3. Milling machine tenders benefitted equally from the system, with a mean PBZ respirable quartz exposure of 8 μg/m^3 (n = 4) and exposures ranging from 4 μg/m^3 to 12 μg/m^3. Compared with a standard milling machine, which uses only cooling water (not aerosolized) on the blade, the use of the aerosolized water and foam system reduced the mean exposure for drivers and tenders combined by 97 percent. Without the added controls (i.e., cooling water only), the mean exposure for drivers was 418 μg/m^3 (n = 2) and the mean exposure for tenders was 509 μg/m^3 (n = 1) (Document ID 1216, p. 4, Table 1).

Water delivery systems are already available on some models of small milling machines (online catalog listing indicates that “weight of water” is included in the total weight listed for these small machines) (Document ID 1229, pp. 1-3), and water upgrade kits area also available for utility tractors with milling attachments. Water spray systems optimized for dust control are becoming an industry standard for large milling machines and can be produced for small drivable milling machines. In testimony on behalf of NAPA and the Silica/Asphalt Milling Machine Partnership, industry representatives agreed that controls using protocols similar to those used on large machines were being developed for small milling machines, although the effectiveness of the controls on the small machines has not yet been tested by the industry (Document ID 3583, Tr. 2213-2215). OSHA finds that wet dust control methods using a foam system will reduce the exposures of most small drivable milling machine operators (and their helpers) to 50 $\mu g/m^3$ or less most of the time.

Local exhaust ventilation may also be effective for small drivable milling machines. OSHA finds that small drivable milling machine specifications show that when workers operate smaller machines, dust is released from a smaller area (only the width and depth of the cutting tool housing) than the area from which dust is released using larger drivable machines. Similarly, a smaller amount of pavement material will be removed (again, only the width and depth of the cutting tool). Evidence comes from a manufacturer’s online catalog, which shows small and large milling machine specifications, and indicates that more than half of small road milling machines (five out of nine) have cutting tools that are 20 inches wide or narrower (although the largest is substantially wider at 48 inches). The same catalog indicates that the median depth that a small drivable machine can mill (8 inches) is less than the median depth a large milling machine can mill (13 inches); one-third of the listed small road milling machines can mill a maximum of 1 to 4 inches in depth (Document ID 1229, pp. 1-3). OSHA finds that the smaller machines have less total dust potential than larger machines, and that LEV can be an effective control for the smaller machines when used on flat surfaces. However, the smaller size of these machines could make it challenging for manufacturers to add an LEV suction device of sufficient capacity. OSHA is not aware of small drivable milling machines currently fitted with LEV systems (and OSHA notes that, as discussed earlier, LEV is only just becoming commercially available for large drivable milling machines in the United States). Large walk-behind milling machines with LEV are increasingly common and can be tethered to a substantial vacuum suction system supported by a separate movable cart (Document ID 1276, p. 2). However, OSHA anticipates that operators of small drivable equipment would find a tethered system inconvenient.

Applicability of Additional Controls to Drivable Machines Milling Concrete

OSHA examined differences between asphalt and concrete milling. As previously noted, exposures among operators milling concrete roads may be somewhat higher than exposures among operators during asphalt milling, although not necessarily to the extent suggested by the dry concrete milling data available to OSHA from the NJDHSS (Document ID 1699). As also discussed previously, a NIOSH trial using only drum cooling water and alternate spray nozzles showed elevated silica exposure levels when the road milling machine intermittently ground through the asphalt layer into an aggregate and concrete underlayment (Document ID 3798, pp. 2, 14).[247] Mr. Bodway (representing NAPA and the Silica/Asphalt Milling Machine Partnership) concurred, stating that exposures are higher in concrete milling than asphalt milling (Document ID 2181, p. 15).

While uncontrolled concrete milling may emit more dust, and possibly more respirable silica, than is emitted during uncontrolled asphalt milling, the integrity of the material (very hard, soft, crumbling) is likely an important factor for determining the amount of respirable dust generated per unit of volume milled.

OSHA finds that wet dust suppression methods are effective for respirable silica generated from either asphalt or concrete milling. Moreover, as explained by NIOSH, the source of the dust makes little difference in terms of the effectiveness of controls. Silica is a mineral, and the primary considerations for mineral particle dust suppression are particle size and "wetting," rather than the source of the mineral dust. As NIOSH explains:

> In the vast majority of cases for mineral processing operations, the wet suppression system used is a water spray system. Although the use of water sprays is a simple technique, there are a number of factors that

[247] Another reason for the elevated dust levels was the depth of the milling (up to 10.9 inches), creating an uneven surface during subsequent passes of the machine (Document ID 3798, p. 19, Table 7).

> should be evaluated to determine the most effective design for a particular application. There are two methods to control dust using water sprays at mineral processing operations: • Preventing dust from becoming liberated and airborne by directly spraying the ore. • Knocking airborne dust down by spraying the dust cloud and causing the particles to collide with water droplets and fall out of the air. ***When considering sprays, one of the primary aspects is the droplet size. ***Uniformity of wetting is also a very important issue for an effective system (Document ID 1539, pp. 34-35).

Water amended with a surfactant performs even better for dust suppression; surfactants are essentially equivalent to dish soap. The soap breaks the surface tension and softens the water, which allows the water to better encapsulate (i.e., wet) the particles (Document ID 1360, pp. 1-2). Based on this information, OSHA finds that both attention to spray droplet size and the use of surfactant will improve silica dust capture, regardless of whether the origin is asphalt or concrete.

OSHA also considers LEV to be equally as effective for controlling silica in concrete dust as it is for controlling silica in dust from asphalt paving material. Airborne respirable size particles behave similarly in air, regardless of their source (Document ID 4146, p. 3). OSHA notes that the physical properties of respirable silica dust, which behaves like a gas regardless of its material of origin, explain why respirable silica particles from concrete will be captured as effectively by LEV as respirable silica particles from asphalt.

Additional Controls for Walk-Behind Milling Machine Operators

Additional controls for walk-behind milling machine operators include LEV and improved water application, both of which are commercially available on walk-behind milling machines (Document ID 0524, pp. 1A-11, 2A-8; 0642, p. 1; 3959, pp. 39, 40). These controls function effectively for large milling machines, as described previously, and similar controls exist for walk-behind milling machines. Control measures used with large milling machines (wet methods and LEV) can be scaled down and should provide similar results for smaller equipment performing analogous activities (like grating, grinding, and polishing) under comparable working conditions (on generally flat surfaces with a minimal gap between the surface and machine). Tenders of large drivable milling machines often stand or walk adjacent to the milling drum box, just as a walk-behind milling operator would. The milling drum on a drivable milling machine is frequently 10 or more times wider than the milling drum on a walk-behind model, and removes correspondingly more material. Therefore, OSHA expects that controls for drivable milling machines will work at least as well for walk-behind machines, and, in fact, dust from the smaller walk-behind equipment might be easier to control.

Wet Methods

Wet methods are widely used to protect equipment on most types of milling machines, such as drivable milling machines, walk-behind machines used for grinding and polishing terrazzo, and some types of stationary stone milling equipment used in cut stone fabricating shops (see Section IV.4.4 – Cut Stone in this technological feasibility analysis). In tests of road milling equipment, NIOSH has shown that water spray on the cutting drum can offer effective dust control under some working conditions. Water spray adjusted specifically for dust suppression on milling machines results in better dust control than water applied simply to wet surfaces (Document ID 1216, p. 4). Water attachments for walk-behind milling machines can be a standard or optional feature, depending on the equipment (Document ID 0524, p. 1A-11; 0642, p. 1; 3959, pp. 39, 40).

As described in the earlier discussion of wet method controls for drivable milling machines, adding a dust suppressant to the water improves the results. Compared with a standard milling machine, which uses cooling water on the blade only (no spray aerosol), the use of an aerosolized water and foam system can reduce mean exposures for drivers and tenders combined by 97 percent (from 449 μg/m^3 to 14 μg/m^3) (Document ID 1216, p. 4).

ERG (ERG MTF-A, 2000) measured exposure levels below the LOD (12 μg/m^3) for workers using wet methods while milling a newly installed terrazzo floor indoors (Document ID 0200, p. 11, Table 1).[248] Echt et al. (2002)[249] tested a custom-built water-

[248] Exposure is reported as none detected (“ND”), with a limit of detection of 10 μg per sample, which results in an 8-hour TWA of 12 μg/m^3 for a sample obtained using a cyclone operated at 1.7 liters per minute: 1000 liters/m^3*10 μg)/(1.7 L/min*480 min)=12 μg/m^3.

[249] This same study also is published as NIOSH EPHB 247-15d (2002) (Document ID 0860).

fed system that provided a copious amount of water (15 gpm) to the concrete work surface (not the cutting teeth) milled by a scabbler with an 8-inch cutting width. The investigators compared results from alternating 5-minute periods of milling with and without the water-feed activated. The water reduced average respirable dust levels by at least 80 percent. Because of low filter loading, respirable dust was often below the LOD in samples associated with the water control, and none of these samples could be analyzed for silica. However, one measurable PBZ respirable dust level of 400 $\mu g/m^3$ was obtained during the wet process, and OSHA estimates that the silica concentration in that sample would be substantially lower (likely 52 $\mu g/m^3$ or less, based on the maximum of 13 percent silica content in the respirable dust collected on the filters during dry milling at this test site).[250] Measurements taken during similar brief periods of intensive dry milling found respirable dust levels of 13,000 $\mu g/m^3$ and 17,000 $\mu g/m^3$ (13 mg/m^3 and 17 mg/m^3), with silica values of 1,700 $\mu g/m^3$ and 2,100 $\mu g/m^3$. Work practices also contributed to the operator's exposure during the scabbler study because the worker generated the most airborne dust when passing the machine over a previously milled area (Document ID 0633, p. 811, Table I).

OSHA notes that the copious water flow of 15 gpm (equal to 1.9 gpm per inch of cutting width) used by the investigators may be impractical and probably more than necessary for walk-behind milling machines. In general, however, carefully directed spray nozzles that deliver an optimally sized water mist can achieve better dust suppression with substantially less water than indiscriminant water spray. A spray nozzle manufacturer explains that "in most operations, drops less than 200 [micrometers] µm do a better job of suppressing airborne dust particles, which are also very small" (Document ID 1152, p. 2). Recent experience with drivable milling machines demonstrates this point. NIOSH reports that under common road milling conditions, water spray provided to the cutting drum area at 12 gpm is capable of suppressing dust generated by a 7-foot wide (84 inches) drivable milling machine cutting drum (an application rate of just 0.14 gpm per inch of cutting width) (Document ID 1251, pp. 7-9, 14). OSHA concludes that, with

[250] OSHA calculated the percent silica in the respirable dust sample by dividing the weight of quartz in the 7-minute sample by the weight of the respirable dust in the same sample: (0.050 mg/0.39 mg)*100 = 13 percent.

careful adjustment, water spray methods using a fraction of the water used in the Echt et al. (2002) scabbler study should prove at least as effective in reducing silica dust exposures generated by scabblers. As a simple example, if the same "gpm per inch of cutting width" ratio holds for both drivable and walk-behind milling machines, then an estimated water mist application rate of 1.1 gpm (0.14 gpm x 8 inches cutting width) would be appropriate for the walk-behind 8-inch scabbler used in the Echt et al. (2002) study (Document ID 0633, p. 809). OSHA recognizes that differences in the way these machines function and other environmental factors (e.g., use indoors versus outdoors) might mean that this model for estimating water flow is too simplistic. However, even if the water application rate is doubled to compensate for these uncertainties, the resulting estimated flow rate needed for the 8-inch scabbler is 2.2 gpm.

As discussed previously in conjunction with drivable milling machines, Blute et al. (1999) evaluated silica exposures among workers using wet dust control methods for scabbling and large-scale grinding tasks at an underground construction site. In this case, rather than being walk-behind equipment, the scabblers and grinders were attached to the articulated arm of heavy equipment (Document ID 0562. p. 633 [front end loaders fitted with grinder/scabbler attachments]). Although these workers are classified in the Final Economic Analysis as heavy equipment operators (addressed in Section IV-5.3 – Heavy Equipment Operators and Ground Crew Laborers), and they used drivable machines (removing more material than the typical walk-behind milling machine), their work (scabbling and grinding excess concrete from tunnel walls) demonstrates the value of wet methods when these activities are performed in enclosed spaces. This is particularly relevant to walk-behind milling machines that are frequently used indoors to mill concrete surfaces. In the underground work environment, all three workers experienced task-based silica concentrations below the previous PEL.[251] The authors suggested that this was "most likely due to the use of hoses to wet down the concrete and the greater distance from the source of silica dust to the worker"[252] (Document ID 0562, p. 636).

[251] The PEL was calculated using OSHA's preceding general industry PEL equation for silica in respirable dust (Document ID 0562).

[252] Blute, et al. (1999) did not mention the presence of equipment cabs as a control, and so these might not have been available or did not influence exposures because windows were open.

Although one of the sample results (79 μg/m^3) exceeded 50 μg/m^3 (Document ID 0562, p. 637, Table III (scabbler)), these values are substantially lower than sample results available for workers performing dry milling of any type, even above ground. As discussed below, adding LEV near the scabbling and grinding attachments, or increasing general dilution ventilation, would likely have further reduced exposures for all three workers.

Local Exhaust Ventilation

Local exhaust ventilation is an effective dust control option for millers (and helpers) using walk-behind equipment. OIS contains six exposure results for millers and helpers using walk-behind equipment at two indoor construction sites. OIS records indicate that workers used LEV at both locations. At one site, where a second piece of milling equipment operated in the same room and the LEV system may not have been used properly, the operator experienced an exposure to respirable crystalline silica of 504 μg/m^3 (the highest level reported for a miller). At the second site, the operator used sequential levels of milling equipment while a helper moved hoses out of the way and vacuumed behind the walk-behind concrete grinder (preventing re-entrainment of milling debris). At this second site, all sample results for both workers were below the limit of detection (12 μg/m^3).

The similarity between vehicular and walk-behind milling machines also supports the use of vacuum dust collection (exhaust suction) methods for the smaller form of milling equipment. As discussed previously, the TNO Bouw (2002) study found that when exhaust suction methods were applied to the milling drum area of drivable milling machines, exposure levels for operators obtained over a five-day period ranged from less than 4 μg/m^3 to 28 μg/m^3. The study also found similar exposure results for machine tenders, who walked next to the machines; sample results ranged from less than 3 μg/m^3 to 29 μg/m^3 (Document ID 1184, p. 25, Table 11). Additional exposure sources for tenders include conveyors and transfer points, neither of which are components of walk-behind milling machines; instead, on these smaller milling machines, the vacuum suction immediately carries all dust and small debris into the vacuum cleaner where the air is filtered before release. However, operators of walk-behind milling machines can experience additional exposures when they empty the vacuum cleaner and clean or change the dust filter. This type of exposure is illustrated by, for example, a concrete finisher using a handheld grinder at a construction site evaluated by NIOSH, who cleaned the vacuum filter by shaking it and banging it on the wall. These actions likely created a second source of dust exposure (Document ID 0857, p. 4). To the extent that vacuum emptying and debris disposal methods contribute to milling machine operator exposures, work practices that limit silica dust released during these activities will also help limit operator exposures.

In a European study of control equipment (Hallin, 1983), walk-behind floor-milling machines equipped with dust extractors (i.e., LEV) were tested indoors. The study estimated a median concentration of 280 μg/m^3 for five short-term samples taken over periods of 10 to 60 minutes. The machine still released a substantial amount of dust into the surrounding environment, however (Document ID 1391, p. 28).[253] The authors indicated that the position of the air release from the pneumatically powered equipment and the milling tool cover design could both be changed to improve the working environment. In the same study, indoor silica concentrations measured over 1 to 2 hour periods ranged from 80 to 240 μg/m^3 for floor grinding machines used with large-scale dust extractors and grinding tool enclosures. The authors also noted a dramatically greater silica concentration of 2,300 μg/m^3 (35 minute sample) when the floor grinding tool housing cover was removed, such as would occur if the worker removed the housing cover because its design interfered with grinding (Document ID 1391, p. 25).

Equipment designed for use near a wall or with an edger attachment for use near vertical surfaces is commercially available, and a better choice for work at room edges (Document ID 0642, p. 1). Using a vacuum fitted with a high-efficiency particulate air (HEPA) filter would also minimize silica concentrations by filtering out airborne particles prior to releasing the air back into the work environment. An alternative would be to exhaust the vacuum air outside the workplace. In addition, recent research suggests

[253] The value of 280 μg/m^3 (reported as 0.28 mg/m^3) is the median quartz concentration measured for five combinations of large floor milling machines/scabblers equipped with milling tool covers and large-capacity dust extractors. The five individual measurements were <0.09 (two samples), 0.28, 1.6 and 6.9 mg/m^3 (Document ID 1391, p. 28).

that studies such as this one might not have used vacuum suction equipment that provided an adequate or consistent level of exhaust ventilation. As discussed in more detail in Section IV-5.11 – Tuckpointers and Grinders, construction sites that use LEV must choose a portable vacuum with the capacity and design to offer consistent vacuum suction. Many of the challenges associated with tuckpointing also must be addressed for construction sites where workers perform aggressive floor milling with walk-behind machines. Specifically, both of these construction activities generate a quantity of debris that can rapidly reduce vacuum suction. To prevent this, vacuum cleaner design should protect filters from rapid dust loading (by, for example, cyclonic pre-separation) and offer sufficient suction (measured in inches of water gauge) to move air even when filters begin to load (Document ID 0600, pp. 878 [see Dust Control vacuum], 879-Airflow measurement section (and relationship to static pressure), 882-Table IV, 883-Figure 7, 885 [see section on flow rate maintenance]).[254]

One milling machine manufacturer that produces walk-behind scabblers specifically for removing layers of contaminated concrete from floor surfaces recommends the use of a vacuum source that provides at least 75 to 90 cubic feet per minute (cfm) suction for a 6-inch wide scabbler. The contaminants mentioned by the equipment manufacturer (like lead paint and radioactive materials) generally have occupational exposure limits similar to the PEL for silica, suggesting that this rate of exhaust would also be effective for silica (Document ID 1276, pp. 1-2).[255] Proportionally greater exhaust rates would be required for larger walk-behind milling equipment. For example, another manufacturer of commercially available scabblers recommends specific vacuums for use with specific scabblers: a 160 cfm vacuum with a smaller scabbler and a 500 cfm vacuum with a larger scabbler (for which an industrial dust control vacuum system is recommended as an alternative) (Document ID 0636, p. 7). Some scarifiers, particularly those intended for

[254] The suction of an industrial vacuum is influenced by numerous factors, such as filter loading, hose clogs, and the vacuum fan's strength (ability to pull against static pressure). Document ID 0600 relates to tuckpointing, but the same principles apply to industrial vacuums used to capture dust from other construction tools that also generate substantial volumes of dust (including walk-behind milling machines).

[255] The same company produces a remote control option for their milling equipment, allowing the operator to work a greater distance from the abrasive action, or even to stand in another room (Document ID 1276, pp. 1-2).

indoor use, are available with both a vacuum port (for connecting to a portable industrial vacuum system) and a water mist system as standard equipment (Document ID 0642).

However, there are several limitations to the use of LEV-equipped walk-behind milling machines. First, the vacuum suction device needs to be emptied frequently. Workers might need to empty the dust extractor as frequently as every 30 minutes in some work environments; emptying the dust extractor requires shutting down the vacuum (Document ID 0599). A vacuum with a pressure gauge can alert workers when the vacuum needs to be emptied and filters need to be cleaned. Second, a vacuum powerful enough to support most common walk-behind milling machines will be large and heavy. A vacuum with a cyclonic pre-separator that achieves sufficient airflow to support a scabbler can weigh 100 to 200 pounds when full (based on a collection volume of 10 to 19 gallons of concrete debris (Document ID 0628, p. 45 [PDF p. 15] – see collecting volume row). Furthermore, when operating milling machines outdoors, the dust collector generally needs a generator for power, and workers might need to transport the generator with an additional truck or heavy handcart (Document ID 0600, p. 878 –Table I [vacuums are mainly electric]; 3959, pp. 41-42 [photos showing large vacuum systems used in manufacturers' initial test of walk-behind milling equipment]; 0628, pp. 3, 5, 17 [photographs of dust collector size/electric for walk behind grinder, all are electric powered], p. 24 [pneumatic (compressed air) powered vacuum available]). Although gasoline and propane powered models are available, electrical powered vacuums are most common. The need for both a large vacuum and an electrical generator to operate it can be an impediment to the use of LEV outdoors, so this option is less common for outdoor work. For example, an 8-inch walk-behind scarifier promoted for sidewalk trip hazard repair comes with "water misting system standard", although the equipment is also equipped with a vacuum port; alternate listed uses for the machine include concrete floor preparation (Document ID 0642, p. 1).

The effectiveness of vacuum suction also depends on minimizing the gap between the bottom of the machine and the surface being milled (as discussed previously). To achieve acceptable dust control, milling must proceed in a manner that limits the gap between the bottom of the walk-behind milling machine and the surface being milled, for example, the floor. Construction sites will find it difficult to control dust emissions if walk-behind milling machines remove excessive depth in one pass; the resulting drop between milled and unmilled surfaces prevents the milling machine from sealing properly against the surface, allowing dust to escape (Document ID 0555, p. 4). Workers can achieve better dust control during deep removals by milling to the final desired depth in several incremental phases. Hallin (2003) observed: “If these machines are to function satisfactorily, the floor surface must be flat and cleaned. The wheels may not be run over electric cables or other uneveness” (Document ID 1391, p. 26). Because milling can dislodge settled dust and create high levels of airborne dust, employers can further reduce exposures by using a HEPA-filtered vacuum to clean up any loose dust on freshly milled surfaces prior to making additional passes over the area (Document ID 0633, pp. 812-813; 1391, p. 28).

Finally, unlike drivable milling machines, walk-behind machines can be used indoors where natural ventilation is poor and the surface being milled is likely to be concrete. Under these circumstances, special precautions will be needed to prevent airborne silica dust from accumulating. Supplemental general exhaust ventilation (in addition to vacuum exhaust or wet methods), in the form of large fans set in open windows or exhaust trunks creating air exchange similar to an outdoor environment, will help prevent silica dust from collecting in the space.

Little information is currently available on LEV in controlling respirable quartz levels associated with walk-behind milling operations. OIS contains samples for a walk-behind milling machine operator and helper (moving hoses, vacuuming behind the milling machine), both of whom had exposure levels below the limit of detection of 12 µg/m^3, with no respirable dust detected in the sample. At another site a worker with an exposure level of 504 µg/m^3 used a walk-behind milling machine with LEV that was not performing well (another milling machine was also used in the same room) (Document ID 3958).

OSHA believes that evidence from similar construction tasks supports LEV’s value for workers performing milling. Although walk-behind milling machines are larger than tuckpointing grinders, the milling blades operate at lower speeds[256] (dust particles are released at lower energy), and the worker's breathing zone is a greater distance from the point of dust release. Thus, OSHA believes that the LEV-dust control option will work at least as effectively for milling machines as it does for tuckpointing grinders. Collingwood and Heitbrink (2007) reported a 95-percent reduction in silica exposures associated with the use of LEV for tuckpointing (geometric mean exposure of 1,140 $\mu g/m^3$ reduced to 60 $\mu g/m^3$). Although the tuckpointers using LEV still experienced a geometric mean of 60 $\mu g/m^3$, walk-behind milling machine operators have the advantages of lower uncontrolled exposure levels, greater distance between the tool and their breathing zone, and equipment that is self-supporting (making it easier to keep the milling drum enclosure sealed against the floor) rather than handheld (Document ID 0600, p. 880, Table II). Therefore, an LEV system with an appropriately sized vacuum will likely reduce most walk-behind milling machine operator exposures to levels lower than those experienced by tuckpointers.

Housekeeping

Exposures among workers using walk-behind milling machines can be further reduced by cleaning up debris. Echt et al. (2002) reported that airborne dust increased when the scabbler described previously passed over previously milled areas (Document ID 0633, pp. 812-813). Milling debris should be cleaned up using a HEPA-filtered vacuum prior to making a second pass over an area when using a machine equipped with a dust collection system. This step prevents the milling debris from interfering with the seal between the machine and the floor and minimizes the gap. Additionally, it prevents debris from being re-suspended and acting as another source of contamination. OSHA's OIS contains a sample for a helper who vacuumed behind the operator of a walk-behind floor grinder and scarifier (indoors) to prepare a concrete floor for repainting (Document ID 3958, Row 211). The sample result detected no respirable dust, indicating that vacuuming

[256] As an example, one type of walk-behind scabbler drum rotates at 1,753 rotations per minute (rpm) (Document ID 1149, p. 1) compared with 11,000 rpm for a tuckpointing grinder blade (Document ID 0567).

effectively cleaned up dust and debris left by the grinder, which otherwise might be re-entrained in the workers' breathing zones.

5.8.4 Feasibility Finding

Feasibility Finding for Drivable Milling Machine Operations

Feasibility Finding for Large Drivable Milling Machine Operators and Helpers

OSHA concludes that more than 70 percent of large drivable milling machine operators and helpers are currently exposed to silica levels at or below 50 μg/m^3. For workers who are currently exposed above 50 μg/m^3, the controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or below in most operations, most of the time. Therefore, OSHA finds that the standard is technologically feasible for these workers.

The construction standard at paragraph (c) requires employers operating large (one-half lane or wider) milling machines to implement the controls described in Table 1 unless they elect to assess and limit their workers' exposures in accordance with the more traditional regulatory approach contained in paragraph (d). The controls specified in Table 1 for cuts of four inches in depth or less are either: (1) use a machine equipped with exhaust ventilation on the drum enclosure and supplemental water sprays designed to suppress dust; or (2) use a machine equipped with supplemental water spray, combined with a surfactant, designed to suppress dust. For cuts of any depth when milling asphalt only, the control option specified in Table 1 is to use a machine equipped with exhaust ventilation on the drum enclosure and supplemental water sprays designed to suppress dust. When these controls are fully and properly implemented, TWA exposure levels are expected to remain at or below 50 μg/m^3 (Document ID 4147, pp. v, 6-7, 13, Table 1; 4149, pp. v, 5-7, 13, Table 1).

All of the major manufacturers of large milling machines currently provide dust-suppressing water spray systems on new equipment and as retrofit kits for older machines. In addition, as discussed previously, new machines will be equipped with both dust-suppressing water spray systems and LEV by 2017 (Document ID 2181, pp. 11, 21-29).

Based on the data in the record, OSHA concludes that exposures among large drivable milling machine operators can be reduced to 50 μg/m^3 or less most of the time. Sample results presented in the exposure profile Table IV-5.8-C indicate that 78.5 percent of all large drivable milling machine operators already experience silica levels at or below 50 μg/m^3 as a result of using water spray intended to cool the cutting drum. Similarly, exposure levels for 67 percent of tenders working alongside large milling machines are already below 50 μg/m^3. Based on the Agency's review of studies showing that low silica exposures can be achieved for both operators and tenders across varying water spray flow rates, OSHA concludes that improvements to cooling water spray systems can help reduce exposure levels of the remaining machine operators and tenders (those who currently experience exposures above 50 μg/m3) (see Tables IV.5.8-D and Table IV.5.8-E). However, information is insufficient to confirm that the use of water alone in existing systems will reliably control all workers' exposures. Based on the Agency's review of these and other studies, OSHA has determined that supplementing with a dust suppressant additive or with an exhaust ventilation on the drum enclosure will achieve levels at or below 50 μg/m^3 for all or almost all workers (operators and helpers) most of the time (see Table IV.5.8-E) (Document ID 1216, p. 4, Table 1; 4147, pp. v, 13, Table 1; 4149, pp. v, 13, Table1).

As discussed previously, a dust suppression system with a foam additive kept exposures below 30 μg/m^3, and the use of water sprays combined with LEV systems kept exposures under 25 μg/m^3 (Document ID 1184, pp. 5, 25, Table 11; 1217, p. 4, Table 1). OSHA concludes that these methods will control silica exposures among vehicular milling machine operators and tenders to 50 μg/m^3 or below during "mill and fill" operations under the typical range of conditions (e.g., day and night, warm and cool weather, asphalt and concrete road surfaces) when milling to a depth of 4 inches or less. OSHA also concludes that worker exposures can be maintained to 50 μg/m^3 or below when large milling machines equipped with both water-based dust suppression systems and LEV at the drum enclosure are used to make deeper cuts into asphalt material only.

Thus, OSHA concludes that the dust control measures specified in Table 1 can effectively reduce exposure to a 8-hour TWA of 50 µg/m^3 or less when operating large milling machines to mill asphalt or concrete.

Feasibility Finding for Small Drivable Milling Machine Operators and Helpers

OSHA concludes that 50 percent of small drivable milling machine operators and helpers are currently exposed to silica levels at or below 50 µg/m^3. For workers who are currently exposed above 50 µg/m^3, the controls described in this section can be implemented to reduce silica exposure levels to 50 µg/m^3 or below in most operations, most of the time. Therefore, OSHA finds that the standard is technologically feasible for these workers.

When following the control methods specified in Table 1, employers operating small drivable milling machines (less than a half-lane in width) on asphalt or concrete, are required to use machines equipped with supplemental water spray systems combined with an appropriate surfactant. When these controls are fully and properly implemented, TWA exposure levels for operators and helpers are expected to be 50 µg/m^3 or below.

Manufacturers of smaller drivable milling machines currently make such systems (Document ID 1229; 4073, Attachment 4a). Unlike for larger milling machines, however, Table 1 does not call for systems that combine water use with LEV, as it appears that such systems are not generally available currently.

Based on the data in the record, OSHA concludes that most of the time, construction employers can achieve exposure levels of 50 µg/m^3 or below for most workers operating small drivable milling machines or helping with that equipment. Fifty percent of these workers already have exposures of 50 µg/m^3 or below (Table IV.5.8-C). The similarities to large drivable milling machines are sufficient to indicate that the wet dust suppression control technology is transferable to the smaller drivable machines. Many of these machines are already fitted with water systems for cooling the cutting tool (Document ID 1229, pp. 1-3). Van Rooij and Klaasse (2007) showed that a wet dust emission suppression system used with a surfactant reduced the PBZ respirable quartz exposures below the action level (Document ID 1216, p. 4, Table 1). Even if these smaller machines do not achieve the same extent of dust suppression demonstrated for larger machines (because, for example, they perform specialty milling operations and not the flat "mill and fill" asphalt milling tasks typically performed by large drivable machines), the intermittent nature of operations for which small drivable milling machines are used will help to maintain worker 8-hour TWA exposure levels substantially lower than they would be for continuous operations (Document ID 3583, Tr. 2213-2215).

Feasibility Finding for Walk-Behind Milling Machine Operators

OSHA concludes that more than 80 percent of workers using walk-behind milling machines are currently exposed to silica levels below 50 μg/m^3. For workers who are currently exposed above 50 μg/m^3, the controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or below in most operations, most of the time. Therefore, OSHA finds that the standard is technologically feasible for these workers.

Employers following Table 1 when operating walk-behind milling and floor grinding machines have two control options. Employers can use a machine equipped with an integrated water delivery system that continuously feeds water to the cutting surface. When the tool is operated and maintained in accordance with the manufacturer's instructions to minimize dust emissions, this equipment is expected to maintain exposure levels to 50 μg/m^3 or below, indoors and outdoors. Alternatively, employers must use a machine equipped with a dust collection system recommended by the machine manufacturer; the dust collector must provide the air flow recommended by the manufacturer and must have a filter with 99 percent or greater efficiency and a filter cleaning mechanism. When these controls are fully and properly implemented, TWA exposure levels are expected to be 50 μg/m^3 or below. When using a machine equipped with a dust collection system indoors or in an enclosed area, exposures can be further reduced to 50 μg/m^3 or below by cleaning up residue after each pass with a HEPA-filtered vacuum.

Walk-behind milling machines are currently available with water systems (e.g., Allen Engineering, Document ID 0524; EDCO, 0642, p. 1; 4073, Attachment 4a [among relevant examples is the record for Intertool walk-behind grinder with water feed]), and with vacuum ports or complete LEV systems (e.g., Pentek, Document ID 1276; EDCO, 0636, p. 6; 0642, p. 1; 4073, Attachment 4a [among examples are records for walk-behind scarifier with vacuum, and CONTRx Pro-polisher with vacuum]).

Based on the data described above, OSHA concludes that most of the time when employers provide equipment with vacuum suction dust collection or a wet system, workers operating small, walk-behind milling machines or helping with the equipment will experience exposure levels at or below 50 μg/m^3 as an 8-hour TWA. OSHA draws this conclusion from its exposure profile (Table IV.5.8-C) and from success with dust controls for larger milling machines and for tuckpointing and grinding equipment. From the exposure profile, 10 of 12 8-hour TWA sample results were below 50 μg/m^3, with the two highest sample results at 80 and 504 μg/m^3. The highest reading was from a worker using a floor grinder equipped with an LEV system indoors, with another worker grinding nearby. Details are not available from the record on the type of LEV system used, whether the LEV system was maintained and used properly, or whether appropriate housekeeping practices were employed. OSHA finds compelling evidence that controls effective for drivable milling machines are adaptable to the smaller (and thus potentially easier to control) walk-behind milling machines.

Even in indoor environments, exposure levels at or below 50 μg/m^3 can be achieved for most walk-behind milling machine operators most of the time through the proper use of controls, including the use of high-flow rate vacuum systems intended to serve the milling equipment and general ventilation that promotes good air circulation in the space.

In summary, most milling operation exposures are currently at or below 50 μg/m^3. Where exposures are currently above 50 μg/m^3, OSHA finds that feasible control methods, as described previously, exist to reduce respirable crystalline silica levels to 50 μg/m^3 or below for most operations most of the time. Therefore, OSHA finds that the standard is technologically feasible for these workers.

5.9 ROCK AND CONCRETE DRILLERS

5.9.1 Description

This section covers workers who use vehicle-mounted drilling rigs to produce deep holes in the ground or in concrete. The holes typically range from 1 inch to more than 6 inches in diameter and can reach a few inches to more than 100 feet deep. The workers typically guide and activate drill bits from control panels mounted on their vehicles and remove a substantial volume of rock or concrete over the course of a shift. This section also covers roof bolters who work at construction sites (but not those who work in the mining industry) and use rig-based drills to produce holes in tunnels (both overhead and in wall surfaces), and workers who use dowel drills (also referred to as gang drills) with one or more drill heads to drill holes in concrete for the placement of steel supports (e.g., a four-gang dowel drill can drill four holes at once) (Document ID 2177, Comment B, pp. 35-36).

When drilling rock, workers typically use rigs that are vertically oriented and equipped to produce a deep hole through the addition of bit extensions. Drill bits can be solid or hollow. These track-, truck-, or trailer-mounted rigs are frequently equipped with compressed bailing air, which is continuously forced through a bit's hollow core (when available) to "bail" rock or concrete dust and debris from the bottom of the deep hole (Document ID 1431, p. 3-10).

To drill concrete, workers often use rigs that consist of an array of drills fixed to the maneuverable arm of a construction vehicle (e.g., backhoe, bulldozer, forklift) or purpose-built mobile machine. This permits the operator to produce a series of precisely spaced mid-size holes, typically with a pre-set depth of a few inches to 4 feet, at any orientation. As with rock drilling, the drill bits can be solid or have a hollow core through which compressed air or water is forced to clear the hole (Document ID 0813). Workers who use these rigs routinely use handheld compressed air nozzles to blow debris from completed holes (Document ID 0871, p. 6). As a standard practice, some types of rock or concrete drill bits (e.g., diamond tip) are water fed to improve function and extend the useful life of the bit (Document ID 1720, p. IV-473).

Although the equipment used for each type of drilling varies, OSHA preliminarily determined, in the PEA, that workers using drilling rigs of all types on rock and concrete could be analyzed together because the workers' activities have much in common and the general methods of silica control are similar (Document ID 1720, p. IV-473). The Construction Industry Safety Coalition (CISC) objected to this grouping, commenting that the workers use different equipment, perform different tasks, and have different levels of exposure (Document ID 2319, Attachment 1, p. 59). CISC argued that OSHA did not analyze how relevant variables impacted baseline exposures (Document ID 2319, Attachment 1, p. 59). CISC contended that exposures would vary depending on the type of hole drilled, the substrate being drilled, and the location of the hole being drilled (Document ID 2319, Attachment 1, p. 59).

OSHA agrees that exposures vary based on differing workplace conditions, and the exposure profile contained in this section reflects a wide variety of those varying conditions. In addition, the studies and activities described in this section, which OSHA has used to make its final feasibility determinations, are representative of the variety of worker activities and the range of exposure conditions that typically occur in this industry. OSHA has determined that the general methods of silica control (ventilation, wet methods) for rock and concrete drilling are similar enough, despite some variability, to be addressed together in this section. An additional discussion of the impacts of varying workplace conditions on baseline exposures is presented in the subsection below (Section IV-5.9.2).

The National Association of Home Builders (NAHB) commented that workers in some job categories in the home building industry are exposed to silica because of their concrete drilling work, including electricians, HVAC installers, plumbers, carpenters, and rock/well drillers (Document ID 4220, pp. 7-10). OSHA agrees that these workers can be exposed to silica during the tasks identified by the NAHB; however, only those workers using rig mounted drills are addressed in this section. Other types of hand held drilling is addressed in Section IV-5.4 – Hole Drillers Using Handheld or Stand-Mounted Drills.

Workers using drilling rigs position and operate the drill rigs from control panels mounted on the vehicles or rigs. These workers may also perform intermittent tasks near the drilling point, such as fine-tuning the bit position, moving debris away from the drill hole, or working directly or indirectly with compressed air to blow debris from deep within the holes. Workers using drilling rigs can be exposed to dust generated by the action of the drill bit and to dust raised by bailing air or a compressed air nozzle. Although rig-based drilling is often a one-person job, some of the associated activities, such as fine-tuning the drill position and clearing debris from in or around the holes, can be performed by a second worker (Document ID 0908, p. 1; 1563, p. 3). OSHA received no comments regarding this description of job duties or tasks that pose potential silica exposure hazards and therefore adopts the description for purposes of this final analysis. Table IV.5.9-A presents job categories, major activities, and sources of silica exposure for workers using drilling rigs.

Table IV.5.9-A
Job Categories, Major Activities, and Sources of Exposure of Workers Using Rock and Concrete Drilling Rigs

Job Category*	Major Activities and Sources of Exposure
Worker Using Drilling Rigs	Position and operate drill rigs from control panel mounted on vehicle or rig. • Dust from action of drill bit. Adjust bit position. • Dust from action of drill bit and bailing air or compressed air nozzle. Clear tailings and dust from in or around the hole, during or after drilling. • Dust raised by bailing air or compressed air nozzle.

* Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.
Sources: Document ID 1720, p IV-474; 1431, p. 3-10.

5.9.2 Exposure Profile and Baseline Conditions

In the PEA, OSHA reviewed 39 exposure results associated with rock and concrete drilling. These results were from four OSHA SEP reports, four NIOSH investigations, unpublished data from a state health department, and a published article (Document ID 0022; 0034; 0090; 0226; 0228; 0512; 0784; 0904; 0908; 0912). These results involved various drilling rig configurations, including track-mounted rigs drilling holes 80 feet deep through granite and multi-drill sets (dowel packs) drilling a few inches into concrete

(Document ID 1720, p. IV-474). The sites where the samples were taken ranged from a concrete highway repair construction site to a 10-acre rock excavation site where drilling rig operators produced blast holes during demolition (Document ID 0022; 0034; 0090; 0226; 0228; 0512; 0784; 0904; 0908; 0912).

In the exposure profile presented in Table IV.5.9-B, OSHA supplements these data with one exposure result from the OSHA Information System (OIS) (for a worker operating an EZ Drill with an attached dust collector while drilling holes in concrete during highway/street construction work) and 11 sample results from two NIOSH reports (Document ID 3958; 4152, p. 14; 4154, p. 17). At the first site visited by NIOSH, two workers each operated a 4-drill slab-riding dowel drill equipped with a dust collection system to drill holes into a concrete runway (Document ID 4154, p. 4). At the second site, three workers drilled holes into a concrete runway with no controls in place. One worker operated a Minnich 4-drill, on-slab dowel-pin drill, while each of the other two workers operated an EZ Drill 4 drill, on-slab dowel-pin drill (Document ID 4152, p. 4). Samples were taken over multiple days at both sites.

Upon reviewing the data in the record, OSHA has determined that working conditions for construction workers (drillers as well as laborers) using drilling rigs vary from job to job. Significant sources of variability for both rock and concrete drilling include:

- The substrate being drilled (rock or concrete);
- The silica content of the substrate (silica levels often vary by 20 to 50 percent from site to site, with the greatest variation occurring between different types of rock);
- The type of hole being drilled, which influences the type of bit used (water-fed diamond/coring bits cut more slowly but are preferred when workers need to minimize chips and fractures in the substrate [“spalling”]);
- The work location and proximity of other activities (including whether the location requires dust emissions control and whether these controls are used effectively); and
- Whether the rig has an enclosed cab (Document ID 1720, pp. IV-474 – IV-475).

The National Ground Water Association (NGWA) stated that varying work conditions impact potential exposures, noting that silica exposure levels can vary during the water well drilling process depending on the geologic formations encountered (Document ID 1983, p. 1).

In the PEA, OSHA preliminarily determined that baseline conditions for workers using drilling rigs include a range of conditions, from no dust controls to systems that integrate one or more of the following: dust extraction (in the form of local exhaust ventilation [LEV]), wet methods at the drill hole, and dust management techniques (such as enclosure and wet methods) at the point where the system ultimately dumps extracted dust (Document ID 1720, p. IV-475). Based on conversations with industry sales representatives, OSHA also determined that water-fed bits are used frequently for many types of drilling, but dust extraction systems and augmented water pumps are less common (Document ID 1720, p. IV-475; 0625; 0813; 0814).[257] In light of that information, OSHA noted that the industry profile in the PEA may have underestimated the proportion of workers using drilling rigs that might require controls.

OSHA received many comments related to the baseline conditions among rock and concrete drillers. CISC noted that it is more common to use wet methods than it is to use dust collection systems when operating vehicle-mounted drilling rigs for rocks (Document ID 2319, Attachment 1, pp. 108-109). A number of other commenters noted the prevalence of using wet methods in the industry (e.g., Document ID 1983, pp. 1-2; 2116, Attachment 1, p. 33; 3496, p. 6). For instance, the Concrete Sawing and Drilling

[257] OSHA reported in the PEA that conversations with drilling rig manufacturers indicate that it is rare for new rigs to be ordered with the upgraded water pumps that permit optimal water flow for dust control (the water pumps provided as standard equipment support only water-fed bits, but not other uses, such as water mist spray in dusty areas above ground, for which a pump upgrade is helpful) (Document ID 1720, p. IV-475; 0625; and 0813). In contrast, hollow-core bits are relatively common in certain sectors of the rock drilling industry, such as for core drilling in granite, and when diamond-tipped bits are used, some water is added to the bailing air to protect the bit. Rock-drilling rig customers, however, rarely purchase the more versatile pumps that permit more than a minimal amount of cooling water to be added (Document ID 1720, p. IV-475; 0625). Water-feed kits for concrete drilling rigs are also purchased infrequently, in part because the process often requires up to 1 to 3 gallons of water per minute. One manufacturer indicated that these water-fed systems are used primarily in underground construction operations (Document ID 1720, p. IV-475; 0813). Furthermore, although diamond-tipped bits are more likely to be hollow, the slower action of these bits reduces their popularity (Document ID 1720, p. IV-475; 0814). Finally, among employers purchasing concrete drilling rigs, water-fed systems are being phased out in favor of dust collecting equipment.

Association (CSDA) commented that nearly 100 percent of CSDA contractors use water on every job in order to prolong the life of the diamond blade (Document ID 3496, p. 6). The National Ground Water Association (NGWA) noted that it is industry practice when drilling water wells to use foam as a wet control method:

> Industry practice is to use the engineering control of soap injection where water is mixed with foam. The foam mixtures of water and foam products are effective in mitigating the hazard of dust when properly used as they can carry particles ranging from .03 mm to the size of a quarter. There are multiple manufacturers of the foam products and these products have been approved for use when drilling sanitary water wells. The foam agents are NSF approved and have also been approved for use in many states (Document ID 1983, pp. 1-2).

NGWA also explained that all rotary drilling machines have been equipped with some type of water injection system since the early 1970s (Document ID 1983, p. 2).

The exposure profile in Table IV.5.9-B includes 23 samples of respirable crystalline silica for workers using drilling rigs with no controls (Document ID 0090, pp. 6-7; 0846, p. 7; 0904, p. 4; 0908, pp. 8-9; 0912, p. 12; 4152, p. 14). These results, summarized in Table IV.5.9-B, include 8-hour time-weighted average (TWA) exposure levels obtained at seven worksites for 18 workers using concrete drilling equipment and one worker using a rock drilling rig. These data indicate that in the absence of controls, 21.7 percent of these workers have silica exposure levels of 50 μg/m^3 or less, and 56.5 percent are exposed to levels above 100 μg/m^3. Substantially lower exposures have been reported for workers who use drilling rigs fitted with one or more features that reduce exposure, such as some form of wet methods, air exhausted from the bit entry point, or an enclosed cab. The data available to OSHA for workers using controls included sample results for 22 workers summarized in the PEA, one sample result (12 μg/m^3) from the OIS, and 4 sample results from a NIOSH EPHB submitted to the docket (Document ID 0022, pp. 8-10; 0034, pp. 23-44, 113-117; 0226, p. 11; 0228, p. 9; 0512; 0784, pp. 211-213; 3958, Row 809; 4154, pp. 15-17). Of the 27 sample results for drillers using controls, approximately 78 percent were below 50 μg/m^3. Just two (7.4%) of the 27 workers experienced exposures exceeding 100 μg/m^3 (Document ID 0784, p. 213; 4154, p. 17).

Overall, the final exposure profile shows that 27 of the 51 workers (53 percent) who use drilling rigs, with or without any controls, have exposure levels of 50 µg/m^3 or below.

The highest exposure for this job category (1,190 µg/m^3, based on an 8.5 hour sample) is associated with a drilling assistant who stood at the back of the rig to help position the drill during a highway construction project (Document ID 0908, p. 8). Other results for this job category are substantially lower, but still often exceed 100 µg/m^3 when dust controls are ineffective or not used. For example, an 8-hour TWA value of 540 µg/m^3 was reported for a drill operator dry drilling, with the dust collection system out of operation, to produce holes in rock that contained 17 to 42 percent quartz. This 8-hour TWA was based on a result of 800 µg/m^3 collected over 324 minutes (Document ID 0904, p. 4). Not unexpectedly, some of the lowest concentrations were associated with the use of dust controls at the drill hole. Results of 12, 31, 35, and 54 µg/m^3 were reported for workers who spent their entire shifts operating or assisting with drilling rigs fitted with water feeds or vacuum dust collection (or both) (Document ID 0034, pp. 23-26, 35-37, 39-42; 0228, p. 9).

OSHA was not able to obtain information on exposures among roof bolters (a type of drilling rig operator) at U.S. construction sites; however, mining data reviewed by NIOSH showed that, in coal mines, 70 percent of respirable dust samples for roof bolters in the United States contain more than 5 percent silica, with 25 percent of those samples (or 17.5 percent of total samples) exceeding 100 µg/m^3. NIOSH suggests that exposures from adjacent sources of silica dust could have caused the elevated exposures (Document ID 0711, p. 1). Although roof bolters work underground and most other drilling rig operators work above ground, the percentage of roof bolters exposed to silica at levels above 100 µg/m^3 is similar to, but slightly less than, the percentage of rock and concrete drillers exposed at those levels. Table IV.5.9-B shows that 29 percent of rock and concrete drillers experience exposure levels greater than 100 µg/m^3. Data available to OSHA shows that dust in drilling rig operator samples also routinely exceeds 5 percent silica (Document ID 1720, p. IV-476).

Roof bolter exposure levels may be generally comparable to the exposures of other drilling rig operators because, even though roof bolters work underground, ventilation is routinely installed at tunnel construction sites and roof bolters regularly use engineering controls, such as vacuum suction collector boxes. See Section IV-5.12 Underground Construction Workers for more detail on tunnel work and the associated ventilation requirements. Poor ventilation during these tasks, however, could result in higher exposures, as suggested by data submitted by the New York State Laborers' Health and Safety Fund (NYSLHSF) from a tunnel project in New York City. This study reported silica exposures for workers drilling and placing rock anchors. As noted in the study, ventilation for these workers was poor because they worked opposite the road header machines (RHMs) with the tunnel air always diverted to the RHMs (Document ID 3759, Attachment 1, p. 6). OSHA appreciates the summary exposure data submitted by NYSLHSF, but is unable to include the data in the exposure profile for drilling rig operators. The data provided is in summary form rather than as individual data points or TWAs, and OSHA could not determine exposures because no total respirable dust, percent of silica, or sample times were provided.[258]

CISC commented that the exposure data that OSHA relied on for rock and concrete drillers in the PEA was flawed and did not support OSHA's conclusions in its exposure profile and technological feasibility study (Document ID 2319, Attachment 1, pp. 59-62). Specifically, CISC argued that the majority of all samples were from the Linch (2002) study, which was based on just two construction worksites where concrete drilling was performed without dust control measures or enclosed cabs (Document ID 2319, Attachment 1, p. 59). OSHA notes, however, that the nine sample results taken from the Linch (2002) study are among a total of 51 sample results for operators of rock and concrete drilling rigs represented in OSHA's exposure profile. These 51 sample results are drawn from 13 reports and reflect exposure measurements taken at at least 14

[258] The data in this study was calculated using the OSHA General Industry PEL calculation ($10mg/m^3/\%SiO_2$ +2) and not the appropriate construction PEL (250 mppcf/$\%SiO_2$+5, where mppcf = million particles per cubic foot). In addition, rather than providing the PEL in a unit of measure (i.e., mg/m^3), which would differ for each sample under the calculation method, the commenter adjusted all the PELs to a standardized value of 1.0. (Document ID 3759). Because of this, OSHA is unable to identify actual quartz concentration values or calculate exposures for inclusion in the exposure profile.

construction sites visited by OSHA, NIOSH, or the State of New Jersey (Document ID 0784).[259]

CISC also believed that a number of the sample results used in the PEA were based on sample times of less than eight hours and therefore underestimated exposures. For instance, CISC argued:

- The NIOSH study (Breckenridge, 1992) consisted of only one 5.5 hour personal breathing zone (PBZ) sample, so if the worker had worked an eight-hour day, he would have been exposed at a level 16 times the PEL.
- The NIOSH study (Shelly, 1995) presented sample results ranging from 160 μg/m^3 to 1,190 μg/m^3 even though the drill was broken down for up to two hours each day.
- Exposure results presented in NJDHSS, 2000 were well over the proposed PEL for sample times of under five hours.
- The NIOSH road demolition study (Document ID 0226) consisted of only one sample, with a result less than 20 μg/m^3, but the worker only drilled for 20 percent of his time during the 7-hour sampling period (Document ID 2319, Attachment 1, pp. 59-60).

OSHA disagrees that any of these sample results underestimate exposures, noting that the amount of time workers spend using drilling rigs varies from day to day and job to job. The majority of the worksite samples presented in these studies fairly represent the exposures of workers drilling for more than half a day, but less than a full day. OSHA believes that the sample result from the NIOSH study, ECTB-233-120c, 1999, fairly represents the exposure of a worker who accomplished the necessary drilling in under 2 hours and spent the rest of the day performing other tasks (Document ID 0226).

CISC further argued that the one sample from the NIOSH study, ECTB-233-122c, 1999, was 31 μg/m^3, even though the sample was taken on a day that it rained and copious amounts of water and LEV were used (Document ID 2319, Attachment 1, p. 60; 0228).

[259] Other documents used to develop the exposure profile are Document ID 0022, 0034, 0090, 0226, 0228, 0512, 0846, 0904, 0908, 0912, 3958, 4152 and 4154.

OSHA notes that drilling occurs in all types of weather and believes that this sample represents the types of exposures that can occur in wet weather.

Finally, CISC was concerned about OSHA's reliance on NIOSH EPHB-334-11a, 2008 in assessing the effectiveness of LEV because the study was performed at the equipment manufacturer's plant and, according to CISC, was "not based on real-work conditions." CISC also criticized that study on the grounds that it evaluated only one piece of equipment, with a short drilling time, and collected only one area sample and no PBZ samples (Document ID 2319, Attachment 1, pp. 60-61, 0871). OSHA recognizes that the NIOSH EPHB 334-11a, 2008 study report evaluates an LEV system under controlled conditions; the study provides an estimate of the effectiveness of a 2008 commercially available LEV system and offers recommendations for improving the effectiveness of this control method. While the report contributes to the body of knowledge on control options, OSHA did not include the exposure results from this study in the exposure profile due to the experimental nature of the evaluation.

As noted above, OSHA based the exposure profile in Table IV.5.9-B on the best available data. OSHA reviewed all exposure studies submitted to the docket for inclusion in the exposure profile. While only two of those studies provided sufficient detail for inclusion in the profile (sampling time, respirable dust concentration and percent silica), those that were not included do generally support the profile.

OSHA considered several studies on workers performing dowel drilling operations on highways or runways: two where no controls were used and one where LEV was used. In the first study where no controls were used (NIOSH EPHB 347-14a), NIOSH collected PBZ samples for two workers operating four-gang dowel drills to drill holes in new concrete runways over a three day period. NIOSH reported six TWA crystalline silica sample results in this study ranging from 22.1 μg/m^3 to 675 μg/m^3, with a geometric mean exposure of 120 µg/m^3 (Document ID 4152, pp. 13-14).[260] Exposure results from this study were found to contain suitable data for inclusion in the profile. In the other study where exposure controls were not used, Valiante et al. reported two 8-hour TWA sample results of 50 µg/m^3 and 160 µg/m^3 for workers performing dowel drilling operations during highway repair (Document ID 3508, p. 878). Upon further review, OSHA determined that this information was already included in the exposure profile as part of the data contained in the NJDHSS 2000 Update of Silica Sampling Conducted under the New Jersey Silica Partnership (Document ID 0912).

In the study where exposure controls were implemented (NIOSH EPHB 347-16a), NIOSH collected PBZ samples for two workers operating four-gang dowel drills to drill holes in new concrete runways over a three day period. In this study, the dowel drills were equipped with LEV (each of the drill bits was surrounded by a close capture hood at the work surface). Respirable quartz exposure levels for these workers ranged from 24 µg/m^3 to 420 µg/m^3, with a geometric mean exposure of 130 µg/m^3 (Document ID 4154, p. 25).[261] Although these silica exposure levels were similar to those in NIOSH EPHB 347-14a, mentioned above, NIOSH reported that the average quartz content of the concrete in the runway at the site where LEV was used was over 4 times higher than that of the runway in the study where dust controls were not used (41 percent compared to 9.1 percent) (Document ID 4154, p. 25). OSHA determined that the exposure results contained in this study were suitable for inclusion in the profile.

Comparing TWA respirable dust exposures at the two sites, however, shows a significant reduction in exposures at the site that used LEV (exposures ranged from 38 µg/m^3 to 490 µg/m^3) compared to the site with no controls (exposures ranged from 445 µg/m^3 for a 501

[260] This study includes sample times ranging from 6 hours to over 10 hours. For those results where the sample time was less than 8 hours (three of the six results), the results are presented here as 8-hour TWAs (study authors assumed no exposure during the unsampled period). For those results where the sample time exceeded 8 hours, the results are presented as TWAs for the sampled time period. The geometric mean is based on the TWAs for the sampled time period.

[261] This study includes sample times ranging from 106 minutes to just over 8 hours. For those results where the sample time was less than 8 hours (four of the five results), the results are presented here as 8-hour TWAs (study authors assumed no exposure during the unsampled period). For those results where the sample time exceeded 8 hours, the result is presented as a TWA for the sampled time period. The geometric mean is based on the TWAs for the sampled time period.

minute sample, to an 8 hour TWA of 15,900 µg/m^3) (Document ID 4152, p. 13; 4154, p. 14). Although the studies demonstrate the potential effectiveness of controls, they also suggest that the exposure profile contained in the PEA may have underestimated exposures during drilling operations at sites where the rock or concrete has particularly elevated silica content. Inclusion of this new data in the FEA gives OSHA a more accurate representation of current exposures on which to base its technological feasibility analysis.

James Callahan of the International Union of Operating Engineers (IUOE) suggested that another NIOSH study of interstate highway repair, which was summarized in a 1996 NIOSH Alert, should be considered as relevant to rock and concrete drilling activities (Document ID 2262, p. 17). OSHA notes that data from this NIOSH Alert (obtained by NIOSH as part of a series of Environmental Surveillance studies conducted by NIOSH's Division of Respiratory Disease) are already included in OSHA's exposure profile discussed above.

The Concrete Saw and Drilling Association (CSDA) submitted data in the form of its Best Practices Silica Data Analysis chart, which is based on data collection from member jobsites and from NIOSH (Document ID 3497, p. 1). Patrick O'Brien of CSDA explained that the chart is based on all sawing and drilling data CSDA has collected over the last decade (Document ID 3585, Tr. 2900, 2907). OSHA commends CSDA (and BCTD) for taking a proactive stance in listing operations, control methods, and exposure levels. OSHA notes that much of the exposure data included in the CSDA matrix is drawn from NIOSH reports, which have been extensively reviewed by OSHA. Relevant exposure data from the NIOSH reports are included in OSHA's exposure profile. CSDA indicates that its members also contributed exposure data to this matrix, and OSHA agrees that this data might not be in its exposure profile; however, OSHA observed that none of the data in the CSDA matrix is specifically attributed to any source, so it is not possible to differentiate member data from NIOSH data already in OSHA's exposure profile. Furthermore, the CSDA matrix does not specify units of measurement; it appears (based on the accompanying NIOSH recommendations for respiratory protection) that the results column presents 8-hour TWA silica exposure levels in mg/m^3. For these reasons, OSHA has not included data from the CSDA matrix in the FEA exposure profile. However, the Agency finds that the data is supportive of the profile. For instance, the chart presents two exposure results for rock drilling (one with no controls and the other occurring in the rain with the drill rig equipped with a water supply). The exposure level with no controls was 66 μg/m^3 while the exposure level for the operation with a water supply was 31 μg/m^3 (Document ID 3497, p. 2) (as noted above, the units were not specified in the CSDA matrix; rather, OSHA made assumptions about the units based on NIOSH recommendations for respiratory protection). These exposure levels are consistent with the exposure profile in Table IV.5.9-B.

In its comments, CISC disagreed that the underlying data shows that rock and concrete drillers could meet the proposed PEL of 50 μg/m^3 in most operations most of the time. CISC believed that the exposure profile was flawed due to limited sampling times, and argued that OSHA had not considered dowel drilling operations in its analysis (Document ID 2319, pp. 20, 59-62). OSHA does not agree with CISC's position. As outlined in this chapter, OSHA based its exposure profile on the best available evidence and presented numerous additional studies that, while lacking sufficient detail for inclusion in the exposure profile, generally supported the profile. OSHA also summarized several studies in this chapter (including those considered in the original PEA and those submitted to the docket during the comment period) illustrating the effectiveness of controls (Document ID 0598; 0712; 0785; 0871; 0967; 1563; 1720; 3613; 3756, Attachment 9; 4150; 4151). In addition, several studies considered in this chapter address dowel drilling operations and found that the use of LEV when dowel drilling can significantly reduce exposures. However, OSHA recognizes that the available sampling data on dowel drilling operations indicate that use of LEV does not, in most cases, reduce exposures to or below 50 μg/m^3 (Document ID 0871; 1720; 3508; 4150; 4151; 4152; 4154; 4155).

Table IV.5.9-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Construction Workers: Drilling Rig Operators, Rocks/Concrete

	Exposure Summary			**Exposure Range**			**Exposure Profile**				
Drilling Rig Operators, Rocks/Concrete	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**		**<25 (μg/m³)**	**≥25 and ≤50 (μg/m³)**	**>50 and ≤100 (μg/m³)**	**>100 and ≤250 (μg/m³)**	**>250 (μg/m³)**
Worker Using Drilling Rig (No Controls)	23	211	125	12	1,190		2 (8.7%)	3 (13%)	5 (21.7%)	7 (30.4%)	6 (26.1%)
Worker Using Drilling Rig (One or More Controls)	27	44	20	5	420		16 (59.3%)	5 (18.5%)	4 (14.8%)	1 (3.7%)	1 (3.7%)
Other	1	12	12	12	12		1 (100%)	0 (0%)	0 (0%)	0 (0%)	0 (0%)
Drilling Rig Operators, Rocks/Concrete Total	**51**	**118**	**50**	**5**	**1,190**		**19 (37.3%)**	**8 (15.7%)**	**9 (17.6%)**	**8 (15.7%)**	**7 (13.7%)**

Notes: All samples are PBZ results and represent 8-hour time-weighted average exposures.
Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.
Percentages may not add to 100 percent due to rounding.

5.9.3 Additional Controls

The exposure profile in Table IV.5.9-B shows that almost half (24 out of 41 samples) of drilling rig operators (rocks/concrete) have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Additional controls for workers using drilling rigs could include environmentally controlled cabs for operators; more consistent use of wet methods specifically adjusted to maximize dust control; optimized dust collection systems involving adequate exhaust air, effective shrouds and shroud placement, and appropriate filtration; and worker position (staying out of the dust plume) (Document ID 1720, p. IV-478). In addition, OSHA finds that, when used together, wet methods and dust collection systems benefit workers as they perform all activities associated with rock drilling rigs.[262] Reducing workers' reliance on compressed air for cleaning holes will minimize another notable source of silica exposure. Worker exposures will be further reduced by supplemental controls on dust collector discharge points and the use of remote control devices that give operators the freedom to adjust their positions within the local work area.

CISC asserted that the data show that drillers cannot meet a PEL of 50 μg/m^3 in most operations most of the time and stated that OSHA provided limited or no evidence of the effectiveness of controls for drillers (Document ID 2319, pp. 59-62). OSHA does not agree. The following summaries demonstrate that wet methods and ventilation are capable of providing significant reductions in exposure to silica dust and that even greater reductions are experienced when these controls are used in conjunction with one another.

Wet Methods

Historically, construction and mining investigators have reported dust control efficiencies of 96 to 98 percent through the routine use of wet dust suppression methods, depending on the methods used; however, the water flow necessary for dust control created

[262] NIOSH commented that wet methods should not be used with a dust collector for concrete drilling rigs due to the fact that the water would add weight to the concrete dust and potentially cause it to solidify, clogging the dust control (Document ID 2177, Comment B, p. 34). Therefore, OSHA is only recommending this control for use with rock drilling.

problems under certain working conditions (e.g., moisture shortening life of certain drill bits [such as tricone roller bits], high-pressure water causing spalling of the drill hole wall) (Document ID 0967). Advances in recent decades have produced equipment that permits workers to use wet methods in a wider range of circumstances. New “water separator sub” designs extend bit life beyond the previous norm and reduce spalling in a variety of rock types (Document ID 0967, p. 6). Several commenters stated that wet methods are used frequently and are effective in controlling dust (Document ID 1983, pp. 1-2; 3580, Tr. 1435; 3496, p. 6).

Edison Electric Institute (EEI) expressed concern over the use of wet methods near electrical equipment or in subfreezing temperatures; additionally, EEI stated that it may be hard to get sufficient water supplies to remote drilling locations (Document ID 2357, Attachment 1, p. 28). OSHA’s exposure profile includes one sample result for a worker using wet methods in freezing weather to drill 60-foot holes in rock. This drill used 20 gallons of water per day, and the operator’s exposure was reported at 12 $\mu g/m^3$ (LOD) (Document ID 0034, pp. 106, 111). This sample confirms that in certain instances it is possible to implement wet methods in cold climates. Even with that evidence, OSHA understands that the use of wet methods may be limited due to other environmental concerns and conditions on the worksite. However, when it can be implemented it is an effective resource for dust control.

OSHA’s exposure profile contains 5 sample results for workers using wet methods with no other controls while drilling. The highest exposure was 57 $\mu g/m^3$, with two results below the LOD (Document ID 0034, 0226). These 5 sample results have a mean exposure of 24.2 $\mu g/m^3$ and a median exposure of 17.0 $\mu g/m^3$ (compared to a mean exposure of 80.9 $\mu g/m^3$ and a median exposure of 31.0 $\mu g/m^3$ for workers using LEV to drill rock, and an exposure of 540 $\mu g/m^3$ for an uncontrolled rock drilling operation), indicating that wet methods are potentially effective at reducing exposures, and potentially more effective than LEV.

A review of studies by NIOSH (2008) evaluated the use of wet methods in different types of drilling, including roof bolting (rock bolting) and surface rock drilling (Document ID

0967). NIOSH found that for roof (rock) bolting, silica dust was best controlled at its source through dust collection or wet drilling, similar to the standard practice in metal mines of using pneumatic percussion drills with water in addition to compressed air to flush the drill cuttings from the hole. This drilling method was found to be the best method of dust control, with dust reductions ranging from 86 percent to 97 percent (Document ID 0967, pp. 2, 4). The high dust reductions from wet drilling were confirmed in later studies that evaluated the use of water mists and foams injected through the drill steel and found that those controls reduced dust concentrations by 91 percent to 96 percent, respectively (Document ID 0967, p. 2). During this testing, it was also shown that large amounts of water are not required to produce good dust control and good penetration rate. A water flow rate of 0.41 L/min (0.11 gpm) was sufficient for dust control and good penetration rate (Document ID 0967, p. 3). NIOSH also found that for surface drilling, wet drilling techniques provided the best dust control. Wet drilling provided dust control efficiencies of up to 97 percent at a water flow rate of 4.5 L/min (1.2 gpm) (Document ID 0967, p. 6).

As previously stated, the highest exposure in OSHA's profile for a worker drilling rock using wet methods is 57 $\mu g/m^3$. Even though the surface ground was damp from rain, this worker was using 1 gallon of water per day, which is substantially less than the flow rates found effective by NIOSH above (Document ID 0034). Had more water been introduced during drilling, lower exposures may have resulted.

In OSHA's profile, the highest exposure result for rock drilling with no controls in place is 540 $\mu g/m^3$ (Document ID 0904, p. 4). The highest exposure result in the profile for concrete drilling with no controls in place is 1,190 $\mu g/m^3$. The median exposure in the profile for workers drilling with no controls is 125 $\mu g/m^3$. Based on the exposure reductions found by NIOSH (86 percent to 97 percent), OSHA anticipates that wet methods will reduce most exposures to or below 50 $\mu g/m^3$. However, OSHA recognizes that some elevated exposures may occur when drilling concrete using wet methods alone.

Based on the evidence in the record, OSHA concludes that wet methods can be used effectively for most drilling operations most of the time.

Shroud with Local Exhaust Ventilation (LEV)

Consistent use of dust extraction shrouds or hoods can reduce worker exposures at both rock and concrete drilling sites. NIOSH showed that dust collector efficiency is optimal when workers use an appropriate suction rate, maintain the shroud (surrounding a bit) in good condition, and keep the shroud positioned to fully enclose the bit as it enters the hole. NIOSH reviewed dust control research conducted from the 1910s through the early 2000s for mine rock drilling, which is nearly identical to rock drilling in the non-mining industry, and found that, when used properly, modern shroud designs now help achieve dust-control objectives more consistently for rock drilling rigs than they once did (Document ID 0967, pp. 5-9). OSHA finds that dust collectors and shrouds are commercially available (Document ID 0669; 0813).

Both rock and concrete drilling rigs are increasingly available with dust collectors that draw air from around the point where the drill bit(s) enter the rock or concrete. Organiscak and Page, 1995, found that enclosing the dust collector discharge area (with a shroud) can reduce respirable dust levels by 80 percent (Document ID 3613, p. 11). Research shows that in the vicinity of the rock drilling rig, dust collector dumping operations were the largest single contributor of airborne respirable particulates, contributing 38 percent of the respirable dust emissions (while the deck shroud contributed 28 percent, and the table bushing contributed 24 percent) (Document ID 0967, p. 5). An 80 percent reduction in the 38 percent of dust emissions attributed to discharge dumping operations could result in a 30 percent reduction in the overall level of respirable dust near the drilling rig (0.80 x 0.38 = 0.30).

NIOSH also tested a similar ventilation system: the dust collector boxes used by roof bolters in the mining industry (a vacuum system pulls dust through the drill steel back to the collector box, where it is captured on a filter). NIOSH concluded that when maintained properly, these systems can be “very effective in capturing and removing dust generated by drilling” (Document ID 0598, p. 7). These authors reported that the effectiveness of these controls can be enhanced by adding dust collector bags to the system. With collector bags added, filter loading was reduced by 80 percent (so the filter needs cleaning less often and lasts longer), and it was much easier for the bolter operator to service the box, resulting in far less dust exposure (Document ID 0598, p. 7). Listak and Beck (2008) reported that the collector (with bag) ran longer between filter cleaning and captured more than 99 percent of dust (Document ID 0785, pp. 3, 6).

Air curtains are another option for reducing silica exposures among roof bolters underground. In this case, a fan pulls air through a filter and releases this cleaned air over the worker, enveloping the worker in a curtain of clean air (Document ID 0598, pp. 7-8). Laboratory tests showed a 40 to 60 percent reduction in dust levels under the curtain, and respirable quartz concentrations that were 40 $\mu g/m^3$ lower than concentrations in a nearby area (Document ID 0712, p. 214).

In three studies, NIOSH sought to quantify the reductions in respirable dust emissions that were associated with LEV from dowel drilling machines in controlled settings. In these studies, NIOSH found that close-capture dust collection hoods ("boots") fitted onto each drill on the array reduced respirable dust concentrations by 87 to 94 percent (compared with drilling without the boots) (Document ID 0871; 4150; 4151). The equipment tested included both four- and five-gang drills and associated commercially-available hoods (Document ID 0871, pp. 4, 7; 4150, pp. vi, 4; 4151, pp. vi, 4-5).

NIOSH recommended several modifications to typical concrete drilling rig dust collection equipment. OSHA finds that these upgrades could help ensure that optimal dust collection efficiency is maintained over time. The modifications include using smooth ducts and maintaining a duct transport velocity of 4,000 feet per minute to prevent duct clogging; providing pipe clean-out points; installing pressure gauges across dust collection filters so the operator can clean or change the filter at an appropriate time; installing static pressure taps in hoods and vacuum gauges on the operator's panel, enabling the operator to confirm that the hoods are operating as designed; including instructions on hood placement in the operating instructions; and extending the height of discharge outlets from the dust collectors to aid in dispersal of emissions (Document 0871, p. 13; 4150, p. 13; 4151, pp. 20-21). In a 1995 U.S. Bureau of Mines (USBM) study, Organiscak and Page further illustrated the importance of proper set up/adjustments on the effectiveness of dust control systems. In this study, Organiscak and

Page conducted dust sampling around several truck-mounted rock drills equipped with Rotoclone exhaust systems. The study found that improving the drill deck shroud containment and increasing Rotoclone (i.e., fan) speed can reduce respirable dust levels by 63 percent, while vertically extending the Rotoclone exhaust can reduce downwind respirable dust levels by 62 percent (Document ID 3613, p. 11). NIOSH reported that improving dust shroud containment can improve dust reduction efficiencies by greater than 99 percent (Document ID 4156, p. 2). In the PEA, OSHA discussed a video of concrete drilling using dust collection equipment that showed an initial plume of dust lasting 5 to 15 seconds after the worker activated the drill (Document ID 0814). Based on this, OSHA determined that the overall collection efficiency of dust collection systems would also be improved by activating the exhaust suction prior to initiating drilling and deactivating it after the drill bit stops rotating to ensure dust is captured through the entire drilling process (Document ID 1720, p. IV-478). This was not disputed. Over the course of the work shift, modifications such as those suggested by NIOSH, USBM, and OSHA would all reduce worker exposure levels.

While the suggested dust collection system modifications can reduce worker exposure levels, OSHA understands that drilling operations are highly mobile and that operators perform drilling activities in a variety of conditions that depend on the worksite and equipment in use. Therefore, employers will need to evaluate dust collection systems to determine the specific additional modifications required to optimally control dust.

The highest sample result in the exposure profile associated with drilling concrete with LEV is 420 μg/m^3. The remaining workers on this job had exposures of 5 μg/m^3, 12 μg/m^3, 20 μg/m^3 and 58 μg/m^3, indicating that the additional task of emptying the dust collector and cleaning the filter was responsible for the elevated exposure and that respirators may be needed to protect some workers during discrete tasks (Document ID 4154, p. 17, 27).

OSHA only has four samples in the profile associated with workers drilling rock while using LEV alone. All four samples were reported as less than the LOD of 12 μg/m^3. However, the reports indicate sampling occurred during or following rainy weather, which may have resulted in underestimating the exposures for LEV alone due to already damp surfaces. Even though the surface ground was damp from rain, one report notes that visible dust was still being emitted from the dust collector itself (Document ID 0512).

The National Stone, Sand & Gravel Association (NSSGA) recommended that OSHA replace the term “shroud” in the Table 1 entry for rock drilling with “engineered fugitive dust control method, e.g., a shroud, water spray, etc.” (Document ID 2327, Attachment 1, p. 21). OSHA has decided not to incorporate the change as requested, but is requiring the use of a close capture hood or shroud around the drill bit. OSHA determined that the term change NSSGA requested was not specific enough to ensure that workers would be protected from elevated levels of silica.

Based on the information contained in the record, OSHA has determined that LEV can effectively reduce silica exposures to below 50 $\mu g/m^3$ for most drilling operations most of the time.

Combination of Wet Methods, Shroud, and LEV

A combination of wet methods and LEV can further reduce exposures to silica during drilling operations. A NIOSH survey of a rock drilling operation in a quarry obtained a sample result of 31 $\mu g/m^3$ for a rock drill operator using a combination of wet methods and LEV. The operator spent 100 percent of his/her time operating the drill rig approximately 8 feet from the drill site, occasionally moving to within 3 feet to check on drilling equipment (Document ID 0228, pp. 8-9). The drill was fitted with a 300 cfm hydraulic fan to draw air and debris from the drill hole through a 5-inch flexible duct, and included a two stage air cleaning system that removed the debris from the air stream. The finer rock dust was carried through the flexible ducting to the fan and a manifold with a bank of 20 air filters (4-inch diameter vertically threaded). These air filters accumulated dust on their surfaces, but when the drill stem was not engaged, a timer and relay controls reverse-pulsed air to clean the filters (Document ID 0228, p. 6). The water spray system included a 100-gallon pressurized tank (80-psi), hoses, and an injection system. Water was injected into the drill stem and released through ports in the drill bit (Document ID

0228, p. 6). NIOSH reported that in most drilling applications (including during this survey), both systems are used in combination (Document ID 0228, p. 6).

OSHA obtained sample results of 54.3 μg/m^3 and 34.9 μg/m^3, for two workers drilling in granite that contained 30-40 percent crystalline silica (Document ID 0034, pp. 8, 23-26, 35-38). Both drills were reportedly using water and LEV, although specific details about the configuration of the controls were not discussed (Document ID 0034, pp. 23, 89-93). A third sample of 12 μg/m^3 was collected on the same site for a laborer who helped with positioning the drills (Document ID 0034, pp. 39-42).

Organiscak and Page (1995) also illustrated the effectiveness of combined wet methods and dust collectors in their U.S. Bureau of Mines (USBM) study, which compared rock drilling using LEV with and without the addition of water for dust suppression. The addition of wet methods to the LEV system showed a 92 percent reduction in respirable dust and eliminated nearly all of the visible dust. Quartz results decreased from 142.8 μg/m^3 when the water was off (LEV alone) to 8.5 μg/m^3 when water was added.[263] USBM estimated that 100 gallons or less of water would be sufficient for 8 hours of continuous exposure using a 0.2 gallon per minute flow rate, noting that too much water can contribute to operational problems (Document ID 3613, pp. 7-8).

OSHA recognizes that in concrete drilling, combining wet methods and LEV at the point source may be problematic. In its written comments, NIOSH said that wet methods should not be used with a dust collector for concrete drilling rigs because adding water would add weight to the concrete dust and potentially cause it to solidify, clogging the dust control (Document ID 2177, Comment B, p. 34). OSHA acknowledges that applying water at the drilling point source has the potential to clog the LEV dust control and concludes that wet methods can be effectively implemented in conjunction with dust collection systems during concrete drilling only when water is applied at the downstream dust collection exhaust point (Document ID 0967, pp. 7-8).

[263] Silica dust levels were calculated by multiplying the dust concentration by the percentage quartz. Milligrams per cubic meter was converted to micrograms per cubic meter by multiplying by 1000.

While LEV and wet methods are able to reduce exposures individually, record evidence demonstrates that the proper combination of these controls can significantly increase the extent to which silica exposures can be reduced during drilling work. As previously mentioned, the highest exposure in the profile for drilling with no controls is 1,190 μg/m^3 and the median exposure is 125 μg/m^3. The highest exposure for a worker drilling using a combination of controls was 54.3 μg/m^3. Based on the exposures reported by NIOSH and the reductions found in the USBM study (92 percent), OSHA has determined that a combination of wet methods and LEV will reduce most exposures to 50 μg/m^3 or below.

Isolation

Wireless or tethered remote controls are available for some types of construction drilling equipment (Document ID 1720, p. IV-479; 0814; 0871, p. 8). A concrete drilling rig tested by NIOSH was fitted with a commercially available remote control that permitted the operator to activate the rig from a moderate distance (e.g., 5 to 20 feet) (Document ID 0871, p. 8; 0814). Though the NIOSH study did not specifically test for the effects of remote control usage on silica exposure, OSHA anticipates that when workers have access to wireless controls, this technology can help minimize workers' silica exposures by permitting the workers to move freely within the local work area. When given an opportunity, workers can step away from plumes of visible dust (Document ID 0784, p. 212; 0814; 0819, p. 2).

The IUOE endorsed the use of enclosed cabs as an effective engineering control that isolates operators from the source during rock and concrete drilling (Document ID 2262, p. 28). IUOE also suggested that if operator booths are determined to be a feasible control, OSHA could consider including them on Table 1 (Document ID 2262, p. 46). OSHA agrees that the use of an operator's booth could provide another effective alternative engineering control for workers using drilling rigs. While OSHA did not have enough information to include remote operation of drills and operator booths as a control option on Table 1, employers who believe that this is the most effective method for controlling exposures on their worksite have the option of using this control method and performing exposure assessments to determine compliance with the PEL.

Enclosed Cab

Cecala et al. (2005) studied modifications designed to lower respirable dust levels in an enclosed cab on a 20-year-old surface drill at a silica sand operation. The researchers studied respirable dust levels collected inside and outside the cab before and after modifications to improve performance and found that effective filtration and cab integrity (e.g., new gaskets, sealing cracks) to maintain a positive-pressure environment are the two key components necessary for dust control in an enclosed cab (Document ID 1563, p. 9). A study published by Bakke at al. (2010, originally published in 2002) on roof bolters using rock drilling rigs at the face of the tunnel at a Norwegian tunnel construction site concluded that the use of a drill rig with a closed cab reduced silica exposure by 85 percent compared to drill rigs with no cabs. The geometric mean respirable quartz exposures for operators in no cab, open cabs, or closed cabs were 273, 16, and 24 $\mu g/m^3$, respectively. Researchers concluded that these sample results were due in part to the fact that workers using drill rigs without cabs were positioned closer to the drill head (Document ID 3756, Attachment 9, p. 794).

The IUOE agreed that an enclosed cab was an effective control for rock and concrete drilling, noting that, “enclosed cabs not only protect operators from silica exposure, but provide the additional benefits of protecting workers from noise exposure and exposure to diesel particulates and other respirable contaminants, such as lead” (Document ID 2262, p. 28). The IUOE also cautioned however, that “since enclosed cabs isolate the operator from the silica source and do not control exposure at its source, cab integrity is essential to reduction of silica exposure to operators of enclosed cabs.” (Document ID 2262, pp. 28-29). The IUOE recommended inspection checklists to ensure that engineering controls are functional and that cab integrity is properly maintained (Document ID 2262, pp. 38-39). OSHA shares IUOE’s concerns and notes that to ensure effectiveness, cab interiors must be kept as free as practicable from settled dust; door seals and closing mechanisms must be maintained in proper working order; gaskets and seals must be in good condition and working properly; cabs must be maintained under positive pressure through continuous delivery of fresh air; intake air must be filtered through a pre-filter that is at least 95 percent efficient in the 0.3-10.0 μg range; and cabs must have heating and cooling capabilities (Document ID 2262, pp. 38-39).

In its written comments, NIOSH recommended that OSHA specify that incoming air for an enclosed cab of mobile equipment be filtered through a pre-filter and then either a Minimum Efficiency Reporting Value (MERV)-16 or HEPA filter, noting that recently-published NIOSH research found that a MERV-16 quality filter media may be more advantageous than a HEPA-quality intake filter on mobile equipment (Document ID 2177, Comment B, pp. 47-48). The information presented by NIOSH indicates that as MERV-16 filters load with dust they become more efficient at intake particle capture, whereas HEPA filters become more restrictive, placing more demand on the cab filtration system (including the intake fan) (Document ID 2177, Comment B, pp. 47-48). Therefore, OSHA is not requiring the use of HEPA filters on enclosed cabs for heavy equipment; where an enclosed cab is used to meet the Table 1 option, the cab must be equipped with an intake filter with a MERV 16 or higher rating.

An NUCA member cautioned that the use of an enclosed cab for drilling rigs limits the operator's ability to communicate with anyone outside the cab and therefore creates a hazard (Document ID 2171, Attachment 1, p. 10). OSHA acknowledges this concern, but believes that proper work procedures and worker training will control any potential hazards associated with communication issues. See Section IV-5.3 – Heavy Equipment Operators and Ground Crew Laborers for further discussion on the use of enclosed cabs as a control method in construction.

In the exposure profile, OSHA identified 10 samples for drill operators working in cabs; the sample results ranged from 10 $\mu g/m^3$ (LOD) to 110 $\mu g/m^3$, with a median exposure of 30 $\mu g/m^3$. These findings support OSHA's determination that the enclosed cabs offer protection against respirable silica dust. OSHA notes that cabs only benefit the operator when he or she remains in the cab and do not control worker exposures during positioning or hole-tending activities. Therefore, additional controls are necessary to protect workers from exposures to silica dust when performing activities outside of the cab. OSHA has determined that the use of water for dust suppression on the drill bit will effectively reduce exposures in these situations. As previously discussed, NIOSH found dust reductions ranging from 86 percent to 97 percent with the implementation of wet methods for dust control (Document ID 0967, pp. 2-4). This would offer protection for operators who must occasionally leave the cab and for other workers in proximity to the drill.

Work Practices

Work practice controls are an important component in reducing exposures to 50 μg/m^3 or below. By using a HEPA-filtered vacuum instead of compressed air to clean holes, worker exposures from this source could be eliminated, except when workers empty the vacuums. Because the vacuum nozzle must be inserted into each hole, workers using vacuums to clean holes are likely to require extra time to complete the task compared with workers using compressed air, which requires less precision (Document ID 1720, p. IV-480). In three surveys of dowel drilling operations, NIOSH observed workers using compressed air to clean holes at only one site; the other two epoxied the dowels without any cleaning (Document ID 4154, p. 26). Similarly, NIOSH found that, at the site where the drilling rig was equipped with LEV, workers used compressed air to clean the filter, resulting in some of the highest measured exposures to respirable dust (Document ID 4154, p. 26). NIOSH recommended prohibiting the use of compressed air in order to eliminate it as a source of exposure (Document ID 4154, p. 26). NIOSH also noted that using compressed air to clean filters could damage the filter (Document ID 4154, p. 26), and that the reverse pulse feature on the dust collector should preclude the need to remove filters for cleaning (Document ID 4154, p. 26). OSHA agrees that using compressed air to clean areas and materials containing silica dust can result in a significant source of exposure to silica and should be avoided. OSHA also realizes that there may be some instances where the use of compressed air is necessary, but notes that when compressed air is used to remove silica dust, it must be used in conjunction with engineering controls to protect employees from exposures to silica levels above the PEL.

5.9.4 Feasibility Finding

Paragraph (c) of the respirable crystalline silica standard for construction (1926.1153) gives employers the option of following Table 1: Specified Exposure Control Methods, which includes fully and properly implementing specified control measures when operating dowel drilling rigs for concrete, see paragraph (c)(1)(viii), and vehicle-mounted drilling rigs for rock and concrete, see paragraph (c)(1)(ix). Alternatively, employers who do not follow the requirements outlined under paragraph (c) must assess and limit employee exposures to silica in accordance with paragraph (d).

When using dowel drilling rigs for concrete, employers following Table 1 must use a shroud around the drill bit with a dust collection system and be equipped with a filter-cleaning mechanism. The dust collector must have a filter with 99 percent or greater efficiency. However, based on exposure sampling by NIOSH (Document ID 4154), OSHA finds that even with these controls, employees engaged in dowel drilling are likely to have silica exposures above 50 $\mu g/m^3$. As such, OSHA cannot find that the new PEL is technologically feasible for these workers, and Table 1 in the final rule requires the use of respiratory protection having an APF of at least 10 when dowel drills are operated. In addition, the specification on Table 1 is restricted to outdoor use and requires HEPA-filtered vacuums be used when cleaning holes.

When using a vehicle-mounted drilling rig for rock or concrete, employers following Table 1 must use a dust collection system with a close capture hood or shroud around the drill bit with a low-flow water spray to wet the dust at the discharge point from the dust collector. Table 1 provides the alternative option for workers to operate the drill from within an enclosed cab meeting the specifications of paragraph (c)(2)(iii) in conjunction with water applied at the drill bit for dust suppression. When these specified dust control methods are fully and properly implemented, TWA exposure levels are expected to remain below 50 $\mu g/m^3$, and therefore, Table 1 does not require the use of respiratory protection for this work.

Most manufacturers of vehicle-drilling rigs equip their machines with water delivery systems, shrouds with LEV filtration, or a combination of both, to minimize dust escaping into the work area (Document ID 0669; 0785; 0871; 2319; 3613; 4154). Accordingly, OSHA has determined that it is feasible for employers to obtain controls for these types of drilling equipment that meet the specifications in Table 1.

Based on the available data in the record, OSHA concludes that exposures among workers using vehicle-mounted drilling rigs, other than dowel drilling rigs, can be reduced to levels of 50 $\mu g/m^3$ or below, for most operations, most of the time. Thus, OSHA finds that the standard is technologically feasible for these workers. As summarized in Table IV.5.9-B and described earlier in this section,(see IV-5.9.3 addressing Additional Controls), OSHA finds exposure levels of 50 $\mu g/m^3$ or below have already been achieved for approximately 78 percent of drillers using one or more controls. And for workers currently exposed above 50 $\mu g/m^3$, the controls described in this section can be implemented to reduce silica exposure levels to 50 $\mu g/m^3$ or below in most operations, most of the time. Controls include: 1) wet dust suppression methods (water-fed drill bits, misting points of dust release, and in some cases using a more powerful water pump than typically provided with the drilling rig); 2) shrouds and hoods connected to dust extraction equipment; and 3) managing dust collection dump points. These controls will benefit all workers working around the drilling rig, not just rock and concrete drill operators. The evidence presented in this section shows that use of the specified control systems results in greatly reduced worker exposures to respirable crystalline silica.

5.10 MOBILE CRUSHING MACHINE OPERATORS AND TENDERS

5.10.1 Description

Crushing machines are used to reduce large rocks, concrete, or construction rubble down to sizes suitable for various construction uses.[264] Once crushed, the material exits the crusher and is carried along conveyor belts into a pile or into secondary and tertiary crushers. Crushing operations sometimes also include magnetic separation, powdering, and vibratory screening (sieving). Mobile crushers, are a subset of crushers, are typically used at construction sites that can be moved from project to project as opposed to larger crushers that are stationary and are used in general industry and at quarrying operations that fall under the jurisdiction of MSHA (Document ID 1431, p. 3-90). A crusher's typical use at a construction site ranges from a six to eight-week period (Document ID 2116, p. 31).

Workers can be exposed to respirable silica generated during crushing operations while they manage the machine's controls, oversee the operation, and signal the loader operator about dumping loads into the crusher hopper or onto the conveyors that lead to the crusher. At most construction sites, the operator overseeing machine function spends a substantial portion of the shift next to the primary hopper to allow the operator to view the inside of the hopper, at which point the operator's breathing zone is about five to ten feet from the edge of the hopper opening. The operator's platform is typically not enclosed and has an area of about ten square feet (Document ID 1431, p. 3-90; 0186, pp. 24-26, 37-38, 41-43, 45, 52-65).

The operator might also periodically tend the crushing machinery from platforms mounted on the side of the crusher or on the ground at various points along the moving conveyor belts to remove foreign material (wood, rebar, wire) from the stone or concrete to be crushed. These workers might also pick up debris that has fallen off the conveyor belts, or clear material that becomes impacted in the crusher, hoppers, or belts. At some

[264] Rock crushing operations at fixed sites associated with mining operations are considered quarrying operations and fall under the jurisdiction of the Mine Safety and Health Administration. Only "portable" crushing operations associated with construction sites are discussed in this subsection (Document ID 1431, p. 3-90).

construction sites, particularly where construction rubble contains a significant amount of foreign material or where multiple crushing machines are run in series, other workers perform these tasks near the crushing machine; such workers are typically referred to as tenders or, alternatively, laborers, belt pickers, ground personnel, or utility operators (Document ID 1431, pp. 3-90 - 3-91).

Table IV.5.10-A summarizes job categories, major activities, and sources of exposure of mobile crushing machine operators and tenders.

Table IV.5.10-A
Job Categories, Major Activities, and Sources of Exposure of Mobile Crushing Machine Operators and Tenders

Job Category*	Major Activities and Sources of Exposure
Worker(s) Operating and Tending Crushing Machines	Managing mobile crushing machine function while working at control position(s). • Dust from crushing, grinding, and screening operations. • Dust from open transfer of silica-containing materials (e.g., open conveyors, material loading or discharge points, sizing screens). Working at access points tending crushers and conveyors to clear foreign or impacted material. Keeping the area clean (picking up debris). • Dust from crushing, grinding, and screening operations. • Dust from open transfer of silica-containing materials (e.g., open conveyors, material loading or discharge points, sizing screens)

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.

5.10.2 Exposure Profile and Baseline Conditions

The exposure information available to OSHA for concrete and rock crushers is limited to workers either controlling the machine or, alternately, controlling and tending the equipment to clear foreign or impacted material. OSHA has no exposure measurements from a worker strictly tending crushing machines in construction without also spending time operating them. Thus, an exposure profile for crusher tenders could not be presented. The exposure profile shown in Table IV.5.10-B summarizes the exposure results for all workers (operators and tenders) associated with crushing machines. These results come from one OSHA Special Emphasis Program (SEP) inspection report (Document ID 0030), which was included in the PEA, and two technical reports of demolition surveys submitted by the Building and Construction Trades Department, AFL-CIO (Document ID 4073, Attachments 9a and 10a). Another technical report of a demolition survey submitted by Building Construction Trades Department, AFL-CIO (Document ID 4073, Attachment 10b) was not included in the profile because the dust sampler was not set at the appropriate flow rate. OSHA removed from the profile in the PEA one measurement from an inspection of a crusher operation at an asphalt plant (Document ID 0186), since it did not represent the exposure of a construction worker, and two measurements from a case file that was inadvertently included and did not contain exposure measurements for crusher operators or tenders (Document ID 0101).

The OSHA Information System database covering 2011 to 2014 was reviewed and no additional mobile crusher operator data associated with construction operations were identified (Document ID 3958). Although limited, these values represent the best data available to OSHA for workers involved in mobile crushing operations.[265]

The exposure profile in Table IV.5.10-Bincludes eight samples of respirable crystalline silica for crushing machine operators and tenders. The median is 92.5 μg/m^3, the mean is 103.7 μg/m^3, and the range is 12 μg/m^3 to 300 μg/m^3. Of the eight samples, five (roughly 63 percent) are above 50 μg/m^3, and three (roughly 38 percent) exceed 100 μg/m^3.

At the one SEP construction site, where full-shift respirable quartz PBZ results of 172 μg/m^3 and 300 μg/m^3 were measured, workers stated that conditions were atypical on the day of sampling, in that the supply of asphalt, which was usually added to the primary hopper to control dust, had run out early in the day. A water hose was used on the hopper along with a water hose being used on the conveyor (Document ID 0030, pp. 34, 60, 62-64, 66-67; 1431, p. 3-91). Although these data might not represent typical conditions at this site, they indicate the potential for exposure in poorly controlled conditions.

[265] As noted in Section IV.2 – Methodology, all results included in the exposure profile are 8-hour time-weighted averages (8-hour TWAs) calculated assuming no additional exposure during any unsampled portion of the shift. Unless explicitly stated otherwise, all results discussed in the additional controls section are also 8-hour TWAs calculated the same way.

Data collected by the Construction Occupational Health Program of the University of Massachusetts Lowell on a crusher operator at a demolition site showed exposures on two separate days at the limit of detection (21 µg/m^3) and 95 µg/m^3, respectively (Document ID 4073, Attachment 9a, pp. 3-4). Data were reported by Pekron Consulting at a demolition site for two crusher operators each sampled on two days; one crusher operator worked on a crusher referred to as the processor which reduced large boulders to smaller size rocks, and the other crusher operator worked a mobile crusher that further reduced the smaller rocks. The two samples for the processor operator were less than the limit of detection. The mobile crusher operator exposures were 90 and 128 µg/m^3, respectively, over the two days (Document ID 4073, Attachment 10a, p. 4).

In Table IV.5.10-B, the exposure profile for workers operating crushing machines includes eight 8-hour TWA silica exposure results from these sources. The range of the exposure data is from 12 (the limit of detection) to 300 µg/m^3, the average exposure is 103.7 µg/m^3 and the median exposure is 92.5 µg/m^3.

Phillip Rice of Fann Contracting, Inc., commented on the large amount of dust created by uncontrolled crusher operations (Document ID 2116, p. 9). The testimony and post-hearing brief of International Union of Operating Engineers (IUOE) provide additional information and data concerning mobile crushing machines, which can create significant exposures during building and road demolition projects. IUOE identified concrete or rock crushing as a construction activity that occurs during demolition (Document ID 4234, Attachment 1, pp. 16-17). In addition, IUOE provided summary exposure data, not included in the profile, from a study of a large highway reconstruction project (Document ID 4025, Attachment 2C, p. 3).[266] The mean exposure from six personal samples[267] for respirable crystalline silica in crushing operations where water suppression was used was 320 µg/m^3 (Document ID 4025, Attachment 2C, p. 3) indicating high exposures for these

[266] The lead researchers are Norman Zuckerman, MS; Katya Wanzer, MPH, and Nancy Clark, MA, CIH, from the Mount Sinai Irving Selikoff Center; and Mark Goldberg, CIH, PHD, from Hunter College.

[267] The sampling time for these samples was not reported nor is it known whether the results represent 8-hour TWAs. Also, only mean levels were reported for these data so the distribution of exposures cannot be determined. Thus, they were not included in the exposure profile for this operation.

dusty operations. Four of these samples were taken at the operator platform next to the crushing operation where the operator was directly exposed to the dust emissions from the crusher hopper, resulting in a mean respirable crystalline silica exposure of 410 μg/m^3 (Document ID 4025, Attachment 2C, p. 3). Two of these samples were taken where the crusher operator used a remote control to operate the crusher from a distance, resulting in a mean silica concentration of 140 μg/m^3 (Document ID 4025, Attachment 2C, p. 3). No details were provided that described the use of water to suppress dust.

OSHA finds that baseline conditions when using crushing machines generally include the use of some form of dust suppression (e.g., water, asphalt) but application is either inconsistent or insufficient (Document ID 1431, p. 3-91; 4025, Attachment 2C, p. 4). Because the final Exposure Profile reflects a variety of conditions, OSHA generally considers the median exposure for workers using mobile crushers (92.5 μg/m^3) to be the best single statistic that characterizes exposure or workers who operate or tend mobile rock and concrete crushers. OSHA thus considers the sampling results reflected in the Exposure Profile below to be the best available evidence of mobile crusher operator and tender exposures.

Table IV.5.10-B
Personal Respirable Crystalline Silica Exposure Range and Distribution of Results for Construction Workers: Rock-Crushing Machine Operators and Tenders

	Exposure Summary			Exposure Range			Exposure Profile				
Job Category	**N**	**Mean (μg/m³)**	**Median (μg/m³)**	**Min (μg/m³)**	**Max (μg/m³)**		**< 25 (μg/m³)**	**≥ 25 and ≤ 50 (μg/m³)**	**> 50 and ≤ 100 (μg/m³)**	**> 100 and ≤ 250 (μg/m³)**	**> 250 (μg/m³)**
Rock-Crushing Machine Operators and Tenders	8	103.7	92.5	12	300		3 (37.5%)	0 (0%)	2 (25%)	2 (25%)	1 (12.5%)

Notes: All samples are personal breathing zone (PBZ) results and represent 8-hour time-weighted average exposures.
Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.
Percentages may not add to 100 percent due to rounding.

5.10.3 Additional Controls

The exposure profile in Table IV.5.10-B shows that roughly 63 percent (5 out of 8 samples) of crushing machine operators and tenders have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. As discussed in more detail below, the primary additional controls for crushers include: water application methods that can include using foam and wetting agents; using remote controls to remove the worker from high respirable dust areas that can include simple distancing or the use of enclosed operator control booths supplied with fresh filtered, climate-controlled air; installing local exhaust ventilation (LEV) at the hopper and other locations along the conveyors; and using dust suppressant and hydroscopic materials on ground areas and roads.

Wet Methods

Use of water spray systems is particularly important for mobile crushing operations of concrete or rock since dust emitted from the operation can contribute to exposures of tenders and bystanders, such as employees who do not operate the crusher or who are performing jobs not associated with crusher operations elsewhere at the site. The California Air Resources Board cites rock crushing as a major source of fugitive emissions (Document ID 3583, Tr. 2396). If the crusher is not located away from areas where others are working, and if water spray applications are not properly implemented, a large dust cloud can be generated that can cause exposures to operators, tenders and other workers at the site. Donald Hulk of Manafort Brothers testified that advance planning is required to avoid secondary exposure to other workers (Document ID 3583, Tr. 2385-2386).

Evidence that water suppression on crushers can effectively reduce silica exposure levels is provided by a full-shift (PBZ) silica result of 54 μg/m^3 obtained for the operator of a stationary crusher at a temporary concrete recycling facility using fine-mist water spray

(Document ID 0203, p. 9).[268] The sampling was performed by the OSHA contractor, the Eastern Research

Group (ERG), on a site visit. Multiple water spray nozzles were located at the crusher hopper, the post-crusher conveyor, the sizing screens exit point, and each major transfer point, including the point where crushed material eventually fell to a pile on the ground. The crusher operator controlled the nozzles from a panel in the control booth. The number of nozzles in action varied according to site conditions; at the time of the visit, only the water spray at the jaw crusher hopper was used since the material being crushed was wet from thawing ice. The objective was to eliminate all visible dust using the least amount of water. Water sprayers were checked frequently and replaced if they became clogged, dripped, or squirted water, rather than producing a mist spray (Document ID 0203, pp. 3-6). At this site, the machine operator spent much of the shift inside a poorly sealed booth equipped with foam (as opposed to higher efficiency filters located directly over the crusher but left the booth frequently to spray extra water (large droplets from a hose with a garden nozzle) as material was dumped into the crusher. During the shift, this worker also inspected conveyors and shoveled dry impacted crushed concrete from clogged hoppers and conveyors (performed without dust suppression) (Document ID 0203, p. 8). Silica concentrations inside the booth (based on area samples, not PBZ samples) were below the limit of detection (LOD) (19 µg/m^3 in this case), while the concentration outside the booth was higher (103 µg/m^3) over the entire shift (Document ID 0203, p. 9) indicating this poorly maintained booth reduced exposure by 5 times or greater. The operator's level of exposure of 54 µg/m^3 was partially caused by the presence in the booth, reducing the operator's average exposure over the course of his shift.

OSHA has concluded that if the water hose (used by the operator at the crusher) had provided a finer mist, if water spray had been available at the clogged hoppers cleared by the operator, and if water sprays located around the conveyors had been activated to

[268] Although it could be disassembled and moved, this equipment was not mobile, and the crusher system size was more typical of an extensive fixed location crushing operation (Document ID 0203). Therefore, the exposure profile (Table IV.5.10-B) does not include exposure results associated with this crusher.

avoid the need to shovel dry material, then this operator's exposure level would have been below 50 μg/m^3 on this sampling date. Although wet ground conditions meant that the concrete being crushed was wetter than usual, which might have helped minimize airborne dust, OSHA notes that most of the water sprays installed on the system throughout the process were not being used because of the wet conditions encountered that day.

The Construction Industry Safety Coalition (CISC) was critical of OSHA not adjusting for the weather conditions encountered by ERG on the site visit (Document ID 2319, p. 27). OSHA notes that although surface ice and moisture combined with wet soil would help reduce exposures of crusher operators and workers in the vicinity, most of the water sprays were not in use that day (Document ID 0203, p. 11). OSHA contends that wet ground conditions alone, in the absence of water sprays, would not be sufficient to achieve control, because once crushed, the dry interior of the concrete pieces becomes exposed and can release dust. Supporting this contention, ERG observed that visible dust was generated when the operator shoveled impacted material from conveyors and removed rocks from hoppers (Document ID 0203, p. 8). OSHA also notes that bulk samples taken by ERG of accumulated dust contained 30 percent crystalline silica (Document ID 0203, p. 11), well in the range of most materials encountered in the construction industry.

During the rulemaking, additional data were introduced that described the successful use of wet methods. The BCTD submitted an internal progress report on an ongoing study of demolition dust and respirable silica dust control prepared by Anito Bello, Sc.D, and Susan Woskie, Ph.D, University of Massachusetts Lowell (Document ID 4073, Attachment 9a). Two measurements were taken on a crushing operator over two days. During the first measurement of the crusher operator's exposure, the crushed material was dry with a sampling result of 120 μg/m^{3}respirable crystalline silica over 378 minutes of sampling, or an 8-hour TWA of 95 μg/m^3. A second 203-minute sample of the crusher operator taken another day after it rained and the material being crushed was wet was below the LOD of 21 μg/m^3 (Document ID 4073, Attachment 9a, pp. 3-4), or 78 percent lower than the exposure when working with dry material. The authors concluded that

"[W]orkers on demolition sites were exposed to levels (of respirable silica) under 50 μg/m^3 with the exception of the crusher operators. Furthermore, our data show that crusher operator's exposures can be reduced significantly if water controls are used to increase the wetness of the materials being crushed" (Document ID 4073, Attachment 9a, p. 4).

Guidance on dust controls developed by the Health and Safety Executive of Great Britain contained in its publication, COSHH Essentials in Construction: Silica (CN4), Crushing and Screening Demolition Material recommends the use of equipment fitted with water suppression to minimize the amount of dust created at crushing and transfer points (Document ID 4073, Attachment 15g, p. 1). The document also states, "Respirator Protective Equipment (RPE) should not be needed if the controls work properly. However, RPE may be needed for work near the equipment while it is running and is often needed for maintenance and some cleaning jobs" (Document ID 4073, Attachment 15g, p. 2).

According to NIOSH, crusher operators' exposures can be reduced with more extensive and improved water delivery systems. A well designed water control system needs adequate flow volume, proper selection of nozzle type and proper nozzle direction and angle of impact. This can generally be obtained from the nozzle manufacturers' literature (Document ID 1152). The NIOSH Dust Control Handbook discusses water dust control techniques in greater depth and also explains nozzle selection for spray water controls (Document ID 3472, pp. 61-76).

Spray systems are commercially available as original equipment options on some mobile crushers and can be added as retrofits or can be added by the owner as shop installations (Document ID 0769; 0830; 0831; 0832). Replacement nozzles are readily available. It is important to match the nozzle type and spray pattern to the dust source, i.e., the location within the crushing machine, that is to be controlled (Document ID 0548; 1152). Spray systems can be installed for remote control activation (Document ID 0203, pp. 11, 12, 14; 0830).

Other wet dust suppression options that can offer a substantial benefit include foam, steam, compressed water fog, and wetting agents (surfactants added to water to reduce surface tension) (Document ID 1360; 1431, pp. 3-93—3-94). Based on evidence in the record, OSHA expects that when used properly and consistently, these wet methods could reduce silica concentrations at least as effectively and more consistently than directional water mist spray alone (i.e., dust suppressants such as foams can achieve an exposure reduction of 70 to 90 percent, or possibly greater) (Document ID 1360; 1431, p. 3-93).

Remote Control or Ventilated Control Booths

Mobile crushing machines are currently available with remote controls as standard equipment (Document ID 0770). The remote operation permits the operator to stand back from the crusher or move upwind of dust emissions. IUOE provided exposure data from large highway reconstruction projects showing the reductions in exposures from use of remote controls (Document ID 4025, Attachment 2C, p. 3). Four samples were collected where the operator platform was next to the crushing operation and the operator was directly exposed to the crusher emissions; the mean respirable crystalline silica exposure was 410 $\mu g/m^3$. Working from a remote location resulted in an approximately 66 percent reduction in exposure to respirable crystalline silica of the crusher operator, for a remote location mean exposure of 140 $\mu g/m^3$ (Document ID 4025, Attachment 2C, p. 3).

An isolated and ventilated operator control booth that provides fresh, climate-controlled air can significantly reduce the respirable silica exposures of workers associated with crushing to the extent that they are able to spend time in the booth. At its visit to a crusher facility, ERG found non-detectable levels of respirable crystalline silica inside the operator's control booth, compared to a concentration of 103 $\mu g/m^3$outside the booth, despite the facts that the booth had poor door seals, used recirculated rather than fresh air, and had foam (rather than higher efficiency) filters (Document ID 0203, pp. 12-13).

In a study of the Australian extractive (mining) industry, eight full-shift PBZ respirable silica samples obtained for rock crushing operators who controlled the dry process from inside air-conditioned cabins ranged from less than or equal to the limit of detection

(LOD) of 20 μg/m^3 to 400 μg/m^3, with a median of 65 μg/m^3 (Document ID 0647).[269] Four of the eight sample results were at or below 50 μg/m^3, and at least two of the sampled workers occasionally exited the cabins to free machinery blockages[270]. The investigators noted that, although air-conditioned cabins were widely used in the crushed granite industry, the air conditioning systems were inappropriate and poorly maintained, and housekeeping within the cabins was poor (Document ID 0644, p. 9). When compared with the measurement of 300 μg/m^3 reported above for the rock crushing operator using LEV but no cabin, the median of 65 μg/m^3 represents an exposure reduction of almost 80 percent. The Australian study also included a 40 μg/m^3 result for an operator of a mobile crusher who worked remotely in a pressurized cabin (Document ID 0647, (pdf) p. 34, sample # 7095). Other studies of operator cabs also report silica or dust exposure reductions ranging from 80 percent to greater than 90 percent (Document ID 0589; 0590; 1431, p. 3-95).

In the Preliminary Economic Analysis (PEA), OSHA recognized that control booths for crushers are commercially available, although they are not commonly used on construction sites[271] (Document ID 1720, p. IV-494). However, Kyle Zimmer, a master trainer with IUOE, stated during the hearings that “contractors report that they are using portable crusher control booths with air conditioning to operate the plant remotely” (Document ID 3583, Tr. 2341). The IUOE addressed the utility of remote controls in their comments on the proposed rule (Document ID 2262, p. 45; 3583, Tr. 2341), and requested OSHA to evaluate remote control technologies as an exposure control method and to include this type of control in Table 1. While OSHA believes that remote control

[269] The sample results representing crusher operators in air-conditioned cabins are as follow: sample # 7036 and 7026 on (pdf) p. 18; sample # 6549 on (pdf) p. 22; sample # 6507 on (pdf) p. 23; sample # 6511 on (pdf) p. 24; sample # 6521 on (pdf) p. 25; sample # 6411 on (pdf) p. 27; and sample # 7100 on (pdf) p. 42.

[270] These sample results could not be added to OSHA’s exposure profile, since they are for workers not regulated by OSHA. These samples were foreign data, and in addition, OSHA does not regulate the mining sector. Nonetheless, these exposure results demonstrate the effectiveness of ventilated booths in controlling exposures during rock crushing operations.

[271] Control booths are more commonly used at fixed plants and mining operations.

operations have significant potential to reduce exposures, the data shown above suggest that it may not achieve exposures at or below 50 µg/m³ by its independent use.

Local Exhaust Ventilation (LEV)

The use of LEV systems at feed hoppers and along conveyor belts can aid in reducing respirable quartz levels. The available data, however, suggest that LEV alone may not always be effective in substantially reducing exposure levels associated with mobile crushing equipment. One sample, obtained by Ellis Drewitt for an Australian worker crushing quartzite stone with a dust extraction system as the only control method, resulted in an 8-hour TWA respirable quartz result of 200 µg/m³ (Document ID 0647, (pdf) p. 25, sample # 6518). ERG-C (2008) describes this study in more detail (Document ID 1431, p. 3-94).

Another international report, this one from Iran, describes a site where workers used rock crushers with only LEV controls. Although the LEV reduced exposures more than 90 percent, exposures were still elevated (Document ID 1720, pp. IV-491--492; 1325).

Although LEV shows promise for some types of construction equipment, it has yet to be proven practicable for mobile construction crushing equipment and is not currently used extensively. William Turley of the Construction & Demolition Recycling Association stated, “While there are crushing operations that have used baghouses on the crusher, none use…ventilation equipment for conveyors” (Document ID 2220, p. 2).

As described below, a notable amount of air (6,500 to 8,500 cubic feet per minute [cfm], with a wet air scrubber system) must be exhausted from crushing machines used underground in the mining industry. A somewhat lesser amount might suffice above ground but other challenges would need to be overcome. The challenges include problems with maintaining airtight enclosures around the crusher and conveyors on this type of equipment, which vibrates violently, and with housing a power generator, fan, and air-cleaning device of sufficient size on the mobile crusher chassis (Document ID 1720, p. IV-492). Phillip Rice of Fann Contracting, Inc., contended that large crushing systems with multiple conveyor belts would make it very difficult to use local exhaust ventilation cost effectively (Document ID 2116, p. 31). In contrast, Mr. Zimmer of the

IUOE testified that employers are using dust collectors with baghouses at some crushing operations (Document ID 3583, p. 2341). Nevertheless, the record does not contain substantial and convincing evidence that LEV alone can be applied when using portable crushing machines to reduce exposure levels to or below 50 μg/m^3.

Combination of Controls

From the discussion above, it is clear that no single exposure control approach is likely to consistently achieve crusher operator exposures at or below 50 μg/m^3. It is not clear from the record whether water spray systems alone would be sufficient. Although one survey of a demolition project found no detectable silica exposure when the material being crushed was wet from rain (Document ID 4073, Attachment 10a), other surveys have found exposures to be in excess of 50 μg/m^3 when using water for dust suppression (Document ID 0030; 4025, Attachment 2C). However, it is not clear from these surveys that water was applied effectively. There are no data in the record that would provide good information on the effectiveness of properly designed water spray systems that follow spray nozzle manufacturers' recommendations or take advantage of foams or wetting agents. OSHA expects a properly designed system would demonstrate improved exposure reduction over the use of manual hoses, as used on the site visited by ERG (Document ID 0203).

It is clear that operators experience high exposure levels when they must operate the crusher unprotected from above the feed hopper where dust emissions are highest (Document ID 0030; 4073, Attachment 10a). Evidence in the record suggests that use of ventilated control booths alone is effective but might not be sufficient to maintain silica exposures at or below 50 μg/m^3. A study of crushers used in the Australian extraction industry found operator exposures ranged from 20 to 400 μg/m^3, with half of the samples below 50 μg/m^3, while crushing dry material and using control booths or cabs (Document ID 0647). OSHA had no data describing exposures to silica that result from using remote controls without water. The combination of water use and either remote controls or a ventilated booth for the operator appears to be the most effective control option for minimizing operator exposures. Summary data submitted by the IUOE shows that, with water use, the addition of remote control stations further reduced operator exposures by a factor of three (Document ID 4025, Attachment 2C, p. 3). At the crusher operation visited by ERG, the operator's TWA exposure was 54 μg/m^3 while working in a booth, and his exposure would have been lower had water been applied to dried material he was shoveling from under the conveyor.

Exposure and controls for crushing machine tenders (laborers)

The use of a tender would depend upon the complexity of the material being crushed. When there is a lot of unwanted debris that has to be removed prior to crushing, this would require the use of tenders. Likewise, when multiple crushers are in a series, it would be more likely that tenders would be used to assist the crusher operator.

OSHA identified one exposure measurement for a laborer working near a mobile crusher at an asphalt plant; the laborer was exposed to a respirable crystalline silica concentration of 43 μg/m^3 (8-hour TWA) based on a half-day of sampling (Document ID 0186, pp. 60-61). In addition to assisting with the crusher operation, he also mixed a blend of sand, crushed concrete, asphalt, and soil, which likely contributed to his exposure. The enforcement officer noted that he worked about 50 feet from the point of dust generation from the crusher and that his exposure from the crusher was "much lower" than that of the operator (Document ID 0186, p. 37). Bello and Woskie found exposures of all demolition workers except for the crusher operator to be below 50 μg/m^3 (Document ID 4073, Attachment 9a, pp. 3-4). The potential exposure of tenders and other workers who are in the vicinity of crusher operations underscores the importance of using water spray systems to reduce dust emissions. Such systems will reduce dust exposures generally, thereby reducing exposures for tenders and other workers in the vicinity of the crusher. Water spraying systems on the crusher and spill points of the belt will reduce exposures to the crusher operator, crusher tender, and other nearby worker bystanders. OSHA thus rejects the contention of CISC that the absence of direct evidence of exposures to tenders means that OSHA cannot regulate them or draw reasonable inferences about the technological feasibility of controlling their exposures (Document ID 2319, Attachment 1, p. 683).

5.10.4 Feasibility Finding

Paragraph (c) of the construction standard gives employers the option of following Table 1, which includes specified engineering controls for crushers; alternatively, the employer must assess and limit exposures in accordance with the more traditional regulatory approach contained in paragraph (d). For crushers, the two specified controls in Table 1 are as follows: (i) equipment designed to deliver water spray or mist for dust suppression at the crusher and at other points where dust is generated (e.g., hoppers, conveyors, sieves/sizing or vibrating components, and discharge points); and (ii) a remote control station or ventilated booth that provides fresh, climate-controlled air to the operator. When the controls described in Table 1 are implemented, the operator is not required to use a respirator even when performing tasks outside of the booth while the crusher is operating. Both water spray systems and remote stations or filtered booths are available for mobile crushers used on construction sites.

Wet spray methods can greatly reduce the exposure levels of operators and laborers who work near crushers, tending the equipment, removing jammed material from hoppers, picking debris out of the material stream, and performing other tasks. These systems are currently available and all crushers and associated machinery (conveyors, sizing screens, discharge points) can be retrofitted with water spray and foam systems (Document ID 1360; 0769; 0770; 0830). Information from the International Union of Operating Engineers, the Building Construction Trades, and the U.K. Health and Safety Executive show that water application can be expected to reduce exposure levels from 78 to 90 percent (Document ID 1330; 4025, Attachment 2C; 4073, Attachment 9a, pp. 1-4; 4073, Attachment 15g, p. 2). Using the mid-point of this exposure control range (84 percent) and applying it to the highest value in the exposure profile (300 μg/m^3), would yield an exposure of slightly less than 50 μg/m^3 TWA for an eight-hour work day. However, other evidence suggests that wet spray methods may not consistently achieve exposures at or below 50 μg/m^3 (Document ID 0030; 4025, Attachment 2C), although little detail was available on how water was applied. Therefore, OSHA finds that it is also necessary to require employers to use remote control stations or filtered booths to ensure the protection of crusher operators. With this combination of controls, OSHA finds that operator exposures will be maintained at or below 50 μg/m^3 and Table 1 does not require respirator use. Table 1 does not require respiratory protection for tenders or others working nearby because the use of water systems should serve to limit dust emissions and, hence, the exposure of nearby workers, to levels below the final PEL.

OSHA concludes that approximately 37 percent of crushing machine operators and tenders are currently exposed to silica levels at or below 50 μg/m^3. For workers who are currently exposed above 50 μg/m^3, the controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or below in most operations, most of the time. Therefore, OSHA finds that the standard is technologically feasible for crushing machine operators and tenders.

5.11 TUCKPOINTERS AND GRINDERS

5.11.1 Description

Tuckpointers and other grinders work with masonry or concrete using handheld tools fitted with rotating abrasive grinding blades, discs, or small drums. Tuckpointers are a subset of grinders who specialize in removing deteriorating mortar from between bricks and replacing it with fresh mortar. Other grinders use various grinding tools to smooth, roughen, or reshape concrete surfaces (including forming recesses or slots). This second group also includes workers who use handheld power tools to remove thin layers of concrete and surface coatings, if present (e.g., performing small-scale spot milling, scarifying, scabbling and needle-gunning).[272] Although tuckpointing is most commonly performed for exterior wall maintenance and so generally occurs outdoors, construction workers who perform concrete surface grinding work both indoors and outdoors (Document ID 1431, pp. 3-16 – 3-17).

Tuckpointing work proceeds in two alternating phases: first, the dusty job of grinding old mortar from between bricks on a section of wall, and second, replacing it with fresh mortar, an activity that does not typically generate dust. At larger job sites, tuckpointing is performed by multiple workers standing a few feet apart, often working from platforms and scaffolding. In addition to grinding, the initial phase includes a cleaning step, during which the worker brushes dust and debris from the joints, although water or compressed air are sometimes also used for this purpose. The second phase involves at least one tuckpointer preparing batches of new mortar (sand, cement, and water), which is distributed to all of the site's tuckpointers who use it to refill the joints between bricks (Document ID 1431, p. 3-17). Using data on time spent on individual tasks and sample duration from a large data set compiled by Flanagan et al., OSHA calculated that the

[272] This section covers workers who use handheld tools. Workers performing large-scale milling, scarifying, and scabbling activities with driving or walk-behind equipment are covered in Section IV-5.8 – Millers Using Portable or Mobile Machines in this technological feasibility analysis.

median task time for mortar grinders during tuckpointing was 212 minutes (range 2-476 minutes) (Document ID 0677, Attachment 2).[273]

Workers who grind on concrete also do other work with concrete when they are not grinding. They might mix fresh concrete to repair damaged surfaces that they previously removed. At some sites, they also perform “sacking”—rubbing a porous sack of cement and silica flour over a damp concrete surface to seal small holes in the concrete surface (Document ID 1431, p. 3-16). The levels of exposure of workers who grind mortar or concrete are determined by work practices, the type of equipment used and environmental factors. When workers reach above shoulder height, debris can fall into their breathing zone, entraining fine particles in the same direction. Additionally, the speed with which dust disperses from the breathing zone of workers is limited at indoor sites or where tarp-style shrouding is erected around the workers to minimize the spread of dust from the construction site during tuckpointing or grinding (Document ID 1720, p. IV-499).

Based on the materials referred to above, including the Flanagan data set, OSHA concludes that handheld grinders are not normally operated for an entire shift, but more often for tasks lasting less than 4 hours (Document ID 1423, p. 833; 0677, Attachment 2). Scott Walker of Walker Flooring and Interiors, on behalf of the World Floor Covering Association (WFCA), stated:

It would be rare for an installer to cut and grind stone, concrete or tile for more than an hour or two on a job, depending on its size. In a given year, it is unlikely that any employee of our company or any employee of any independent installation contractor would cut or grind concrete, stone and tile for more than a total of 20 hours and never for more than 40 hours during that entire year (Document ID 2359, Attachment 4, p. 2). In the Preliminary Economic Analysis (PEA), OSHA preliminarily determined that the time

[273] Task duration calculated from information in Document ID 0677, Attachment 2 using sample duration (column S) multiplied by percent time on task (column O) for the 52 samples with valid information in both columns. Note that a value of 1000 in column O represents a lack of data, so those samples were omitted.

workers spend grinding varies widely, from 1 hour up to a full 8-hours or longer (Document ID 1720, p. IV-499).

Using data on time spent on individual tasks and sample duration, OSHA calculated that the median task time in this data set for cement finishers using surface grinders (described in Table IV.5.11-A as "Grinders") was 88 minutes (range 20-231 minutes) (Document ID 0677, Attachment 2).

Table IV.5.11-A presents a summary of the primary activities associated with silica exposure of workers in each job category.

Table IV.5.11-A
Job Categories, Major Activities, and Sources of Exposure of Tuckpointers and Grinders

Job Category*	Major Activities and Sources of Exposure
Tuckpointer	Using handheld angle grinders to remove deteriorating mortar from joints between bricks. • Dust from high speed abrasive grinding of mortar. • Dust disturbed when debris removed from newly ground joints (brushing or using compressed air).
Grinder	Using various handheld power grinding tools on concrete and other building materials to smooth or modify the surface (including cutting recesses). • Dust from abrasive action on concrete surfaces (e.g., grinding, milling). • Dust from sweeping and brushing (housekeeping). • Dust from "sacking" to seal imperfections in concrete surfaces (occasional).

*Job categories are intended to represent job functions; actual job titles might differ and responsibilities might be allocated differently, depending on the site.

Source: Document ID 1720, p. IV-499.

5.11.2 Exposure Profile and Baseline Conditions

In the PEA, OSHA reviewed 153 personal breathing zone (PBZ) samples associated with tuckpointing and 48 samples obtained for workers performing other types of grinding on concrete. These samples were obtained during NIOSH evaluations, OSHA Special Emphasis Program (SEP) inspection reports, and other published and unpublished sources. In developing its final exposure profile for tuckpointers and grinders, consistent with the procedures in Section IV-2 – Methodology, OSHA added 30 more recent exposure monitoring results obtained through OSHA's Information System (OIS) (Document ID 3958). In addition, OSHA added nine individual exposure results submitted to the rulemaking record by Francisco Antonio Trujillo of Miller and Long (Document ID 3498; 3499) that were identified as PBZ samples representing 8-hour TWA exposures. Two samples were added in a new category: grinding indoors with water. The final exposure profile table, Table IV.5.11-B, contains 168 exposure samples for tuckpointers and 72 samples for grinders, which constitute the best data available on baseline exposures for tuckpointers and grinders. The exclusion of the samples collected before 1990, along with the addition of more recent data in the final exposure profile, resulted in a slight decrease in the overall median exposures for tuckpointers and grinders, an increase in the percentage of samples at or under 50 μg/m^3, and a slight decrease in the percentage of samples over 250 μg/m^3.

Baseline Conditions for Tuckpointers

The OSHA contractor ERG reviewed working conditions for tuckpointers and determined that they typically work outdoors, with no special controls. They frequently work on scaffolding platforms or swing stages, and several tuckpointers often work in close proximity to each other. Tuckpointers also routinely brush dust and debris away from newly ground joints (Document ID 1431, pp. 3-19 – 3-20). The exposure profile in Table IV.5.11-B includes 168 samples of respirable crystalline silica for tuckpointers. The median is 313 μg/m^3, the mean is 1,477 μg/m^3, and the range is 10 μg/m^3 to 75,153 μg/m^3. Of the 168 samples, 133 (almost 80 percent) are above 50 μg/m^3, and 114 (approximately 68 percent) exceed 100 μg/m^3. Only 20.8 percent of tuckpointer exposures are less than or equal to 50 μg/m^3, with 35.7 percent of the samples representing use of local exhaust ventilation (LEV) on the mortar grinder. For 94 samples where tuckpointers worked outdoors with no exposure controls, levels were extremely high and 69.1 percent of the results exceeded 250 μg/m^3, with a median exposure of 591 μg/m^3 and a range of 12 μg/m^3 to 12,616 μg/m^3. These exposure levels are in the same range as those that have been reported or reviewed by Flanagan et al., Yasui et al., Flynn and Susi, Meeker et al., and in additional reports as summarized in the ERG analysis

(Document ID 0676, p. 322; 1237, p. 980; 0681, pp. 271 - 273; 0803, p. 108; 1431, pp. 3-17 - 3-19). One exception is the work from Ireland on stone and monument restoration work where 96 percent (22/23) of the lime mortar repointing exposure levels were less than the limit of detection of 20 μg/m^3 (Document ID 3608, p. 12).[274] Since lime mortar is softer than modern Portland cement mortar, removal may require less vigorous grinding producing less airborne dust.

Table IV.5.11-B shows that even higher sample results (12 samples, with a range of 147 μg/m^3 to 75,153 μg/m^3, a median 793 μg/m^3, and all exposures over 100 μg/m^3) were found when tuckpointing under “other conditions”, that is, indoors or in areas with limited air circulation. The “other conditions” category shown in Table IV.5.11-B also includes exposures where ineffective dust controls were used, for example wetting the wall before grinding, or using damaged LEV equipment. In contrast, the two workers, listed in the table under “mixing mortar”, who primarily mixed fresh mortar and delivered it to other tuckpointers, who then used the mortar to fill joints between bricks, had very low exposures a mean of 15 μg/m^3, and a medium of 15 μg/m^3 (< LOD of 12 μg/m^3 - 18 μg/m^3) indicating that silica concentrations are low during periods of the shift when workers are not grinding mortar.

Despite the potential for extremely high exposures when controls are not used, tuckpointers clearly experience a significant reduction of exposures with the use of LEV. The exposure profile in Table IV.5.11-B shows a range of 10 μg/m^3 to 6,196 μg/m^3, a mean of 348 μg/m^3, and a median when using LEV systems of 68 μg/m^3, with 40 percent of samples at 50 μg/m^3 or below, 60 percent of samples at 100 μg/m^3 or below, and only 25 percent exceeding 250 μg/m^3, for uncontrolled tuckpointing samples, only 9.6 percent were at 50 μg/m^3 or below and 17 percent were at 100 μg/m^3 or below, while 69.1 percent exceeded 250 μg/m^3.

[274] The sampling and analytical method used in this study had an 8-hour TWA LOD of 20 μg/m^3 because a flow rate of 2.2 liters per minute (lpm) was used with a Higgins-Dewell cyclone, and the analytical lab reported a sample LOD of 20 μg (Document ID 3608, pp. 9, 12). NIOSH Method 7500 permits use of a Higgins-Dewell cyclone at 2.2 l pm (Document ID 0901, p. 1).

Baseline Conditions for Grinders

Working either outdoors or indoors, grinders use various handheld grinding and milling equipment to smooth or abrade concrete. The exposure profile in Table IV.5.11-B shows that 67 percent of samples were taken indoors; however, Joe Bonifate of Arch Masonry, which engages in cutting, drilling and grinding, stated that 99.9 percent of their work is done outdoors (Document ID 3587, Tr. 3655, 3671), suggesting that OSHA may have overestimated the percentage of this work that is done indoors, where exposures are generally higher.
The exposure profile in Table IV.5.11-B includes 72 samples of respirable crystalline silica for grinders. The median is 121 μg/m^3, the mean is 353 μg/m^3, and the range is 5 μg/m^3 to 3,831 μg/m^3. Of the 72 samples, 54 (75 percent) are above 50 μg/m^3, and 41 (57 percent) exceed 100 μg/m^3. Overall, only 25 percent of surface grinder exposures are less than or equal to 50 μg/m^3, with 44.4 percent of those samples representing use of some kind of engineering control (Table IV.5.11-B). Sampling results summarized by Croteau et al.; Linch; Flynn and Susi; Flanagan et al.; and numerous other reports noted in ERG-C (2008) also indicate similarly elevated exposure among workers performing grinding (Document ID 0611, p. 463; 0784, pp. 213 - 215; 0681, pp. 271-273; 0676, p. 322; 1431, pp. 3-17 – 3-19).

The exposure profile in Table IV.5.11-B shows that when working outdoors, grinders use dust controls approximately 25 percent of the time. Table IV.5.11-B further shows that 38.9 percent (7 out of 18) of uncontrolled outdoor samples exceeded 250 μg/m^3, with a range of 12 μg/m^3 to 737 μg/m^3, a mean of 214 μg/m^3, and a median exposure of 134 μg/m^3. Grinding indoors produced higher exposures with a range of 117 μg/m^3 to 1730 μg/m^3, a mean of 427 μg/m^3, and a median of 223 μg/m^3 for 10 uncontrolled samples. The exposure profile for controlled outdoor grinding shows a range of 29 μg/m^3 to 96 μg/m^3, and a mean of 55 μg/m^3, with 50 percent of exposures at 50 μg/m^3 or below and 50 percent of exposures at 100 μg/m^3 or below (median 47 μg/m^3). Thus, exposures for grinders are generally lower outdoors than indoors. As OSHA noted in the PEA, indoor workers often lack even the natural ventilation that can help keep silica concentrations from building up to extremely high levels (Document ID 1720, p. IV-504).

The exposure profile also shows that exposure levels are generally much lower overall where effective controls like LEV are used. Shrouds for grinding equipment are increasingly available; however, at sites that implement LEV dust control, the NIOSH reports submitted to the record suggest that these methods are generally not implemented in the most effective manner. For example, in one NIOSH assessment of LEV systems, dust leaks at connections of the air handling system were observed for one system, while another system had a vacuum hose that needed to be taped in place, and which fell off during one sampling event (Document ID 1385, pp. 5-6, 14). A worker at another site evaluated by NIOSH cleaned the vacuum filter by shaking it and banging it on the wall, which likely created a second source of dust exposure (Document ID 0857, p. 4). Nevertheless, compared with workers who use no controls, the median values provided in Table IV.5.11-B for workers using LEV are notably lower, both outdoors (47 μg/m^3) and indoors (122 μg/m^3) and none of the samples with LEV in use exceeded 250 μg/m^3. The data summarized in Table IV.5.11-B also includes two samples taken when grinding indoors with water material with low silica content. Both of these samples were below the LOD for silica.

Some concrete grinders perform "sacking" as part of their normal activities. Flanagan et al. compiled 13 silica results for workers performing sacking and although the geometric mean was 30 μg/m^3, 40 percent of results (5 of 13) exceeded 50 μg/m^3. The respirable dust samples contained a mean quartz content of 11 percent (Document ID 0676, pp. 321-322). These results were provided in summary form and lacked sufficient detail to include them in the exposure profile in Table IV.5.11-B. NIOSH obtained an 8-hour silica sample associated with an exposure of 64 μg/m^3 (18 percent silica on the filter) for a worker performing only sacking during the shift. The same report indicated that three other workers performed sacking in addition to concrete grinding during their shifts (Document ID 0217, pp. 5-6). Based on the relatively lower concentration of respirable crystalline silica and frequency of task, OSHA concludes that sacking contributes only modestly to the overall silica exposure for concrete grinders who perform this task during a portion of their shift; however, controlling exposure levels during sacking would be necessary in order to reduce grinders' silica exposures to below 50 µg/m^3. Grinders performing sacking are not presented separately in OSHA's exposure profile, since this activity is commonly a part of a grinder's work activities.

5.11.3 Additional Controls

Additional Controls for Tuckpointers

The final exposure profile in Table IV.5.11-B shows that approximately 79 percent (133 out of 168 samples) of tuckpointers have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers, including local exhaust ventilation and work practices, as discussed below.[275]

Important attributes of effective local exhaust controls, described in the following sections, include use of shrouds, vacuum cleaners employing a cyclone to reduce the debris reaching the filter (pre-separation), larger vacuums, and larger vacuum hoses.

Extensive research demonstrates the effectiveness of local exhaust ventilation systems that include use of a shroud around the grinding blade combined with a vacuum cleaner system that is used to suction (exhaust) air from these hoods to collect dust and debris (Document ID 0600; 0728; 0731, pp. 374-375; 0863, p. 27-35). These shroud and vacuum combinations were estimated to produce dust reductions of 83 to 95 percent (Document ID 0600, p. 880; 1143). A more recent study evaluated a variety of combinations of tuckpointing grinder shrouds and vacuum systems and found respirable silica reductions of 95.6-98.7 percent for three of these selected systems, with task-based short-term measurements of 0.091, 0.276, and 0.823 μg/m^3 (Document ID 4073, Attachment 9h, pp. 11-17).

Grinding related to tuckpointing and surface smoothing may take place on scaffolds. There were comments from CISC that the addition of LEV systems or water hoses may be both difficult and add some additional hazards (i.e., fall/tripping) to the work at heights (Document ID 2319, pp. 106, 110). Dust collector systems are currently used on scaffolds, however, as evidenced by one building project evaluated by Cooper et al. where dust collectors were used on scaffolds to grind mortar from the exterior walls of a

[275] Wet methods are rarely used for dust control during mortar removal due to a number of factors, including problems related to slurry management when grinding on horizontal surfaces. Slurry can lead to discoloration and staining of the brick (Document ID 1431, 3-21).

12-story building (Document ID 4073, Attachment 9L, p. 1). OSHA concludes that while LEV systems may pose some practical challenges in some work performed at heights, employers can usually surmount those challenges using the same techniques that they routinely use to hoist equipment and building materials onto scaffolds.

Shroud and Local Exhaust Ventilation

Recent dust control efforts for tuckpointing have focused on using a dust collection hood (also called a shroud) that encloses most of the grinding blade and a vacuum cleaner system that is used to suction (exhaust) air from these hoods to collect dust and debris. These shroud and vacuum combinations (standard for tuckpointing LEV dust control) generally capture substantial amounts of debris. In hearing testimony, Tom Ward of the International Union of Bricklayers and Allied Craftworkers showed a video of local exhaust engineering controls for tuckpointing and described them as "extremely effective" (Document ID 3585, Tr. 3069).

However, although capable of significantly lowering exposures, a shroud-and-vacuum LEV system may not be fully effective to achieve the PEL. Air monitoring samples summarized in Table IV.5.11-B show that even with these controls, silica exposures often exceed 100 μg/m^3, usually by many times (e.g., 25 percent of results exceed 250 μg/m^3 when workers use LEV for outdoor tuckpointing). An additional survey added to the docket reported results at two tuckpointing sites using vacuum and shroud systems. Exposures were measured for durations from 201 to 385 minutes of mortar grinding. These results were all above 50 μg/m^3 (range from 74 to 1100 μg/m^3). However, these data could not be added to OSHA's exposure profile because the individual sampling points could not be correlated to the task categories used in Table IV.5.11-B (Document ID 4073, Attachment 9L, p. 4).

A series of studies has shown that LEV control methods for tuckpointers can be improved dramatically by improving air flow rates through shrouds, ensuring that the air flow rates are maintained over the course of the work, and taking steps to train workers to use tools correctly. Computational and laboratory studies found that an air flow rate of 80 to 85 cubic feet per minute (cfm) is needed to efficiently capture dust generated by angle grinders used for tuckpointing (Document ID 0728, p. 366; 0600, p. 877).[276] This air flow rate captures most dust, as long as the shroud fully encloses the grinding blade. For tuckpointing, this means that dust is efficiently captured only if the airflow rate remains steady at the recommended flow rate and if the shroud fits snuggly against the wall, with minimal gaps due to work practices or variations in the wall surface.

Even a small decrease in flow rate has a negative impact on shroud effectiveness. Laboratory tests conducted by Heitbrink and Bennett indicate that a vacuum and shroud used by tuckpointers during grinding can reduce respirable dust emissions by a factor of more than 400 under ideal circumstances,[277] but this reduction factor dropped to 10 when vacuum airflow was reduced to less than 80 cfm (Document ID 0728, p. 375). The authors reported observing excessive visible dust during grinding of mortar with air flow rates of 20- 30 cfm, and concluded that a higher air flow is needed to control the dust exposure generated by mortar removal (Document ID 0728, p. 367). Furthermore, computational modeling showed that even a modest decrease in the airflow rate, from 85 cfm to 70 cfm, cuts the shroud's ability to capture dust by more than half. This research demonstrates the importance of maintaining flow rates in accordance with the manufacturers' instructions for effective dust control when using vacuum systems.

During typical use of these grinders, however, many factors can cause the air flow rate to diminish, such as grinding debris clogging the vacuum, vacuum hoses or vacuums that are too small, incorrect direction of the grinding wheel, and having too large of a gap

[276] ACGIH (2010), in Figures VS-40-01 to VS-40-03, recommends 25 cfm to 60 cfm per inch of blade diameter. For a 4-inch tuckpointing blade, 25 cfm/inch of diameter is equivalent to 100 cfm, slightly higher than the 80 to 85 cfm used by Heitbrink and Bennett (2006) (Document ID 0728) and Collingwood and Heitbrink (2007) (Document ID 0600).

[277] In this case, "ideal circumstances" were defined as a gap between shroud and wall of no greater than 0.5 inch at any time. This means that the wall structure must be even and intact, and the mortar must be in good condition—not chipped, cracked, or recessed more than 0.5 inch at any point during the tuckpointing. This is considered the ideal circumstance for studying the effects of air flow rate on dust capture. Investigators recognize, however, that most walls requiring tuckpointing are not in good condition, and this factor cannot be controlled at construction sites. This limitation increases the importance of managing the vacuum air flow rate, which can be controlled by selecting appropriate equipment and encouraging workers to use it correctly.

between the lowest surface (mortar) and the shroud.[278] Controlling these factors can improve the performance of tuckpointing grinder shrouds. Other factors, such as work technique and wall condition, interfere with the way the shroud fits against the wall, but only some of these factors can be controlled.

OSHA received several comments that shrouds would prevent tool operators from seeing their work (Document ID 2183, p. 3; 2316, p. 2; 2243, p. 1). NIOSH notes that a number of tool manufacturers have commercially available shrouds designed to ensure that operators can see their work:

> The shroud evaluated by Collingwood and Heitbrink [2007] by Industrial Contractors Supply has a large open area to allow the bricklayer to see his work. A shroud by Bosch includes a clear plastic insert to serve that purpose, while a shroud by DeWALT has a large cut-out for visibility. A thorough search of tool catalogs would identify other devices that offer visibility and meet the safety standards" (Document ID 4233, p. 9).

A tool catalog submitted to the record shows a grinding shroud that allows for "complete blade visibility" that "installs on *your* angle grinder – no need to purchase a separate or specific angle grinder" and goes on to list seven brands of grinder that this shroud can be used with (Document ID 3998, Attachment 10, p. 47).

In addition, OSHA has determined that there are several vacuum features, including filtration technology such as cyclonic pre-separators, together with larger vacuum hoses, and larger vacuums, that can enhance the efficacy of vacuum cleaners to maintain proper air-flow rate and thus reduce worker silica exposure. These features are described below. Heitbrink and Santalla-Elias experimentally observed that air flows decreased substantially as grinding debris accumulated in the vacuum cleaner. They found that as

[278] Combinations of hoods and vacuums have been evaluated in the past and were typically found to offer some level of silica exposure reduction, but exposure levels remained high (Document ID 0829, p. 9; 0632, pp. 459-460; 0611, p. 463; 1237, p. 980; and 0803, p. 108). These studies focused on other aspects of grinder-shroud use and were usually less prepared to provide the higher air flow rates used in the studies described in this section, or to confirm that air flow rates remained constant throughout the test periods.

the vacuum filled with debris, an initial flow rate of 80 cfm fell to levels as low as 30 cfm (Document ID 0731, pp. 374, 380).

One option for reducing exposure during grinding is using vacuum cleaners that include cyclones to collect debris before the air reaches the filters. Cyclonic pre-separators minimize the accumulation of debris on filters in the vacuum, enhancing the ability of the vacuum cleaner to maintain the initial air flow rate. When testing a vacuum cleaner model equipped with a cyclonic pre-separator, Collingwood and Heitbrink showed that the collected debris caused the average air flow rate to decrease only from 90 cfm to 77 cfm (Document ID 0600, p. 884).

In addition, using actual grinding debris obtained from tuckpointing worksites, Heitbrink and Santalla-Elías experimentally confirmed that vacuum airflow is quickly affected by dust load on vacuum cleaner bags and filters. In vacuum cleaners designed with filters, laboratory tests showed large pressure losses across filter material as the filters became clogged with dust. Pressure losses from clogged filters translate into reduced air flow, which in turn limits how well a shroud attached to the vacuum captures dust. During particularly dusty activities (such as mortar removal), the vacuum is required to capture more than 20 pounds of debris, including fine dust that cakes onto filters (Document ID 0731, p. 379). As the vacuum collects debris, vacuum airflow diminishes rapidly until the filter is properly cleaned according to the vacuum manufacturer’s instructions (Document ID 0731, pp. 374, 377, 380 – 382).[279] Heitbrink and Santalla-Elías evaluated two different brands of commercially available vacuum cleaners incorporating cyclonic pre-separation, manufactured by Tiger-Vac and Dustcontrol. Air flow rates for both of these vacuums was “largely unaffected” by debris accumulation up to 35 pounds. Debris accumulation also had very little effect on the flow rate measured before and after the filter was cleaned (Document ID 0731, pp. 377, 380). Similarly, during the Collingwood and Heitbrink field trials, the Dustcontrol vacuum cleaner with cyclonic pre-separator did not lose as much air flow as the vacuum cleaners designed with vacuum cleaner bags (bags are a

[279] Industrial vacuum cleaners use filters that can be cleaned and reused many times. These vacuum cleaners often include a feature that allows the vacuum to clean its own filter using a beater or puffs of air blown in the reverse direction to dislodge dust.

more common pre-separation method but are subject to clogging) (Document ID 0600, pp. 883-884).

Cooper and Susi used a Dustcontrol 2900c vacuum with ICS Dust Director shroud and Bosch tuckpointing grinder to evaluate dust control in a field experiment and found that use of the LEV system produced a 98.7 percent reduction in respirable crystalline silica concentration compared to tuckpoint grinding without the LEV system. Collecting short-term samples of about 16 minutes resulted in a range of silica concentrations between 0.069 and 0.137 μg/m^3, which when extrapolated to 4 hours of continuous tuckpointing in an 8 hour day would produce exposures with a mean of 45.5 μg/m^3 (range of < 34.5 μg/m^3 to 68.5 μg/m^3). The authors reported that in 4 hours of continuous grinding up to 130 pounds of dust would be collected and that flow rates in the vacuum dropped from 90 cfm to 80 cfm in as little as 8 minutes. Thus, regular stops to conduct the proper reverse air pulse filter cleaning procedure were crucial to successful dust control (Document ID 4073, Attachment 9M, pp. 4-5, 7-9).

Gail and Robert Brandys of Occupational and Environmental Health Consulting Services, Inc. submitted comments emphasizing the importance of effective HEPA filtration in protecting workers from silica dust, and recommend that Table 1 require that dust collectors used with grinders be equipped with HEPA filters (Document ID 1953, pp. 3-4). The Power Tool Institute (PTI) also recommended that HEPA filters be required for tuckpointing and grinding LEV (Document ID 1973, pp. 2-3).

Where a vacuum will discharge into an occupied workspace, best practice dictates the use of HEPA-rated final filters (Document ID 3581, Tr. 1561, 1594, 1652). However, in the case of grinding, and particularly tuckpointing, under field conditions, HEPA filters may rapidly clog, leading to an increase in static pressure drop. As described in the numerous studies by Heitbrink et al., an increase in static pressure leads to the loss of the airflow needed for LEV to effectively capture silica dust at the point of generation (Document ID 0731, pp. 375, 384). Respirable sized particles can be captured with 99 percent efficiency using filters with a lower rating than HEPA filters, which must remove particles of the most penetrating particle size, 0.3 μm (Document ID 3883, pp. 8-36 – 8-39). OSHA reviewed the information submitted on options for commercially available vacuums and noted that that many provide a filter efficiency of at least 99 percent (Document ID 0628, 4073, Attachment 9h, p. 49). This would allow longer tool usage before significant drops in static pressure of the dust collection system. These filters can provide an acceptable protective range to contain the large quantities of silica containing dust generated during mortar removal (Document ID 3883, pp. 8-36 to 8-39). Therefore, OSHA has decided not to require HEPA filters in Table 1 for dust collection systems used to support grinding or tuckpointing. Instead, Table 1 requires dust collectors that have a filter with 99 percent or greater efficiency.

To achieve the air flow rates needed for capturing debris during the grinding phase of tuckpointing, vacuums equipped with a cyclonic pre-separator require a 2-inch inside-diameter hose (to reduce resistance in the hose, which slows airflow), rather than a 1.5-inch hose. Some vacuums might require a minor modification to adapt them for use with a 2-inch suction hose and air flow rates must remain above 76 cfm to maintain sufficient air velocity in the hose to prevent debris from accumulating and plugging the hose (Document ID 0600, p. 885). ACGIH recommends an air velocity of 3,500 feet per minute to prevent debris such as mortar from accumulating in the hose (Document ID 3883, p. 5-10). An air flow rate of 76 cfm provides this air velocity. OSHA notes that accumulated material in the hose would further decrease the air flow rate.

Another method for reducing exposure is using larger, more capable vacuum cleaners. NIOSH reported on a field trial of ventilated grinders (i.e., grinders fitted with shrouds) attached to an oversized vacuum cleaner, which used two vacuum cleaner motors in parallel and also includes a cyclonic pre-separator. These two features, combined with a large, 1.7 square meter filter area, allows the powerful vacuum to generate a greater air flow rate (111 cfm) than smaller vacuums, including an identical vacuum with just one motor, which only generated an air flow rate of 76cfm (Document ID 0863, p. 27).[280] The second motor also provides more power so the vacuum could be expected to maintain

[280] The vacuums were Dustcontrol DC3700 model vacuums (one with a second motor factory installed). This model has been replaced with the DC3800 in the company catalog (Document ID 0628;0630).

that flow rate for longer under the dust loads created by tuckpointing than is typical of smaller vacuums (Document ID 0863).

During the field trial of this large and powerful vacuum, NIOSH measured the amount of debris collected, the percent of silica in the collected debris, and the concentration of respirable dust in the surrounding air when two otherwise identical vacuums were run at two different flow rates (76 cfm and 111 cfm) (Document ID 0863, pp. 24-28). NIOSH made these measurements over two days while two construction workers performed grinding for tuckpointing, each using the vacuum at a different air flow rate (Document ID 0863, p. 24). Data show that at the higher 111 cfm air flow rate, the shroud captured more debris while maintaining breathing zone respirable dust exposure levels that were lower (by one-half) than the levels achieved at the 76 cfm air flow rate. On both days, estimated silica levels were also lower (19 $\mu g/m^3$ and 26 $\mu g/m^3$) for the worker using the 111-cfm flow rate compared with estimated silica levels for the worker using the lower flow rate (49 $\mu g/m^3$ and 60 $\mu g/m^3$) (Document ID 0863, pp. 24-35).

Work Practices

In addition to using vacuums equipped with features to optimize flow rates and minimize filter loading, employers must train workers on the specific measures the employer has implemented to protect employees from exposure to respirable crystalline silica, including proper work practices to minimize exposure, and how to operate and maintain engineering controls.

OSHA's proposed entry for tuckpointers on Table 1 of the construction standard incorporated a number of important work practice controls (78 FR 56274, 56497). Proposed Table 1 required that the grinder be operated flush against the working surface, with grinding operations performed against the natural rotation of the blade (i.e., mortar debris directed into the exhaust). Computational modeling showed that to efficiently capture particles, the direction of the grinding wheel must rotate from the uncut mortar into the exhaust takeoff section of the shroud. Workers also need to use care in adjusting the grinding depth to the minimum depth necessary and in holding the shroud close against the wall. Minimizing the space between the shroud and wall to the extent practical is critical for optimal capture of the pulverized dust emitted from the grinding point (Document ID 0728, p. 376; 0600, p. 876). These proposed specifications received extensive comment from the regulated community.

A number of commenters discussed the difficulties of complying with the work practice controls specified in the proposed entry for tuckpointers on Table 1. Western Construction Group commented that it is not possible to always keep the grinder flush with the surface because the blade will be spinning at its full speed when cutting into the wall and when the blade is extracted from the surface, and explained that it would be difficult to keep the blade flush when removing vertical mortar joints (Document ID 2183, p. 2). OSHA acknowledges there are circumstances that do not always permit the tool to be operated in this manner, and has therefore removed this requirement from Table 1. However, OHA expects full and proper implementation of Table 1 controls, which may include keeping the blade flush with the surface whenever possible, in order to optimize the effectiveness of local exhaust capture.

Western Construction Group also commented that it is not always possible to operate the grinder against the natural rotation of the blade, because a wall needs to be “prepped” in order to be in sufficient condition for mortar to be placed back into the wall (Document ID 2183, pp. 2-3). Western Construction Group explained that during final preparation, the blade needs to make short passes back and forth to clean the joint and prepare it, and that if workers only operated in one direction, they would place a significant burden on their shoulders and backs by having to make more passes on the wall to clean the joint (Document ID 2183, p. 3). Similarly, CISC commented that workers must move the grinder back and forth in short, deliberate motions when detailing the joint in order to provide the necessary quality finish (Document ID 2319, p. 106). OSHA recognizes that the requirement to operate against the direction of blade rotation may have an impact on job quality and may increase ergonomic stressors. While OSHA has removed this specification from Table 1, OSHA expects full and proper implementation of Table 1 controls, which may include operating against the direction of blade rotation, in accordance with manufacturers’ instructions, whenever practical.

The proposed entry for Table 1 also specified that the equipment must be operated such that no visible dust is emitted from the process, and that sufficient ventilation must be provided when working in enclosed spaces to prevent build-up of visible airborne dust (78 FR at 56497). OSHA has retained a specification in Table 1 requiring that for tasks performed indoors or in enclosed areas, the employer is to provide a means of exhaust as needed to minimize the accumulation of visible airborne dust. Western Construction Group noted that "the use of air scrubbers and fans … have been proven to be a very efficient, practical, tool in the control of silica exposures" and that "[t]hese control measures should [be] researched by OSHA as-an acceptable method in certain circumstances" (Document ID 2183, p. 3). OSHA is not specifically requiring the use of air scrubbers when working in enclosed spaces or indoors, but employers are free to use then in order to reduce visible airborne dust accumulations and comply with Table 1.

OSHA received many comments to the effect that the original specification that no visible dust be emitted from a process is not workable (Document ID 2563; 2169; 2171; 2183). For example, the Power Tool Institute commented that there will always be visible dust when tuckpointing when working around corners of a building (Document ID 1973, pp. 3-4). However, Power Tool Institute stated that an unusual amount of dust would signal to the operator that the dust collection system is not operating properly, and suggested that OSHA specify: "During operation, if excessive visible dust is emitted from the process, immediately stop work and verify that the dust control system is functioning properly" (Document ID 1973, p. 3). OSHA recognizes that brief, intermittent release of visible dust does not necessarily indicate that local exhaust ventilation controls are not performing optimally. Nonetheless, OSHA expects employers to train workers to ensure they can recognize unusual conditions that would be indicative of exhaust system performance degradation. The written exposure control plan required by the standard must include procedures to ensure the full and proper implementation of the engineering controls and work practices. In response to these comments, OSHA has modified Table 1 to no longer prohibit the emission of visible dust, but to require that employers use grinders equipped with commercially available shroud and dust collection systems that are operated and maintained in accordance with the manufacturer's instructions to minimize dust emissions.

Additional work practice controls include training workers to know when and how to clean vacuum filters to prevent caking. Filter caking causes pressure losses that eventually limit air flows in even the most powerful vacuums. These air flow limitations fluctuate in a predictable cycle: First, as debris accumulates, the pre-filter becomes caked with collected dust and air flow decreases; then, periodically, the worker shifts to a new position on the surface being worked and moves the vacuum cleaner or at least turns it off and on. These activities cause a modest portion of the caked debris to fall off the pre-filter, increasing flow rates temporarily. Unless the filter is properly cleaned following manufacturers' recommendations, these cyclic increases are short-lived, and airflows decline again rapidly (Document ID 0730). To assist workers in determining when it is time to run a filter cleaning cycle, vacuums can be fitted with a gauge indicating filter pressure (Document ID 0731, p. 885). Construction site policies must also ensure that vacuum equipment is routinely maintained and kept in good working order.

Studies have shown that worker training improves dust capture even for vacuum designs that do not maximize air flow rate. Even when workers used standard vacuums designed with bags, filters, and 1.5-inch hoses (all features that ultimately decrease air flow rates as debris accumulate), Collingwood and Heitbrink recommended workers periodically dislodge debris on filters, (Document ID 0600, p. 885). The authors reported a geometric mean result of 60 µg/m^3 when using grinders equipped with LEV, which represents a 95-percent reduction compared with the geometric mean of 1,140 µg/m^3 for a group of tuckpointing exposure levels obtained from numerous other construction worksites and used for comparison.[281]

OSHA finds that a key factor in ensuring control effectiveness is the full and proper implementation and maintenance of commercially available engineering controls designed for dust control when operating handheld grinders for tuckpointing or surface smoothing. To that end OSHA agrees with the approach recommended by NIOSH and other commenters who strongly endorse the role of a competent person in the

[281] For this comparison, Collingwood and Heitbrink (2007) report that they used a database of silica exposure values collected by OSHA and compiled during numerous construction site inspections. Qualifying data from this Shields (2000) database were included in ERG's exposure profile (ERG-C, 2008) and in OSHA's present exposure profile.

implementation of controls as well as the performance of regular checks to assure that required engineering controls are used, are functioning properly, and are maintained in proper operating condition; (Document ID 2177, Attachment B, p. 9; 2371, pp. 19-21).

Additional Controls for Grinders

The final exposure profile in Table IV.5.11-B shows that approximately 75 percent (54 out of 72 samples) of workers using handheld grinders to smooth surfaces or for uses other than mortar removal have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers. Control options include wet grinding methods, LEV, remote operations, sustainable design, and, for grinders who perform sacking, substitution.

Wet Methods

Wet methods are an option when workers can use pneumatic grinders on concrete surfaces where emphasis is on structural integrity rather than aesthetics (e.g., parking garages, support columns, surfaces that will be covered during build-out). OSHA notes that the two exposure samples included in Table IV.5.11-B where wet grinding was performed, both indoors, were below the action level of 25 μg/m^3. Linch et al., (2002) found that silica exposures were below 100 μg/m^3 when a worker applied water from a sprayer can at the area where another worker was grinding a vertical concrete surface (Document ID 0784, p. 214). However, the 2007 and 2010 studies by Akbar-Khanzadeh et al. found that wet grinding in an enclosed test area with a retrofit system was significantly less effective than using LEV systems, and resulted in crystalline silica exposures between 331 and 929 μg/m^3 in one series of tests (Document ID 0522, p. 774), and between 270 and 2,080 μg/m^3 in the second (Document ID 3609, p. 707). These results indicate that the retrofit system studied by Akbar-Khanzadeh et al. was likely not as efficient as commercial wet grinding systems, and that the laboratory set-up reflected extremely confined conditions, with test conducted in a 24 by 15.4 by 17.3-foot space (Document ID 3609, p. 701).

The effectiveness of wet methods when using hand held grinders is demonstrated by sampling results from the cut stone industry where fabricators use hand held grinders to shape and polish granite counter tops. Simcox et al. reported that the 8-hour TWA exposures were reduced from 490 μg/m^3 when dry grinding to 60 μg/m^3 when using water-fed grinders on granite counter tops (Document ID 1146, pp. 578-579). Based on the exposure reductions observed when using wet grinders in the cut stone industry, along with the two measurements taken on workers using similarly equipped wet grinders in the exposure profile, OSHA concludes that the PEL of 50 μg/m^3 can be achieved most of the time through the use of wet methods when grinding outdoors.

OSHA received a number of comments related to the use of wet methods as a control for handheld grinders. Thomas Service from the Saw Manufacturers Institute (SMI) commented that use of a grinder that continuously feeds water to the cutting surface is not practical because “[t]here are no options available that are effective safety guards and feature water supply capability” (Document ID 2316, p. 2). SMI noted that “[w]hile some handheld spark-engine powered saws have coolant flow, coolant flow is not available for smaller electric and pneumatic grinders” (Document ID 2316, p. 2). SMI and CISC commented that some grinders equipped with a water delivery system are designed to cool the blade, rather than control the dust, and that the dust mitigation effects of the water are speculative (Document ID 2316, p. 2; 2320, p. 10) However, Dr. Paul Schulte of NIOSH reported that “several manufacturers of smaller grinders do offer electric grinders with integrated water supply capability” and included the catalog of such suppliers (Document ID 4233, Attachment 1, pp. 7-8; 3998, Attachment 10). OSHA concludes that there are commercially available grinders with integrated water supply capability, and that wet methods can be an effective control for grinding in many circumstances (Document ID 0522, p. 778; 1146, pp. 578-579).

Francisco Trujillo of Miller and Long commented that wet methods often present significant slip and fall hazards and present problems when the wet slurry dries and silica is introduced into the workplace through wind or foot traffic (Document ID 2345, p. 2). Mr. Trujillo also stated that attempting to apply wet methods to any non-horizontal surface has proven ineffective and often hazardous when using grinders (Document ID 2345, p. 2). Similarly, Stuart Sessions, testifying on behalf of CISC, noted that it is difficult to use wet methods in winter in locations where the water may freeze (Document

ID 3580, Tr. 1322). OSHA acknowledges that not every control option is practical in every situation. However, OSHA has concluded that wet methods represent a feasible and effective option in many settings.

CISC questioned the specification in the proposed Table 1 entry for handheld grinders to use a “water-fed” grinder when using water as an engineering control, asserting that there may be other ways to effectively deliver water through another mechanism (Document ID 2320, p. 10). The Power Tool Institute (PTI) commented that the use of a water feeding system not specified by the tool manufacturer could result in a serious personal injury and an electric shock for tools that are electrically operated (Document ID 1973, p. 1). Due to the potential electrical hazard from using a water delivery system not specified by the manufacturer, OSHA has modified Table 1 to require the use of integrated water controls that are operated and maintained in accordance with the manufacturer’s instructions to minimize dust emissions.

Based largely on the work of Akbar-Khanzadeh et al. described above, NIOSH recommended that respiratory protection be used to supplement the use of wet grinding systems even when used for less than four hours (Document ID 2177, Attachment B, p. 28). OSHA recognizes the precautionary principle in erring on the side of caution in respiratory protection recommendations; however, based on OSHA's conclusion, stated above, that wet methods are an effective control that will reduce grinders’ exposures to 50 $\mu g/m^3$ or below most of the time during outdoor grinding, OSHA is not requiring in Table 1 any respiratory protection when grinding outdoors and using an integrated water delivery system. However, OSHA acknowledges that confined and enclosed spaces may restrict air movement, resulting in higher exposures. Other than the experimental study by Akbar-Khanzadeh et al. and the two non-detect sample results for workers wet grinding a low-silica-containing material indoors, the record contains no evidence that would permit the Agency to determine the exposures to silica of workers using commercial wet grinding equipment indoors or in enclosed areas. Therefore, OSHA has not included an entry on Table 1 of the final rule for wet grinding indoors or in enclosed areas.

Shroud and Local Exhaust Ventilation

The LEV-based exposure controls for surface grinding function similarly to the LEV-based controls for tuckpointing described in the previous paragraphs, as tuckpointing is simply a specialized form of grinding. Tuckpointing is normally done on mortar between bricks, whereas grinding is performed on concrete; mortar and concrete are both mixtures of cement, sand, and water.[282] In both cases, a shroud encloses an abrasive disc- or wheel-style blade in order to capture the high-speed particles released from material pulverized by the blade.

Surface grinding differs from tuckpointing, however, in the shape and location of the surfaces that are worked. First, tuckpointing is generally limited to exterior masonry. Additionally, the aggressive cutting action of the tuckpointing blade tends to remove a greater volume of material at a faster rate than the smoothing action of the surface grinding blade, and so tuckpointing generates higher concentrations of dust. Tuckpointing and grinding are compared in Table IV.5.11-B.

The factors that influence vacuum flow rate for tuckpointing are equally important to LEV dust controls for all types of surface grinding, and for other hand-operated power tools as well. Collingwood and Heitbrink note that "vacuum cleaners will probably continue to be an important control option for respirable dust exposures in construction for dust exposure sources such as mortar removal, concrete grinding, hole drilling, and brick cutting where water application is impractical" (Document ID 0600, p. 884). Akbar-Khanzadeh & Brillhart and Echt & Sieber both reported reduced silica exposures when workers used LEV shrouds with vacuum attachments during surface grinding, although the silica exposure results were variable and some exceeded 50 μg/m^3 even with controls (Document ID 0521, pp. 344 - 345; 0632, pp. 459-460). Exposures measured within a test chamber during grinding operations confirm that high exposures result from grinding concrete indoors, even with good dust collection equipment, with mean task-based sample results generally falling between 100 and 200 μg/m^3 (Document ID 0522,

[282] The primary difference between concrete and mortar is the ratio of cement, sand, and other ingredients. Concrete is intended to stand alone and is fortified with stone aggregate, while mortar is intended to hold bricks together and so is created thin enough to be forced between bricks and is formulated to adhere well to masonry.

p. 774). However, older studies of LEV effectiveness have found reductions of 86 to 99 percent (Document ID 0611, p. 463; 0247, pp. 6, 8). A more recent study by Akbar-Khanzadeh et al. found 98 to 99 percent reductions, depending on the vacuum type used (Document ID 3609, p. 707). The use of ventilated overhead grinders on a cantilevered stand was reported not only to result in low dust exposures but also to improve the ergonomic stressors of overhead grinding (Document ID 1235, pp. 1-2).

OSHA received a number of comments from stakeholders about the effectiveness of using LEV dust control systems on handheld grinders. Miller and Long's Safety Director Francisco Antonio Trujillo stated "[D]ust collection systems used on hand grinders received very disappointing results. In fact, no hand grinder equipped with a dust collection system was capable of bringing exposure levels below the current PEL" (Document ID 3585, Tr. 2963). He further explained that this was due to the limited capabilities of the dust collection systems maintaining complete surface contact during the frequent grinding of columns and walls (Document ID 3585, Tr. 2963-2964.) But he also testified that a vacuum system designed for use with ceiling grinders "greatly reduced the amount of dust expelled from the process but did not completely eliminate it. It was a very, very dusty activity, and now it's moderately so" (Document ID 3585, Tr. 2962). Mr. Trujillo reported that although all sampling results were below the current 100 μg/m^3 PEL, three out of five samples were still above 50 μg/m^3. He also reported that none of the hand grinders with dust controls that Miller and Long evaluated were effective with columns and wall corners and that even with these LEV systems, Miller and Long had the same number of workers in its respiratory protection program (Document ID 3585, Tr. 2962-2964, 3012).

However, OSHA has reason to believe that the effectiveness of controls available today is likely higher than those that were used during the sampling included in the exposure profile. Gerry Scarano, Executive Vice President of the International Union of Bricklayers and Allied Craftsworkers, for instance, testified that since 2009, "the availability and effectiveness of control options have improved, adding force to OSHA's conclusion that it is feasible to reduce the dust in most cases down to the proposed PEL" (Document ID 3581, Tr. 1562).

Because the same factors that cause air flow to decline during tuckpointing affect air flow during other tasks such as surface grinding, the measures discussed for tuckpointing (e.g., larger vacuums and vacuum hoses, with effective means for preventing clogging of filters, such as cyclonic pre-separators) need to be used when surface grinding in order to minimize hose and filter clogging.

Echt and Sieber reported respirable quartz concentrations ranging from 44 μg/m^3 to 260 μg/m^3 during 2- to 3-hour surface grinding tasks with LEV at a construction site. Each day, one or two 18-pound bags of debris were collected in a vacuum cleaner. The investigators measured actual air flow rates three times over the course of five sampling days, reporting an air flow range from 86 to 106 cfm (Document ID 0632, pp. 459 - 460).[283] As noted in the discussion of LEV controls for tuckpointers, Heitbrink and Santalla-Elías also reported that portable shop vacuum air flow is affected by filter loading (Document ID 0731, p. 383). Using more extensive measurements (continuous data logging every 8 seconds), Collingwood and Heitbrink evaluated the same vacuum model used by Echt and Sieber and found that average initial air flow was 71 cfm, which declined to 48 cfm over the task-based work sessions during which trained workers performed normal tuckpointing, knocking the dust from filters using the manufacturer's recommended method as deemed necessary (Document ID 0600, p. 884).[284]

These changes in air flow can have a dramatic effect on dust capture. As discussed in the previous section on the review of additional controls for tuckpointers, experimental testing conducted by Heitbrink and Bennett indicates that a vacuum and shroud used for tuckpointing reduced the dust emission rates by a factor of more than 400 under ideal circumstances when air flow rates exceed 80 cfm. This factor dropped to approximately

[283] In this configuration, the vacuum did not use a cyclonic pre-filter (Document ID 0632, p. 460).

[284] OSHA notes that this comparison does not account for possible differences in hood entry loss for surface grinding shrouds compared to tuckpointing grinding shrouds (judged to be minor), or for other factors not reported in the reports by Echt and Sieber and by Collingwood and Heitbrink (Document ID 0632; 0600).

10 when vacuum air flow was less than 80 cfm (Document ID 0728, pp. 374-375).[285] The study authors reported that there was visible leakage of dust from the grinder shroud when the vacuum operated at flow rates between 20 to 30 cfm, and concluded a higher flow rate is needed for effective capture of dust generated by grinders during mortar removal (Document ID 0728, p. 367).

In some cases underpowered vacuums have been used to test grinder shroud effectiveness. Evaluating the effect of a standard shop vacuum (i.e., one not equipped with a filter-cleaning mechanism) and shroud on worker exposure during periods of intensive surface grinding, Akbar-Khanzadeh et al. (2007) determined that this LEV system significantly reduced geometric mean silica exposure levels compared with uncontrolled grinding by 99.7 percent; however, even with LEV controls, the average exposure measured over 6 trials was 155 µg/m^3 (Document ID 0522, pp. 774, 776). The grinder in this study was fitted with a 6-inch diameter blade and was equipped with a vacuum with a capacity of 105 cfm. Based on the ACGIH criteria air flow rate of at least 25 cfm per inch of blade diameter, an air flow of at least 150 cfm is recommended (Document ID 0515, p. 13-63).

Akbar-Khanzadeh et al. compared silica and respirable dust exposure samples during grinding in a test chamber with different vacuum systems: the Dustcontrol HEPA vacuum with cyclonic pre-separator (DC 2800c) and the tank based Eibenstock 1500 HEPA vacuum, and the 85L575 Shop-Vac Corp common shop vacuum. The study found that mean exposures when using the HEPA vacuums were lower (110 µg/m^3 and 170 µg/m^3 with and without general ventilation, respectively) than when the common shop vacuum system was used (120 µg/m^3 and 920 µg/m^3 with and without general ventilation, respectively). The Dustcontrol and Eibenstock systems operated with little maintenance during the experiments but the shop vacuum system experienced problems, including complete failure of 3 units (Document ID 3609, p. 707). Thus, similar to tuckpointing, surface-grinder LEV requires more capable vacuums than common shop vacuums. The

[285] Heitbrink and Santalla-Elías found that vacuum air flow rates declined from 80 to 30 cfm when vacuums captured 35 pounds of grinding debris in a laboratory test (Document ID 0731, p. 380-381). That study also showed that at a construction site, debris collected by vacuum bags during tuckpointing caused the average air flow rate to decrease from 80 cfm to 30 cfm (Document ID 0731, pp. 382-383).

effect is increasingly important when workers use larger grinding wheels. Akbar-Khanzadeh et al. (2010) also reported that when a 180mm grinding cup was used the mean silica task exposures were more than three times higher than when using a 100-125 mm grinding cup, even when using the stronger vacuum systems (Document ID 3609, p. 706).

OSHA received a number of comments about the proposed entry on Table 1 for handheld (or hand-operated) grinders using LEV. The proposed entry specified use of a grinder with a commercially available shroud and dust control system (78 FR at 56497). Several commenters questioned why shrouds need to be commercially available and whether appropriate shrouds are, in fact, commercially available (Document ID 2319, p. 105; 2316, p. 2; 2171, p. 9).

SMI and National Utility Contractors Association (NUCA) noted that use of non-compliant plastic shrouds could create a safety hazard for high-speed broken wheel fragments (Document ID 2316, p. 2; 2171, p. 9). OSHA agrees the shrouds which are not properly rated in accordance with the appropriate standards can pose a serious safety risk if grinding wheels break and has maintained the requirement for employers use commercially available shrouds.

SMI commented that there are no commercially available dust shrouds that currently meet ANSI B7.1 (and OSHA) guard design requirements (Document ID 2316, p. 2). SMI stated that available dust shrouds are plastic and are used in place of the original equipment’s steel guards but do not meet the requirements of ANSI B7.1, which is a safety design specification standard for grinding wheels (Document ID 2316, p. 2). However, NIOSH reported that several major tool manufacturers sell grinders with integrated dust shrouds designed to meet applicable safety standards and the tools are labeled accordingly. For example, the Underwriter’s Laboratory (UL) mark carried by the products of several manufacturers signifies that their tools meet the requirements of ANSI (American National Standards Institute)/UL/CSA 60745-2-3, which incorporates ANSI B7.1 by reference (Document ID 4233, p. 8). Catalogs of tool manufacturers submitted to the docket by NIOSH include grinders that meet this standard, and other tools that bear the SA approval mark of the Canadian Standards Association, an OSHA Nationally Recognized Testing Lab (NRTL, described under 29 CFR 1910.7) (Document ID 3998, Attachment 10, pp. 7-9, 15, 45). OSHA expects that, once there is a market demand, additional tool manufacturers will offer shrouds meeting these machine guarding requirements. Therefore, OSHA finds that compliant shrouds are commercially available, and will not create a greater hazard.

OSHA's proposed Table 1 entry for handheld grinders using LEV required the dust collection system to be equipped with a HEPA filter and operated at a 25 cfm or greater airflow per inch of blade diameter. CISC commented that for larger blades, it may be difficult to design and operate a system that pulls air flow at 25 cubic feet per minute per inch of blade diameter (Document ID 2319, p. 105). The Power Tool Institute (PTI) recommended revising the Table 1 entry for grinders to require use of vacuums equipped with a HEPA filter that operates at 80 cubic feet per minute or greater, noting that commercial dust collection systems are typically rated at approximately 130 cfm (Document ID 1973, pp. 2-3). The National Association of Home Builders (NAHB) expressed concern that a dust collector with a HEPA vacuum would need to be at least 112.5 CFM for a small, 4.5 inch grinder (Document ID 2296, Attachment 1, p. 29). The Building and Construction Trades Department of the AFL-CIO (BCTD) requested that OSHA specify flow rates for grinder LEV based on blade diameter (Document ID 2371, p. 32). In the proposed rule, OSHA set different cfm requirements for grinders and tuckpointers (25 cfm per inch for grinders, versus 80 cfm for tuckpointers). Since tools used for tuckpointing and other handheld grinding are so similar, OSHA finds that the same requirement is applicable to both. OSHA has opted for the 25 cfm per inch of blade diameter as the more protective approach, and more consistent with established engineering principles as reflected in the ACGIH Industrial Ventilation Manual, 28th Edition, which generally expresses minimum cfm requirements for a variety of (stationary) grinders in relation to the wheel diameter (Document ID 3883, pp. 13-147-13-152).

The exposure profile in Table IV.5.11-B shows that 60 percent of ceiling grinders who perform overhead grinding using LEV, and 50 percent of outdoor grinders using LEV or water have achieved exposures below 50 μg/m^3, while 25 percent of other grinders working indoors with LEV have achieved exposures below 50 μg/m^3. These results clearly demonstrate that the PEL of 50 μg/m^3 has already been widely achieved, with technology available at the time of sampling. Much of the data in the exposure profile reflects samples collected over ten years ago, before many of the engineering studies described in this chapter were conducted. OSHA expects that capture technology will continue to improve in response to market demand. When fully and properly implemented, as further described below under Work Practices, OSHA expects that exposures of 50 μg/m^3 or less can be achieved without reliance on respiratory protection for outdoor workers. OSHA notes that Table 1 specifies that exhaust ventilation must be used as needed to minimize accumulation of airborne dust when grinding indoors or enclosed areas. OSHA expects that these controls will be sufficient to protect workers during short-duration indoor grinding tasks, but has determined that respiratory protection will still be needed for indoor grinding tasks anticipated to last more than four hours per shift.

The conditions that cause the air flow rate of vacuum systems to decline during tuckpointing have the same effect on vacuum system air flow during surface grinding. As with tuckpointing, vacuum design components like cyclonic pre-separators, vacuums with two vacuum cleaner motors in parallel, and a gauge indicating filter pressure will all aid in maintaining adequate air flow rates during on-site usage. As these components are increasingly used in grinding applications it is expected that exposures will decline, particularly indoors and in enclosed areas.

Remote Operations and Combined Controls

Grinders who are able to distance themselves from the grinding point in addition to using LEV have substantially lower silica results than those whose breathing zone is within arm’s length of the grinder. Woskie provided information on a grinding tool fitted with LEV (shroud and HEPA-filtered vacuum, not described further) that was attached to a movable lever that allowed the worker to press the grinder against the overhead surface (at some distance ahead) by pressing down on the opposite end of the lever (Document ID 1235, p. 1). The three 1- to 2-hour personal breathing zone (PBZ) samples obtained were all below the LOD (29 μg/m^3 to 41 μg/m^3 in this case, based on an assumed 10 μg per sample LOD) for the period monitored, or 5 μg/m^3 to 10 μg/m^3 as 8-hour TWAs. Respirable dust results were between 9 μg/m^3 and 94 μg/m^3 during the period monitored, indicating that the workers experienced very little dust in their breathing zones during this task, as well as improved ergonomic considerations for the job. Although this dust control strategy appears highly effective, there is no other information in the record to indicate how broadly remote operations can be conducted or under what kinds of conditions it is feasible to employ remote operations. Therefore, although remote operations are not required, they remain an option for reducing exposures during overhead grinding.

Sustainable Design

When precast concrete is formed, design practices should indicate the placement of necessary grooves, cutouts, and contours so they can be cast into the concrete, nearly eliminating the need for high-silica-exposure activities such as grinding and cutting to produce these features. Similarly, WorkSafeBC supports work pre-planning as an effective strategy in eliminating the need for drilling holes in concrete (Document ID 4072, Attachment 14, p. 7). Careful form placement can also reduce the need for grinding to remove bulges and blemishes often caused by shifting or flawed forms. A factory evaluated by OSHA usually placed grooves in the precast concrete delivered to the construction site. On one occasion when the factory neglected to perform this task, workers experienced extremely elevated silica exposures while grinding overhead grooves at the construction site (Document ID 0031, pp. 27-33). These exposures (four results all between 2,420 μg/m^3 and 3,831 μg/m^3), the highest for workers grinding on concrete, would have been eliminated if the factory had placed the grooves in the precast product. Employers can drastically reduce grinders' silica exposures by selecting precast concrete that is formed to eliminate the need for grinding at the construction site. In hearing testimony, Mr. James Toscas of the Precast/Prestressed Concrete Institute stated that "[i]t's not typical for any fit-up work to be done that involves sawing or drilling concrete in the field. When that happens, it is usually because there was an error in the plans" (Document ID 3589, Tr. 4381). This suggests that preplanning is a practical and commonly used strategy for reducing the need for concrete grinding or use of other handheld power tools at a construction site, although grinding may be needed on occasion.

Substitution

Grinders that also perform “sacking” to seal imperfections in concrete surfaces can use alternate materials and methods to eliminate silica dust. Construction contractors can switch to concrete patching compounds that create the desired surface without labor-intensive finishing that involves rubbing dry concrete powder over the surface. Over the past decade, newer types of commercially available patching materials have begun replacing traditional sacking and patching methods previously used to repair concrete surface defects, thus eliminating that potential source of silica exposure (Document ID 1138, pp. 5-6). These patching compounds are suitable for patching both cast-in-place and precast concrete surfaces.

Where traditional methods are still in use, worker silica exposures can be reduced by using low-silica sacking powder (e.g., Portland cement) or by using mortar or concrete sacking powders made with silica sand that are larger than respirable size. For example, as part of the dry mix, some construction contractors performing sacking use 30-mesh sand instead of 60-mesh or smaller sand particles (Document ID 1138, p. 5). A 30-mesh sand contains a maximum particle size of approximately 230 micrometers (µm), compared with 100 µm for a 60-mesh sand or even smaller particles for sands with larger mesh numbers. As discussed in Section IV-4.9 – Glass Products, washing can remove the very fine respirable size particles (1 to 10 µm).

Mean quartz levels for sacking results reported by Flanagan et al. indicate that quartz was below the limit of detection in more than half (54 percent) of the samples for this activity, suggesting that many workers already use these alternate materials and methods (Document ID 0676, p. 322).

Work Practices

The same work practices described previously for tuckpointers are equally applicable for grinders. As with mortar grinding, it is equally important to maintain the grinder shroud as close as possible to the surface being worked, in order to better capture the maximum quantity of particles.

In the hearings, Francisco Antonio Trujillo of the Miller and Long concrete framing company testified that “there is no completely dustless method that I have personally observed in the real world” (Document ID 3585, Tr. 2960). CISC stated that “for certain types of tools, such as grinders and other handheld pieces of equipment, it is impossible to perform the work with the tool flush against the surface being impacted. At times, there may be a gap, this will mean some visible dust is emitted, even when local exhaust ventilation or wet methods are utilized” (Document ID 3580, Tr. 1356). OSHA recognizes that, due to corners and other changes in the work surface, gaps will momentarily occur.

OSHA also recognizes that brief, intermittent release of visible dust does not necessarily indicate that LEV systems are not performing optimally. OSHA expects that, in addition to as part of full and proper implementation of Table 1 controls and required training, workers will receive training to ensure they know how to effectively utilize controls to minimize dust release by minimizing gaps between the tool shroud and the work surface, and to recognize unusual conditions that would be indicative of exhaust system performance degradation. Where local exhaust is used, OSHA expects that employers will ensure that workers are trained in the proper use of grinders to ensure maximum capture efficiency of the shroud, and in when and how to clean vacuum filters to ensure that airflows are maintained, in order to ensure optimal performance of these engineering controls. In addition, the standard requires a competent person to make frequent and regular inspections of job sites, materials, and equipment to verify controls are properly implemented. In regards to wet methods that may be used for grinding activities, Table 1 specifies that water be applied at flow rates sufficient to minimize release of visible dust. OSHA intends that these work practice controls be used as part of the full and proper implementation of Table 1 controls.

5.11.4 Feasibility Findings

Paragraph (c) of the construction standard gives employers the option of following Table 1, which includes specified controls for tuckpointing and grinding activities; alternatively, the employer must assess and limit exposures in accordance with the more traditional regulatory approach of compliance with the PEL contained in paragraph (d). For handheld grinders used for mortar removal (i.e., tuckpointing), Table 1 requires employers to use a grinder equipped with a commercially available shroud and dust collection system. The tool must be operated and maintained in accordance with the manufacturer's instructions to minimize dust emissions. The dust collector must provide 25 cubic feet per minute (cfm) or greater of airflow per inch of wheel diameter and have both a filter with 99 percent or greater efficiency and either a cyclonic pre-separator or filter-cleaning mechanism. In addition, the entry for tuckpointing on Table 1 requires the use of respiratory protection (APF 25 for work that lasts more than four hours a shift; APF 10 for work of four hours or less). For handheld grinders used outdoors for other than mortar removal, Table 1 requires either a grinder equipped with an integrated water delivery system that continuously feeds water to the grinding surface or a grinder equipped with a commercially available shroud and dust collection system. In both cases the tool must be operated and maintained in accordance with the manufacturer's instructions to minimize dust emissions. If the employer uses the dust collection option, the dust collector must provide 25 cubic feet per minute (cfm) or greater of airflow per inch of wheel diameter and have both a filter with 99 percent or greater efficiency and either a cyclonic pre-separator or filter-cleaning mechanism. For tasks performed indoors or in enclosed areas, Table 1 requires that LEV systems be used and that respiratory protection (APF 10) be used for tasks performed more than four hours in a shift. Employers who choose to use wet grinding systems indoors or in enclosed areas must comply with the PEL and exposure assessment requirements in paragraph (d) of the final rule.

Feasibility Finding for Tuckpointers

Based on the evidence in the record, OSHA concludes that, for tuckpointing, commercially available shroud and vacuum LEV systems exist that significantly reduce exposures during mortar removal; manufacturers include Bosch, Hilti, Flex, Metabo, and others (see examples in Document ID 4073, Attachments 4a, 4b, and 9h; 3998, Attachment 10). Based on the exposure profile in Table IV.5.11-B, OSHA concludes that most tuckpointers (79.2 percent) currently experience exposures above 50 μg/m^3. Although some of the samples with exposure levels below the PEL are associated with mortar replacement and related tasks, 35.6 percent of those with low exposures were using mortar grinders with LEV systems while tuckpointing. OSHA notes that among tuckpointers using LEV outdoors, 40 percent of samples measured exposures below 50 μg/m^3.

When these systems are used in a manner consistent with the practices observed during the field trials reported by Collingwood and Heitbrink, silica exposures will be significantly reduced (Document ID 0600, p. 707). However, due to the high-intensity material removal associated with this task, the need to maintain a continuous air flow with the high volume of debris produced by tuckpointing, and the fact that mortar grinders cannot always be used flush with the surface, mortar grinding often results in exposures above the PEL even with proper implementation of engineering controls. For example, according to OSHA's exposure profile, tuckpointing outdoors with LEV systems will result in exposures exceeding 50 μg/m^3 more than half the time, and exceeding 250 μg/m^3 a quarter of the time, with a mean exposure of 348 μg/m^3. Task-based sampling of mortar grinding operations where modern dust collection equipment was used generally has shown exposures above 100 μg/m^3 (but not above 1000 μg/m^3) for the duration of the task (Document ID 4073, Attachments 9h and 9m). Based on these data, a worker engaged in mortar grinding for fewer than 4 hours per day can be expected to experience TWA exposures below 500 μg/m^3, while a worker performing this task more than 4 hours per day will be exposed up to nearly 1000 μg/m^3 TWA.

Thus, even using the controls described in this section, employers cannot attain the PEL of 50 μg/m^3 in most tuckpointing operations most of the time. As a result, OSHA cannot conclude that the final PEL is feasible for this type of work (Document ID 1720, p. IV-513). For employers following Table 1, the final rule requires, in addition to LEV, the use of respiratory protection having an assigned protection factor (APF) of at least 10 for operations taking less than 4 hours per day and an APF of 25 for longer operations. For tasks of less than four hours, OSHA has reduced the required APF from 25, as specified in the NPRM, to 10, but has added a general requirement that, for tasks performed indoors or in enclosed areas, employers implementing controls specified in Table 1 must provide a means of exhaust as needed to minimize the accumulation of visible airborne dust. OSHA anticipates that the addition of ventilation sufficient to prevent the accumulation of dust will result in exposures lower than those identified in the PEA (when an APF of 25 was proposed). Based on the evidence of continuing improvements in the effectiveness of LEV as reported in the literature, and the requirement to provide a means of exhaust as needed to minimize the accumulation of visible airborne dust, OSHA concludes that the reduction to an APF of 10 is appropriate for tasks of less than four hours duration.

OSHA notes that maximum exposures recorded in the profile for tuckpointers exceeded a tenfold multiple of the 50 $\mu g/m^3$ PEL. Whether employers follow the Table 1 option or the PEL option, the competent person and exposure control plan provisions apply and are essential in ensuring the effectiveness of engineering controls, work practice controls, and respiratory protection.

Feasibility Finding for Grinders

OSHA finds that 25 percent of grinders are currently exposed to silica levels at or below 50 $\mu g/m^3$. For workers who are currently exposed above 50 $\mu g/m^3$, the controls described in this section can be implemented to reduce silica exposure levels to 50 $\mu g/m^3$ or below in most operations, most of the time, with exceptions for grinding done indoors or in an enclosed area for more than four hours per shift. Both wet grinding and LEV systems described on Table 1 are commercially available; therefore, OSHA finds from the evidence in the record discussed above, that engineering controls, including LEV and wet methods, are feasible, effective in reducing exposures during grinding, and commercially available. There are several manufacturers of grinding tools equipped with dust collection or wet systems (Document ID 4073, Attachments 4a and 4b; 3998, Attachment 10). In addition, several participants testified about the commercial availability of such equipment, including Mr. Scarano of the Bricklayers; Mr. Johnson of the Operative

Plasterers and Cement Masons International Association; and Mr. Trujillo of Miller and Long (Document ID 3581, Tr. 1562; 3581, Tr. 1592-1593; 3585, Tr. 2962-2964). These sources indicate that Makita, DeWalt, Bosch, and Ostec all make grinding dust control systems.

When grinders are operated with controls outdoors, half of all grinders experience exposures below 50 μg/m^3, and OSHA expects exposures for most of the remaining grinders (outdoors) can be reduced to or below 50 μg/m^3 with increased use of more effective engineering and work practice controls. Based on the evidence in the record, OSHA concludes that both LEV and wet methods can be an effective control that will reduce grinders' exposures to 50 μg/m^3 or below most of the time during outdoor grinding. Therefore, OSHA finds that the standard is technologically feasible for workers using handheld grinders outdoors. However, unlike tuckpointing, surface grinding is a common indoor task. Based on task durations summarized by Flanagan, workers typically perform grinding tasks for less than four hours per shift (Document ID 0677). The available data presented in the FEA Table IV.5.11-B suggest that the mean indoor grinding exposure level with dust collection systems is about twice that for grinding outdoors, with 50 percent of exposures between 100 and 250 μg/m^3.

OSHA notes from its exposure profile that the vast majority of exposure samples taken during indoor grinding where dust controls were used made use of LEV systems rather than water-based dust control systems (21 out of 23 samples). Exposures measured within a test chamber during grinding operations confirm that high exposures result from grinding concrete indoors, even with good dust collection equipment (Document ID 3609), with mean task-based sample results generally falling between 100 and 200 μg/m^3. Based on the available data for indoor grinding, OSHA believes that, when grinding with a commercially available shroud and dust collection system for four hours or less per shift, resulting exposures should generally be no higher than grinding outdoors for a full shift and thus should not necessitate the use of respiratory protection. However, for indoor grinding with a shroud and dust collection system performed more than four hours per shift, the Agency believes that exposures would consistently exceed 50 μg/m^3, but that the use of the required means of exhaust sufficient to minimize the accumulation of visible airborne dust will ensure these exposures do not exceed 50 µg/m^3 by more than a factor of ten. Therefore, Table 1 requires respiratory protection with an APF of at least 10 when grinding with dust collection systems for more than four hours per shift indoors or in an enclosed area. OSHA also finds that there is inadequate evidence in the record to demonstrate that wet grinding indoors or in an enclosed area is as effective as using LEV. Accordingly, Table 1 permits the use of water-based dust control for grinding outdoors only.

5.12 UNDERGROUND CONSTRUCTION WORKERS

5.12.1 Description

Tunneling accounts for most of the construction work performed underground and includes the construction and renovation of underground tunnels, shafts, chambers and passageways.[286] Tunnel construction techniques include: tunnel boring, drilling and blasting; excavation; pipe jacking; and microtunneling.[287] In Chapter IV of the Preliminary Economic Analysis (PEA), OSHA preliminarily concluded that underground construction activities fell into three major groups: 1) activities related to explosive blasting (not addressed in this analysis for reasons discussed below); 2) construction activities that are also typically conducted aboveground (discussed in other sections of this analysis); and 3) activities related to tunneling with rapid excavation machines (discussed in this section). Only the third group of activities, which are unique to underground construction and a significant source of respirable crystalline silica exposure, are addressed in this section.

The Agency determined that workers are not exposed to respirable silica dust from explosive blasting. Explosive blasting is performed only when the tunnel is vacant and reentry is allowed only after exhaust systems clear the air. Therefore, explosive blasting activities are not included in the profile. This finding was not disputed by any commenters; accordingly, OSHA has not included these workers in the final analysis of underground construction work.

With respect to underground construction activities that are also typically conducted aboveground, OSHA preliminarily determined that it was appropriate to address those

[286] It should be noted that tunneling for the purpose of extraction (e.g., for coal or minerals) is considered a mining operation and falls under the jurisdiction of the Mine Safety and Health Administration. Tunneling for other purposes is regulated by OSHA.

[287] Pipe jacking is a tunneling technique in which powerful hydraulic jacks push (advance) specially designed pipe through the ground. Excavation of soil takes place at the front of the pipe string manually or mechanically. The process requires workers to occasionally enter into the pipeline being jacked to clear obstructions or to make connections at junctions (Document ID 0955, 0956; and 1720, p. IV-520). Pipe jacking is typically done with pipes 42 to 120 inches in diameter (Document ID 0582; 1720, p. IV-520). Microtunneling is used to construct smaller diameter pipelines, which are typically too small for humans to enter. Microtunneling uses a remotely controlled microtunnel boring machine (MTBM) with the pipe jacking technique to install pipelines (Document ID 0535; 1720, p. IV-520).

activities (like chipping, sawing, drilling, and grinding) in other sections of the PEA because they are not unique to underground construction. Controls for these activities, which are discussed in other sections, would not be unique to working above or below the ground. OSHA's preliminary determination to consider workers performing these activities in other sections of the PEA was based, in part, on a report by Blute et al. (1999), on the quartz-silica exposures of ten workers using chipping equipment during underground tunnel construction. Their mean respirable quartz exposure was 280 $\mu g/m^3$, with overall exposures ranging from10 $\mu g/m^3$ to 1,640 $\mu g/m^3$. These levels were lower than the results reported for 109 workers performing similar activities aboveground (operating jackhammers and impact drillers indoors and outdoors). See Section IV-C 26 Jackhammer and Impact Drillers of the PEA (Document ID 1720, p. IV-521).

The exposure profiles in this Final Economic Analysis (FEA) support OSHA's determination that the workers doing these activities underground are exposed to levels of respirable silica dust that are no greater than those to which workers doing the activities aboveground are exposed. The final exposure profile for workers using chipping hammers in this FEA contains 139 samples with exposures ranging from 12 $\mu g/m^3$ to 2,350 $\mu g/m^3$ and a mean of 243 $\mu g/m^3$; these levels of exposure are consistent with the exposure levels reported for underground chipping operators by Blute. See Section IV-5.5 – Jackhammers and Other Powered Handheld Chipping Tools.

Furthermore, the FEA exposure profile for grinders supports the determination that exposures for underground workers are no greater than those among their aboveground counterparts. Indeed, controls for underground grinders appear to be used more effectively to control respirable silica dust exposures than the controls used aboveground. The exposure profile for grinders includes six samples for workers grinding in a tunnel. See FEA Section IV-5.11 – Tuckpointers and Grinders. The tunnel construction workers using no additional controls were exposed to respirable silica levels of 178 $\mu g/m^3$, 628 $\mu g/m^3$, and 985 $\mu g/m^3$, compared to levels of 12 $\mu g/m^3$ to 737 $\mu g/m^3$ for workers grinding aboveground outdoors, and 117 $\mu g/m^3$ to 1,730 $\mu g/m^3$ for those grinding indoors with no controls.[288] Grinders using LEV in the tunnel had results of 5 μg/m³, 5 μg/m³ and 10 μg/m³, compared to a range of 12 μg/m³ to 460 μg/m³ for the aboveground equivalent (Table IV.5.12-B).

Even though underground workers perform tasks in an enclosed space, they experience exposures similar to their aboveground counterparts due to the ventilation requirements associated with underground and tunneling work. The ventilation provides sufficient air to mimic the working conditions of an aboveground work setting.[289] See 29 CFR 1926.800(k). In addition, most dust control techniques available to the general construction industry (wet methods, local exhaust ventilation [LEV]-equipped tools, enclosed operator cabs and booths (these terms are used interchangeably in this section), and increased general ventilation) are also available below ground to control dust exposures (Document ID 1431, p. 3-99; 1720, p. IV-521; 1423, p. 883; 1235, p. 1).

Because underground workers performing impact drilling and grinding experience exposures that are similar to or less than their aboveground counterparts, and because controls work equally well belowground and aboveground, OSHA maintains its original determination that it is appropriate to address workers who perform these underground construction activities is in other sections of the FEA. As further discussed in those sections, the Agency has determined that achieving the PEL is feasible for these activities. See Sections IV-5.3 – Heavy Equipment Operators and Ground Crew Laborers through IV-5.11 – Tuckpointers and Grinders.

While the Construction Industry Safety Coalition (CISC) did not disagree with OSHA's finding regarding the similarity of the tasks conducted aboveground and underground, or with the determination that underground tasks could be addressed in other sections of OSHA’s analysis, they commented that OSHA had not met its burden of showing

[288] Two additional sample results for outdoor grinding with no controls contained no silica and were reported as the limit of detection (12 μg/m³).

[289] 29 CFR 1926.800(k)(3) requires a linear velocity of air flow in the tunnel bore, in shafts, and in all other underground work areas of at least 30 feet (9.15 m) per minute where blasting or rock drilling is conducted, or where other conditions likely to produce dust, fumes, mists, vapors, or gases in harmful or explosive quantities are present.

technological feasibility for these tasks (Document ID 2319, p. 68). These feasibility concerns are addressed in the sections that discuss these activities in more detail.

The third category of underground construction activities – the category addressed in this section – is tunneling. During rapid, large-scale tunneling operations, construction workers use rapid excavation machines (such as roadheaders, continuous miners, and tunnel-boring machines [TBMs]) that use aggressive grating action to cut into the rock face (Document ID 1720, p. IV-520). Workers working on or supporting tunneling operations (tunnel borers) may be exposed to silica when they operate excavation or in-tunnel transportation equipment, tend the equipment (e.g., conveying belts, excavating machinery), lay track, extend utility lines as excavation machinery advances, or remove excavated material from the tunnel. These activities are never performed aboveground.[290]

CISC questioned OSHA's decision to focus its preliminary technological feasibility analysis for underground construction work on TBMs. Specifically, it questioned the extent to which TBMs are or could be used for all underground work, particularly to the exclusion of roadheaders, which can create a significant amount of very fine silica dust. CISC asserted that OSHA did not analyze the technological feasibility of the proposed PEL for all underground construction workers, but instead analyzed the feasibility of achieving the PEL only for workers using TBMs (Document ID 2319, p. 69).

The primary differences between the various types of excavators are in their cutting tool configurations, the rate at which they remove material, and the type of rock for which they are typically used (Document ID 1431, pp. 3-99 – 3-100). A review of the characteristics of the various types of excavators shows that the exposure levels found around TBMs are likely typical of, if not higher than, the levels found around the other types of excavators.

[290] Typical job titles for workers in the tunnel borer job category include rapid excavation machine operator, locomotive operator (carries workers and equipment between tunnel entrances and excavation machines), mechanic (maintains the rapid excavation machinery and conveyor belt systems), miner (lays track and extends water, air, and electrical lines as excavation machines advance), and bottom shaft worker (removes excavated material from the tunnel).

Roadheaders are configured for mobility and used for short distances to cut around tunnel corners or to refine hard rock tunnel shapes. These machines use cutting heads on a boom manipulated by the operator in a cab. The roadheaders' pine-cone shaped cutting heads are notably smaller and remove rock at a substantially lower rate than continuous mining machines or TBMs; the modest amount of rock debris created is typically carried away by truck. Due to the potential for air contaminants in the exhaust from mobile roadheaders, ventilation is typically provided near the cutting heads by the manual placement of ducts (Document ID 1431, pp. 3-99 – 3-100).

Continuous miners are configured to remove large quantities of material rapidly using a rotating drum with teeth that is driven into a soft rock face. This equipment is most frequently found in coal mines; however, workers can operate continuous miners at construction sites where roads are built through soft sandstone or limestone. These rock formations often have lower crystalline silica content, or produce less fine silica dust when abraded, than formations with harder rocks, resulting in lower exposures than those experienced with TBMs, which cut harder rock (Document ID 1431, pp. 3-99 – 3-100).

TBMs come in a wide range of sizes and cut the entire tunnel face in one pass. This extensively used equipment is only minimally maneuverable and usually cuts a straight line or a slightly curved tunnel. This type of excavator is typically cylindrical and similar in diameter to the tunnel being cut (Document ID 1431, pp. 3-99 – 3-100). TBMs cut a notably larger cross-section of rock face than other rapid excavation equipment and are used on the hardest material, creating the greatest potential quantities of dust (Document ID 3759, Attachment 1, p. 5).

No information on the frequency with which the various types of excavators are used was submitted to the Agency. The exposure and use information for TBMs summarized in the PEA therefore continues to represent the best available information for underground construction workers (Document ID 1720, pp. IV-521 – 528). In the absence of more detailed exposure information associated with the use of roadheaders and continuous miners, OSHA continues to consider the sampling data associated with the use of TBMs to be the best available information for analyzing exposures associated with tunnel operations.

OSHA has determined that the similarities in the various types of rapid excavation machines and their uses allow for the use of similar types of controls, such as water sprays and ventilation, to reduce exposures. Additionally, underground construction work includes all workers who perform activities related to tunneling, including the operation of rapid excavation machines (such as roadheaders, continuous miners, and TBMs) and support activities related to tunneling with rapid excavation machines (including workers who tend to the equipment (e.g., conveying belts, excavating machinery), lay track, extend utility lines as excavation machinery advances, and remove excavated material from the tunnel).

Underground construction workers involved in rapid excavation are exposed to dust that is generated by the rapid excavation of silica-containing dirt and rock. They are also exposed during the performance of related support activities (including the open transfer of silica-containing materials) and when working near ventilation system exhaust air.

Job categories, major activities, and sources of exposure for underground construction workers involved in rapid excavation are summarized in Table IV.5.12-A.

Table IV.5.12-A
Job Categories, Major Activities, and Sources of Exposure for Underground Construction Workers

Job Category*	Major Activities and Sources of Exposure
Underground Construction Worker (Tunnel Borer)	Excavating, removing debris, operating rapid excavation machines, transporting workers and equipment, laying track and installing/extending utility lines (air, water, electrical), performing maintenance and repair, and others. • Dust from rapid excavation and related support activities. • Dust from open transfer of silica-containing materials. • Dust from working in close proximity to ventilation system exhaust air.

*Job categories are intended to represent job functions; actual job titles might differ, and responsibilities might be allocated differently, depending on the site.
Source: Document ID 1720, p. IV-522.

5.12.2 Exposure Profile and Baseline Conditions

The exposure profile in Table IV.5.12-B for underground construction workers associated with tunnel excavating machines includes 27 full-shift, personal breathing zone (PBZ) samples of respirable crystalline silica. These exposure data were obtained at two tunnel construction sites, one evaluated by NIOSH (Document ID 0225) and one evaluated by OSHA (Document ID 0070). The median exposure is 12 μg/m^3, the mean is 41 μg/m^3, and the range is 7 μg/m^3 (the limit of detection (LOD)[291] to 257 μg/m^3. Of the 27 samples, 6 (22 percent) are above 50 μg/m^3.

The job titles of sampled workers included TBM operator, drill operator, mechanic, locomotive or brake operator, miner, welder, electrician, bottom shaft worker, and inspector. The TBMs were equipped with engineering controls that included water sprayers, LEV systems, and shields designed to reduce the release of rock fragments and dust as the TBM cut the rock face (Document ID 1720, p. IV-522; 0070, pp. 53, 72-84; 0225, p. 4-6, 8).

Two respirable quartz sample results (46 μg/m^3 and 38 μg/m^3) were obtained for workers inside a TBM's enclosed, ventilated operator booth. This result suggests that workers in enclosed booths already experience levels below 50 μg/m^3 (Document ID 1720, p. IV-523; 0070, pp. 31, 53, 72-84; 0225, pp. 6-9, 11).

Two additional sample results (136 μg/m^3 and 87 μg/m^3) were obtained for workers who spent part of their time in the enclosed booth and part of their time outside the TBM (Document ID 0070, p. 31). The OSHA report noted that the tunnel's ventilation system had not been extended the full length of the tunnel, providing less fresh air into the work area than required, and recommended an increase in the air flow through the TBM's LEV system and an increase in the amount of water sprayed on the machine's rotating cutting wheels (Document ID 0070, pp. 52-53). A combination of factors – insufficient general

[291] LODs are as reported by the original study author. LODs are discussed in further detail in Section IV.2 – Methodology.

ventilation, LEV, and water –likely contributed to the elevated exposures (Document ID 0070, pp. 52-53; 1720, p. IV-523).

The two remaining highest sample results (124 $\mu g/m^3$ and 257 $\mu g/m^3$) were obtained for two workers who loaded and unloaded locomotive flat cars and assisted with crane operations at the bottom of a tunnel shaft (Document ID 0225, pp. 9-11). NIOSH attributed these elevated results to the workers' positions near the tunnel shaft, which acted as the exhaust air duct for the tunnel's ventilation system, and, more significantly, to their proximity to the last transfer point of rock moving from the horizontal belt conveyor to the vertical bucket conveyor (Document ID 0225, p. 10). Although a water spray bar was reportedly located at each of the two other transfer points in the tunnel, engineering controls were absent from this last transfer point (Document ID 0225, p. 10). The other two elevated sample results (55 $\mu g/m^3$ and 75 $\mu g/m^3$) were obtained for two miners operating equipment in TBM trailing gear, laying track, and extending water and air lines (Document ID 0225, pp. 9, 11). NIOSH suggested that these two exposures might have been associated with a booster fan malfunction on the third sampling day, which reduced the tunnel's exhaust volume by 10 to 20 percent (Document ID 0225, p. 10).

The remaining 21 sample results showed exposures below 50 $\mu g/m^3$ (Document ID 0225, p. 11; 0070, p. 31).

In an attempt to collect more information, the Agency reviewed exposure sampling from studies for other underground construction workers, including electricians and pipe jacking operators (Document ID 0546; 0929; 0562; 3759, Attachment 1).

Bakke et al. (2002) evaluated the exposures of eleven TBM operators working on a Norwegian tunnel project and found exposures with a median of 490 $\mu g/m^3$ and a geometric mean of 390 $\mu g/m^3$ silica (n=43). The TBM had an enclosed operator cab; however, the operator kept the doors open in order to monitor the flow of material on the conveyor (Document ID 0546, pp. 786, 795). Bakke noted that the miscellaneous tasks of monitoring and loading broken rock onto conveyors were associated with higher exposure results (Document ID 0546, p. 790). While the study notes that 43 samples were evaluated, no individual results were available for inclusion in OSHA's profile.

Oliver and Miracle-McMahill (2006) sampled 51 workers involved in tunnel construction using the tunnel-jacking technique. The process consisted of a "jacking box" being propelled forward with cables and the use of roadheaders (Document ID 0929, pp. 984-985). Exposure results were reported in summary form as a percentage of the previous OSHA PEL *ranging from zero to 1,617 percent) and did not include enough information for inclusion in the exposure profile (Document ID 0929, pp. 985, 987). Limited information on working conditions was included in the report; the authors noted that wetting was used at the tunnel face. Operations continued, however, even during periods when water was not available for wetting. Additionally, a granite seawall and a manmade concrete obstruction were encountered during tunneling; these circumstances may explain some of the high exposures (Document ID 0929, pp. 987-988, 992).

Woskie et al. (1999), evaluated exposures for workers constructing a tunnel using "cut and cover" methods, where a wide trench is dug, decks and walls are established, a roof is poured, and, finally, the tunnel is covered with dirt (Document ID 0562, pp. 632-633). Equipment and tasks onsite included pneumatic chipping guns (hammers), grinders/scabbers, and pneumatic drills (Document ID 0562, p. 637). No tunneling machines were used, so this study contained no sample data for inclusion.

The New York State Laborers' Health and Safety Fund submitted an industrial hygiene study by Silverstein (2010). That study included 84 samples on TBM operations. Exposures ranged from 0.01 to 139, with a mean of 9.8. Sixty-six additional samples collected on roadheader operations showed exposures ranging from 0.035 to 19.5, with a mean of 2.2 (Document ID 3759, Attachment 1, pp. 4-5, 10). Because the underlying data (total dust, percent of silica, and sampling times) were not provided, the Agency was unable to include this data in the final exposure profile.[292]

[292] Exposure values in the Oliver and Miracle-McMahill (2006) and Silverstein (2010) studies were reported without units and represent the actual exposure divided by the previous OSHA PEL of (10-2*% silica)/10 (Document ID 3759, Attachment 1, p. 8; 0929, p. 987). The percent silica was not reported; therefore, OSHA was unable to determine respirable crystalline silica (RCS) values.

Even though these studies did not provide sufficient information for inclusion in the exposure profile (as outlined in Section IV-2 – Methodology), OSHA has determined that the studies do contain useful information establishing current exposure conditions and show that the elevated exposures identified were associated with poor dust controls and inadequate work practices.

No OSHA Information System (OIS) data were identified for inclusion in the exposure profile for underground construction work. So although limited, the data from the NIOSH site evaluation and the SEP inspection represent the best data available to OSHA for underground construction workers involved in tunneling. Because no exposure sampling data containing sufficient information (as outlined in the Methodology section, IV-2) was submitted to the docket, the Agency has not made any revisions to the exposure profile (Table IV.5.12-B**)** for underground construction work.

Providing further insight into baseline conditions for underground construction, the National Rural Electric Cooperative Association (NRECA) and the Laborers Health and Safety Fund of North America (LHSFNA) testified at the public hearings on the exposures for underground construction workers.

Brian Lazarchick from NRECA commented that the only potential exposures utility workers have are during the auguring of holes into the ground for the placement of utility poles and during the installation of underground lines. He stated that they use wet boring methods and mini enclosed-cab excavators to complete these tasks, resulting in no exposures to respirable-size crystalline silica dust for their workers (Document ID 3583, Tr. 2274, 2277). However, NRECA did not submit any sampling data to support this assertion. Other representatives from the utilities industry submitted written comments to the docket stating that the use of wet boring methods and enclosed, ventilated cab mini-excavators has allowed them to minimize dust exposures. Due to the use of water to inhibit dust creation, they do not expect their work to produce respirable crystalline silica (Document ID 2365, pp. 7, 15).

LHSFNA stated that the confined nature of tunneling work, the often-limited ventilation, and the ability of TBMs and other tunneling equipment to generate dust can lead to substantial silica exposures. Some of the most severe exposures for their union members occur during tunneling (Document ID 3589, Tr. 4207-4208).

Eddie Mallon from LHSFNA Local 147, who has experience working on multiple tunnel construction projects in New York City, testified about the working conditions, shift length, and the availability of controls in underground tunnel construction. He testified that exposures have increased due to the use of higher powered equipment in lieu of manual methods (Document ID 3589, Tr. 4209-4248). Mr. Mallon stated that the most common trades working in tunnels are laborers and operating engineers, and that these tunnel workers are typically exposed to respirable crystalline silica eight hours per day while actively tunneling. He added that it is not uncommon for workers to be 10 feet away from the dust-generating activities, and that while it is typical for operators to work from inside enclosed cabins, the laborers are not inside any enclosures and remain exposed to airborne silica dust. Depending on the equipment being used, a laborer may stand beside the operator with a water hose to control the dust (Document ID 3589, Tr. 4246-4248).

Mr. Mallon also stated that water is available for use on site and is most often used on the TBM and at the head of the tunnel. Although foam can also be used, Mr. Mallon has never seen it used; he attributed this to the cost of foam. Water is the primary control implemented to reduce dust in tunnels, but water also requires significant cleanup efforts. Mr. Mallon testified that it is not uncommon to arrive on a jobsite and see that no water has been used to control dust (Document ID 3589, Tr. 4230-4231).

Ventilation is another available control for underground construction. According to Mr. Mallon, most projects begin with functioning ventilation systems to remove the dust from the tunnel and exhaust it aboveground. Lack of maintenance, however, results in the decreased effectiveness of the ventilation systems. Without proper ventilation, tunnel work is excessively dusty. He testified that, generally speaking, work is stopped only to allow dust to clear when it becomes difficult to see other people - but “it’s like pulling teeth to have a job stop.” He has seen tunnel construction projects where ventilation controls were maintained properly and visible dust was minimal (Document ID 3589, Tr. 4242-4243, 4246).

OSHA agrees with the comments from the utility industry and LHSFNA that the effective use of ventilation, enclosed cabs and wet methods can reduce exposures to levels below the PEL.

Final Baseline Conditions and Exposure Profile

Based on the descriptions of tunneling workers' activities and rapid excavation operations discussed in the PEA and in the rulemaking record, OSHA concludes that baseline conditions for this group of workers include wet methods (water sprayers), LEV Systems (for tools, excavating equipment, and conveyor transfer points), general dilution ventilation (ventilation requirements in OSHA's underground construction standard), and enclosed operator cabs or booths. These controls are not always used properly. The results summarized in Table IV.5.12-B were obtained under these conditions and represent the best data available to the Agency. The final exposure profile for this industry shows that 78 percent of sample results fall below the PEL of 50 $\mu g/m^3$, 11 percent of samples results fall between 50 $\mu g/m^3$ and 100 $\mu g/m^3$, and the remaining 11 percent of sample results are over 100 $\mu g/m^3$.

Table IV.5.12-B Respirable Crystalline Silica Exposure Range and Distribution of Results for Construction Workers: Underground Construction Workers											
	Exposure Summary			**Exposure Range**			**Exposure Profile**

5.12.3 Additional Controls for Underground Construction Workers

The exposure profile in Table IV.5.12-B shows that 22 percent (6 out of 27 samples) of tunnel borers have exposures above the final PEL of 50 μg/m^3. Therefore, OSHA finds that additional controls will be necessary to achieve the PEL for these overexposed workers.

OSHA determined that the majority of tunnel borers work inside TBM trailing gear (that is, the equipment behind the bit or head, including the operator's booth or cab) or outside the TBM. The primary exposure controls for these workers include controls provided by the TBM, such as water sprays positioned at cutting heads and conveyor transfer points, and LEV at cutting heads.[293]

In those operations where elevated exposures still occur, employers will need to ensure the full operation of the TBM engineering controls and also ensure the optimum operation of ventilation systems installed inside tunnels, improve the application of water sprays wherever dust is generated, enclose conveyor transfer points, and take other steps to reduce dust from conveyors as necessary to reduce exposures.

Ventilation

OSHA enforces ventilation requirements in construction under 29 CFR 1926.800(k)(3), which provides that "the linear velocity of air flow in the tunnel bore, in shafts, and in all other underground work areas shall be at least 30 feet (9.15 m) per minute where blasting or rock drilling is conducted, or where other conditions likely to produce dust, fumes, mists, vapors, or gases in harmful or explosive quantities are present" (Document ID 1720, p. IV-521). NIOSH currently recommends 100 feet-per-minute air flow across the full diameter of the tunnel if the rock contains more than 10 percent silica (Document ID 0887, p. 105). Additionally, NIOSH recommends an air flow of at least 60 feet-per-minute for roadheaders, depending on the size of the tunnel, with the duct inlet five feet from the rock face and ten feet forward from the operator (Document ID 0887, p. 91).

[293] It should be noted that OSHA already has a standard in place requiring the use of controls (such as wet drilling, the use of vacuum collectors, or water mix spray systems) when drilling rock or concrete during underground construction activities. See 29 CFR 1926.800(k)(9).

Bakke et al. (2001), found that minimum flow rates of 40 to 70 cubic feet-per-minute resulted in arithmetic mean exposures of 11 μg/m^3 and 34 μg/m^3 for construction workers at four tunneling sites, demonstrating that the use of such ventilation rates can reduce average exposures below the mean exposure of 41 μg/m^3 reflected in Table IV.5.12-B (Document ID 1720, p. IV-528; 0545, pp. 251, 254).

Both industry and labor commented on the importance of having effective general ventilation during underground construction to reduce exposures (Document ID 2253, p. 5; 4073, Attachment 15i, p. 1; 3759, Attachment 1, pp. 2, 5-6). The Agency agrees.

The Agency also notes that proper maintenance of the ventilation system is essential to minimizing exposures. Dust collection systems with screens and filters can clog, and need to be properly maintained in order to ensure sufficient air movement to prevent the build-up of dust and overexposures to silica (Document ID 0887, p. 102; 4073, Attachment 15i). The effectiveness of the tunnel's general dilution ventilation system can be maintained by performing routine maintenance and by ensuring that the duct extends to the face of the tunnel and is free of leaks (Document ID 1720, p. IV-528; 4073, Attachment 15i, p. 1).

In conclusion, increasing general ventilation air flow rates has been shown to reduce exposures during tunnel excavation. Such changes in air flow rates are an additional control employers can use to reduce their workers' silica-dust exposures

Improved Material Transfer Systems

In addition to increased ventilation, NIOSH IC-9465, the *Handbook for Dust Control in Mining*, recommends improving controls along the material conveyor systems by enclosing conveyors and conveyor transfer points, adding effective clean up mechanisms (such as belt scrapers), and increasing exhaust ventilation to conveyors to minimize the conveyor belt as a source of silica exposure (Document ID 0887, pp. 97-106; 1720, p. IV-527).

NIOSH recommends enclosing transfer points and adding water sprays to reduce exposures from this source. However, if that alone is not enough, the addition of ventilation along enclosed conveyors exhausted to a dust collector can reduce exposures even further (Document ID 0887, p. 104).

Both the top and the bottom of conveyor belts should be wet for optimal dust suppression (Document ID 0887, p. 105). The addition of belt scrapers or a belt washing system can further reduce exposures by preventing wet material from sticking to the belts and becoming re-suspended (Document ID 0887, p. 104).

Enclosed Cabs and Booths

For workers who ride inside the machine, including drill operators and cutter-head mechanics, an enclosed, ventilated cab can reduce exposures.

Pannell and Grogin (2000) reported that pressurized, enclosed cabs without high-efficiency filtration can provide a high degree of protection for operators performing excavation work where the silica content of the soil is unusually high (Document ID 0952, pp. 14-16). The investigators obtained 44 samples associated with workers operating a water wagon and a scraper from these types of cabs, and reported mean respirable dust results of 72 $\mu g/m^3$ during sampling periods of approximately 4- to 5-hours (Document ID 0952, p. 15). These respirable dust values were roughly 80 to 90 percent lower than the results for operators of open-cab equipment, who had mean respirable dust exposures of 426 $\mu g/m^3$ (four results for grader operators), 672 $\mu g/m^3$ (40 results for dozer operators), and 837 $\mu g/m^3$ (10 results for workers operating a second dozer) (Document ID 0952, p. 15). Respirable dust samples collected inside and outside the scraper showed that this equipment reduced operators' exposures by nearly 90 percent (Document ID 0952, pp. 15-16). The project studied, construction of a solid low-level radioactive waste disposal facility, was unusual in that 64,000 cubic meters of soil, containing up to 65 percent silica, was excavated in a semi-arid environment, creating unusually high respirable silica dust exposures. Bulldozer operators routinely performed soil ripping, a task that is likely to abrade and fracture silica-containing rock. While this study was not conducted during tunneling operations, the abrading and removal of soil is a similar task; the use of pressurized enclosed cabs or booths to protect operators of rapid excavating equipment is expected to lead to similar reductions in exposures.

NIOSH recommends several design and operational features for cabs in order to minimize operators' exposures to respirable dust (Document ID 0839). Workers using cabs that follow these recommendations can experience exposures 90 percent lower than those experienced by workers in open cabs (Document ID 0590; 0844). The NIOSH recommendations are as follows:

- Cabs should be equipped with a recirculation filter that continuously filters the air circulating within the cab. This is the only way to eliminate dust that has entered the cab (e.g., on shoes, or through an open door);
- The inlet for intake air should be strategically located so that it avoids, as much as possible, the equipment's major dust sources;
- Cabs should avoid the use of floor heaters or any discharge of clean air that is low in the cab, which entrains dust from the floor and dirty work clothes before entering the worker's breathing zone. Ideally, air flow would circulate from the top of the cab to the bottom, and recirculation pick-up would occur low in the cab;
- Cabs must be well maintained and kept clean. Filters must be changed regularly so that they do not become overloaded with dust, and seals must be maintained to preserve pressurization inside the cab. A gritless, natural base sweeping compound should be applied to the floor of the cab to bind dirt and dust tracked in during normal work activities. The compound should also be used for regular housekeeping activities (Document ID 0839, pp. 1-3).

In addition, NIOSH recommends remote operation for roadheaders when available, as this is, in most cases, the most effective way to lower the operators' dust exposures (Document D 0887, p. 92).

OSHA estimates that improved filtration systems and improved work practices, such as operating only when doors are closed, should further lower exposures. While properly functioning enclosed, ventilated cabs offer the best protection for workers inside the booths or cabs, wet methods and LEV that suppress dust at the source benefit workers both inside and outside the cab (Document ID 1720, p. IV-525).

Wet Methods

Improving water spray quality, possibly reducing droplet size, modifying the direction and quantity of spray, and ensuring adequate pressure and filtration can increase the effectiveness of water as an exposure control.

Achieving optimal wetting at the cutting head offers the best opportunity for controlling dust at its source; wetted material is less likely to contribute to exposures (Document ID 0887, p. 103). NIOSH found that uniform wetting of the broken rock was the most important factor in reducing rock dust as a source of exposure and that increasing the number of water sprays can promote uniform wetting of the material. An increase in from 17 to 46 sprays resulted in a 60 percent decrease in respirable dust, even when the total water flow and pressure remained the same (Document ID 0887, p. 103). While the best moisture content can be as high as 5 percent, even one percent moisture has been shown to result in significant reductions in dust levels (Document ID 0887, p. 103). NIOSH has also found that spray location is important in reducing exposures. TBM sprays directed at the rotating head and at falling rock are more effective than those directed at the face or the crown (Document ID 0887, p. 103).

Using foam spray or other wetting agents increases particle agglomeration and can reduce airborne dust levels another 20 to 60 percent when compared with plain water (Document ID 0887, pp. 105-106). Foam used at belt transfer points averaged a 30 percent reduction in dust compared to water alone (Document ID 0887, p. 105).

For roadheaders, NIOSH recommends lowering spray pressures to reduce air turbulence (which can actually increase exposures). The sprays on the boom head should be located close to the cutting head, wetting the broken rock falling down from it, and the water pressure should be maintained at 50 psi or less. Hole and Belle (1999), as cited by NIOSH, found that a roadheader wet head operating at 20 psi led to a 40 percent reduction in dust compared to external sprays (Document ID 0887, pp. 92-93). If this is not enough to reduce exposures, or if it is determined that more water is necessary, larger orifice nozzles can be used (Document ID 0887, p. 92). For the gathering pan where material is collected, high volume, low pressure nozzles should be used (Document ID 0887, p. 92).

CISC questioned whether water was available as a control for use with non-TBM excavators (Document ID 2319, p. 69). Two documents submitted to the docket show that various types of excavation equipment used in underground construction can be equipped with water sprays. First, NIOSH discussed the use of water sprays on various types of tunnel equipment, including continuous miners, longwall shearers and roadheaders, in NIOSH IC-9465, the *Handbook for Dust Control in Mining*, and made recommendations on adjusting or improving existing manufacturer sprays for optimal dust reduction (Document ID 0887, pp. 8, 92, 103). And second, the 2010 Silverstein study noted the use of water sprays on roadheaders, stating: “Worker exposures to silica during roadheader machine operations are controlled by two methods, water sprays at the cutting head and ventilation in the tunnel” (Document ID 3759, Attachment 1, p. 5).

Combination of Controls

OSHA expects that it will require a combination of the controls listed above to consistently maintain exposures below the PEL. This is seen in a report by NIOSH where silica-containing excavated tunnel material was wetted at the area removed with water from four spray hoses directed at the cutting heads (50 gallons per minute), and wetted again along the conveyor line at transfer points. In addition, LEV with an air scrubber was used, and the operator worked from inside a control booth (Document ID 0225, pp. 5-6, 8). All but four of the exposures (27 total samples were taken) were below the PEL (Document ID 0225, p. 11). NIOSH attributed two of the overexposures to a reduction in tunnel exhaust air due to a booster fan failure and the other two overexposures to the fact that spillage had been allowed to accumulate at the transfer point between the vertical and horizontal conveyors (Document ID 0225, p. 10). The workers with the overexposures (“miners” and “bottom men”) also had exposure samples under the PEL during the same visit, confirming that it is possible to reduce their exposures to levels at or below 50 $\mu g/m^3$ (Document ID 0225, p. 11).

5.12.4 Feasibility Finding

As previously noted, workers performing underground activities not specific to tunneling (such as grinding, hole drilling, or chipping) have silica exposures similar to those faced by workers who perform the same activities aboveground. See Sections IV-5.3 – Heavy Equipment Operators and Ground Crew Laborers, IV-5.4 – Hole Drillers Using Handheld or Stand-Mounted Drills, IV-5.5 – Jackhammers and Other Powered Handheld Chipping Tools, IV-5.6 – Masonry and Concrete Cutters Using Portable Saws, IV-5.8 – Millers Using Portable or Mobile Machines, IV-5.9 – Rock and Concrete Drillers, and IV-5.11 – Tuckpointers and Grinders for OSHA's findings related to those types of activities.

CISC commented that OSHA's analysis failed to demonstrate that the PEL was feasible for all of the various operations involved in underground construction because OSHA relied on "a limited scope of activities [TBMs] in concluding that the proposed PEL of 50 μg/m^3 is capable of being done in most underground operations most of the time" (Document ID 2319, p. 69). OSHA relied on the best available evidence of tunnel workers' exposures (i.e., the sampling exposures described in the final exposure profile) and compared that information with studies that included samples associated with other types of equipment (even though those samples could not be used in the final exposure profile). OSHA finds that TBMs, due to their larger size and their ability to cut through harder materials, have the potential to create more silica-containing dust than other types of machines. Thus, if anything, TBM data overestimates current exposures for workers using other types of machines. OSHA specifically found that the operation of TBMs result in higher exposures then roadheaders. And finally, the dust sources for the various types of machines are the same or similar. These sources are the broken rock removed from the tunnel face and its movement to the rear and out of the tunnel along conveyors or other types of conveyances. Irrespective of the type of machine being used, water sprays and dust suppressants, ventilation, and proper maintenance of controls, can control dust levels in order to keep silica exposures below 50 μg/m^3 for most underground construction activities most of the time (Document ID 0225, p. 11).

OSHA concludes that exposure levels are already below the PEL of 50 μg/m^3 for most workers inside excavating machines that have pressurized enclosed cabs or booths and fully functioning water spray, general ventilation systems, and LEV (as necessary). Where exposures exceed 50 µg/m^3, improved maintenance of the cab, cab filtration, and increased ventilation and water spray systems in the tunnel can reduce exposures. And with respect to tunnel workers who work outside the cabs or booths, OSHA concludes that silica exposures of 50 µg/m^3 or lower can be achieved for most of the workers most of the time by making sure that the controls, including water sprays and LEV, as well as the tunnel's dilution ventilation system, operate optimally.

Due in part to the complexity of excavating machines, dust controls, and the ventilation systems required to control dust for underground operations, OSHA did not include underground construction and tunneling operations in Table 1 of paragraph (c) of the construction standard. OSHA received no comments requesting that tunneling machines be included on Table 1.

Additionally, OSHA has determined that TBMs and other types of tunneling machines are often operated at the same job site for extended periods of time and that, for this work, periodic air monitoring is the best method to accurately evaluate exposures. And there are numerous other hazards that must be routinely monitored in accordance with 29 CFR 1926.800(j)-Air quality and monitoring. Therefore in this context, the sampling required by the rule to evaluate silica exposures will not be overly burdensome because employers are already conducting routine on-site sampling.

For the reasons discussed above, OSHA determined that rapid excavating machines will not be included on Table 1. Employers who use these machines will therefore be required to assess and monitor exposures to respirable crystalline silica in accordance with paragraph (d) of the standard. Employers will also be required to establish a worker control plan describing necessary controls. For underground construction workers who are involved in a task listed on Table 1 (e.g., drilling, grinding, chipping), employers can implement the controls in Table 1 without also needing to sample those employees for respirable crystalline silica and are considered to be in compliance with the table for those workers, even if they are working in the proximity of tunnel boring work covered by this section of the analysis.

5.12) Underground Construction Workers

OSHA concludes that most workers performing underground construction activities are currently exposed to silica levels below the PEL of 50 μg/m^3. For workers who are currently exposed above 50 μg/m^3, the additional controls described in this section can be implemented to reduce silica exposure levels to 50 μg/m^3 or below in most operations, most of the time. Therefore, OSHA finds that the standard is technologically feasible for workers performing underground construction activities.

APPENDIX 1 – OSHA INFORMATION SYSTEM (OIS) RESPIRABLE CRYSTALLINE SILICA DATA

This appendix contains the results of air samples obtained from the OSHA Information System (OIS) that were taken to assess exposure to respirable crystalline silica. The OIS sampling results include 964 personal breathing zone (PBZ) samples taken during compliance inspections conducted between January 1, 2011 and April 17, 2014. The OIS sampling results were submitted to the silica rulemaking docket as Document ID 3958, and used to update the final exposure profiles presented in the FEA.

The OIS samples were taken to assess compliance with the preceding PEL, and therefore, the sampling results were reported as respirable dust concentrations in units of milligrams per cubic meter of air (mg/m^3). The final PEL is expressed in units of micrograms per cubic meter of air (μg/m^3) of respirable crystalline silica. Therefore, the respirable dust concentrations from the OIS report were converted to respirable silica dust concentrations for comparison with the final PEL and for inclusion in exposure profiles. (See IV-2.0 Methodology for details). This appendix presents the results of the OIS samples as respirable silica concentration in units of μg/m^3 grouped by general industry sector, or by application group for construction.

Table IV.A-1
OIS Data Description

HEADING	CONTENTS DESCRIPTION
Sec.	The FEA Chapter IV section number in which the record is included. NA means “not applicable" - the record is not included in a specific exposure profile.
Section Name	The title for the indicated section of FEA Chapter IV. For records not included in an exposure profile, this column indicates whether the sample was obtained in general industry or the construction industry.
Job Category	The worker group to which OSHA assigned the record, based on the available information about the worker's job function within the sector or application group. Worker exposure data within a job category share similar source(s) of silica exposure and control options. Some Job Categories are further divided into subcategories based on available information regarding the types of controls in use.
Sample Duration (min.)	The number of minutes over which the silica sample was collected. This information is not shown in Document ID 3958. OSHA retrieved the sample durations for individual records at a later date and has included them here to provide more complete information on individual samples.
Resp. Dust (mg/m^3)	The 8-hour TWA PBZ concentration of Respirable Dust reported in column N of Document ID 3958. Most results are reported in milligrams of respirable dust per cubic meter (mg/m^3); ten samples were reported in mppcf, and are noted as such.
Pct. Silica	The percentage of crystalline silica in the respirable dust collected on the sample filter. The percent silica values presented in this appendix were calculated from the PEL reported in column P of Document ID 3958 as described in the methods section.
PEL (mg/m^3)	The individual sample PEL calculated by the OSHA compliance officer using the equations described above, and reported in column P of Document ID 3958 (e.g., for General Industry the PEL = 10 ÷ [% silica + 2] for samples reported in mg/m^3).
Severity	The ratio of the calculated PEL and the measured respirable dust level, as reported in column R of Document ID 3958 (i.e., Severity= PEL/[respirable dust concentration]). A severity greater than 1.0 means the sample exceeded the calculated PEL for respirable silica.
Resp. Silica (µg/m^3)	The 8-hour TWA PBZ respirable crystalline silica concentration, in µg/m^3, which was calculated from the percent silica and the respirable dust concentration reported in column N of Document ID 3958.
Included in Profile	"Yes" indicates that OSHA was able to associate the silica sample result with an identifiable job category within a sector (or application group) and that the sample is included in the exposure profile for that sector (or application group). Samples in NAICS for which the available information did not demonstrate systematic silica exposure to a recognizable group of employees (job category) could not be included in an exposure profile, although they may be summarized in general statistics regarding general industry or the construction industry; these samples are listed as "No" in this column.
Inspec. ID	The number assigned by OSHA to the establishment inspection during which the sample was collected.
Opening Date	The date OSHA opened the establishment inspection under which the sample was collected. Samples were typically obtained on that date, or shortly thereafter.
NAICS	The North America Industrial Classification System (NAICS) code reported for the establishment employing the sampled worker, which is used in determining the sector in general industry.
Docket File Row #	The row in which this sample appears in Document ID 3958.

CHAPTER V: COSTS OF COMPLIANCE

INTRODUCTION

This chapter assesses the costs to establishments in all affected industry sectors of reducing worker exposures to silica to an eight-hour time-weighted average (TWA) permissible exposure limit (PEL) of 50 μg/m^3—or, alternatively, for employers in construction to meet the Table 1 requirements—and of complying with the standard's ancillary requirements. This cost assessment is based on OSHA's technological feasibility analysis presented in Chapter IV of this FEA; analyses of the costs of the standard conducted by OSHA's contractor, Eastern Research Group; testimony during the hearings; and the comments submitted to the docket as part of the rulemaking process.

OSHA estimates that the standard will have a total cost of $1,029.8 million per year in 2012 dollars. Of that total, $370.8 million will be borne by the general industry and maritime sectors, and $659.0 million will be borne by the construction sector. Costs originally estimated for earlier years in the PEA were adjusted to 2012 dollars using the appropriate price indices. In general, all employee and supervisor wages (loaded) were from the 2012 BLS OES;[1] medical costs were inflated to 2012 dollars using the medical services component of the Consumer Price Index; and, unless otherwise specified, all other costs were inflated using the GDP Implicit Price Deflator[2].

All costs were annualized using a discount rate of 3 percent, which—along with 7 percent[3]—is one of the discount rates recommended by OMB.[4] Annualization periods

[1] Bureau of Labor Statistics (BLS) Occupational Employment Statistics (OES) (BLS, 2012b). Fringe markup is from the following BLS release: Employer Costs for Employee Compensation news release text; For release 10:00 AM (EDT) Wednesday, March 11, 2015; USDL-15-0386; Employer Costs for Employee Compensation – December 2014; Fringe markup equals 1.462693.

[2] Gross Domestic Product (GDP): Implicit Price Deflator; Series ID: GDPDEF; U.S. Bureau of Economic Analysis (BEA); seasonally adjusted; annual frequency; aggregation method: average; Index 2009 = 100; date range: 1947-01-01 to 2014-10-01; last updated: 2015-03-27 8:01 AM CDT; BEA Account Code: A191RD3.

[3] Appendix V-D of this FEA presents costs by NAICS industry and establishment size category using, as alternatives, both a 7 percent discount rate and a 0 percent discount rate. In the sensitivity analysis presented in Chapter VII of this FEA, OSHA compares the estimated cost of the rule using the 3 percent discount rate to the estimated cost using these alternative discount rates.

[4] The annualized cost of the final rule is derived by converting the discount present value (PV) of costs by year into an equivalent uniform annual stream of costs. So, $PV = \Sigma\, C_i/(1+r)^i$ where i = the ith year and r = the discount rate and C_i is the cost in the ith year. The annualization factor is $a = (r * (1+r)^i) / ((1+r)^i$

for expenditures on equipment are based on equipment life, while there is a 10-year annualization period for one-time costs. Note that the benefits of the standard, discussed in Chapter VII of this FEA, were annualized over a 60-year period to reflect the time needed for benefits to reach steady-state values. Therefore, the time horizon of OSHA's complete analysis of this rule is 60 years. Employment and production in affected industries are being held constant over this time horizon for purposes of the analysis. All non-annual costs are estimated to repeat every ten years over the 60-year time horizon, including one-time costs that recur because of changes in operations over time or because of new entrants that must comply with the standard.[5] Table V-1 shows, by affected industry in the sectors of general industry and maritime, annualized compliance costs for all establishments, all small entities (as defined by the Small Business Act and the Small Business Administration's (SBA's) implementing regulations; see 15 U.S.C. 632 and 13 CFR 121.201), and for all very small entities (those with fewer than 20 employees).

Table V-2 similarly shows, by affected industry in construction, annualized compliance costs for all entities, all small entities, and all very small entities. Note that the totals in these tables and all other tables in this chapter, as well as totals summarized in the text, may not precisely sum from underlying elements due to rounding.

OSHA's exposure profile, presented in Chapter III of this FEA, represents the Agency's best estimate of current exposures (i.e., baseline exposures). Except for compliance with Table 1 in construction, OSHA did not attempt to determine the extent to which current exposures in compliance with the new silica PEL are the result of baseline engineering controls or the result of other circumstances leading to low exposures. This information is not needed to estimate the costs of (additional) engineering controls needed to comply with the new PEL, but it is relevant to estimate the costs of complying with Table 1 in construction.

For both construction and general industry/maritime, the estimated costs for the silica rule represent the additional costs necessary for employers to achieve full compliance with the new standard, assuming that all firms are compliant with the previous standard. Thus, the estimated costs do not include any costs necessary to achieve compliance with previous silica requirements, to the extent that some employers may not be fully complying with previously-applicable regulatory requirements. OSHA almost never assigns costs for reaching compliance with an already existing standard to a new standard

– 1). Thus, the annualized cost equals a*PV, where r = .03 in the primary case, and i is summed over a 10-year period.

[5] To the extent one-time costs do not recur, OSHA's cost estimates, when expressed as an annualization over a 10-year period, will overstate the cost of the standard.

addressing the same health issues. Nor are any costs associated with previously-existing compliance with the new requirements that has already been achieved included.

Because of the severe health hazards involved, as well as current OSHA regulation, the Agency expects that the estimated 11,640 abrasive blasters in the construction sector and the estimated 3,038 abrasive blasters in the maritime sector are currently wearing respirators as required by OSHA's abrasive blasting provisions (29 CFR 1915.154 (referencing 29 CFR 1910.134)). Furthermore, an estimated 264,761 workers, including abrasive blasters, will need to use respirators at least once during a year to achieve compliance with the new silica rule, and, based on a respirator use survey jointly administered by the National Institute for Occupational Safety and Health (NIOSH) and the Bureau of Labor Statistics (BLS) (NIOSH/BLS, 2003), an estimated 56 percent of construction employees whose exposures are high enough that they will need respirators under the new rule currently use such respirators. OSHA therefore estimates that 56 percent of affected construction employees already use respirators in compliance with the respirator requirements of the final silica rule.

Other than respiratory protection, OSHA did not assume baseline compliance with any other ancillary provision, even though some employers have reported that they currently monitor silica exposure, provide silica training, and conduct medical surveillance.

The remainder of this chapter is organized as follows. First, unit and total costs by provision are presented for general industry and maritime. Second, unit and total costs by provision are presented for construction. The chapter concludes with a summary of the estimated costs of the rule for all affected industries.

Table V-1: Annualized Costs, by Industry, for All General Industry and Maritime Entities Affected by the Silica Standard

NAICS	Industry	All Establishments	Small Entities (SBA-Defined)	Very Small Entities (<20 Employees)
213112	Support Activities for Oil and Gas Operations	$97,927,752	$24,247,594	$11,907,226
324121	Asphalt Paving Mixture and Block Manufacturing	$513,042	$257,611	$57,921
324122	Asphalt Shingle and Coating Materials Manufacturing	$3,811,893	$1,272,241	$267,935
325510	Paint and Coating Manufacturing	$1,008,627	$572,603	$96,372
327110	Pottery, Ceramics, and Plumbing Fixture Manufacturing	$8,788,336	$5,059,640	$2,389,156
327120	Clay Building Material and Refractories Manufacturing	$21,252,204	$13,647,591	$1,765,486
327211	Flat Glass Manufacturing	$725,452	$129,486	$11,319
327212	Other Pressed and Blown Glass and Glassware Manufacturing	$2,208,578	$970,207	$276,747
327213	Glass Container Manufacturing	$2,212,672	$2,113,092	$23,711
327320	Ready-Mix Concrete Manufacturing	$30,004,503	$20,250,184	$5,616,970
327331	Concrete Block and Brick Manufacturing	$7,020,737	$4,550,565	$1,383,138
327332	Concrete Pipe Manufacturing	$3,810,088	$1,900,067	$336,697
327390	Other Concrete Product Manufacturing	$20,878,235	$14,539,705	$4,568,859
327991	Cut Stone and Stone Product Manufacturing	$14,628,182	$13,106,845	$5,664,898
327992	Ground or Treated Mineral and Earth Manufacturing	$4,288,421	$2,075,935	$426,975
327993	Mineral Wool Manufacturing	$2,615,391	$990,251	$140,721
327999	All Other Miscellaneous Nonmetallic Mineral Product Manufacturing	$11,597,806	$5,872,264	$2,430,981
331110	Iron and Steel Mills and Ferroalloy Manufacturing	$646,402	$146,290	$0
331210	Iron and Steel Pipe and Tube Manufacturing from Purchased Steel	$163,038	$83,666	$0
331221	Rolled Steel Shape Manufacturing	$51,060	$42,989	$0
331222	Steel Wire Drawing	$92,206	$67,130	$0
331314	Secondary Smelting and Alloying of Aluminum	$35,312	$19,590	$0
331420	Copper Rolling, Drawing, Extruding, and Alloying	$135,310	$68,335	$0
331492	Secondary Smelting, Refining, and Alloying of Nonferrous Metal (except Copper and Aluminum)	$70,791	$37,734	$0
331511	Iron Foundries	$23,362,955	$12,442,276	$967,507
331512	Steel Investment Foundries	$5,450,435	$2,672,675	$124,895
331513	Steel Foundries (except Investment)	$11,118,366	$5,503,027	$559,542
331524	Aluminum Foundries (except Die-Casting)	$4,120,657	$3,130,109	$842,096
331529	Other Nonferrous Metal Foundries (except Die-Casting)	$2,569,518	$1,693,459	$816,991
332111	Iron and Steel Forging	$154,626	$79,975	$0
332112	Nonferrous Forging	$40,101	$13,664	$0
332117	Powder Metallurgy Part Manufacturing	$52,988	$29,903	$0
332119	Metal Crown, Closure, and Other Metal Stamping (except Automotive)	$340,536	$266,352	$0
332215	Metal Kitchen Cookware, Utensil, Cutlery, and Flatware (except Precious) Manufacturing	$48,090	$27,196	$0
332216	Saw Blade and Handtool Manufacturing	$179,774	$120,315	$0
332323	Ornamental and Architectural Metal Work Manufacturing	$44,015	$35,067	$13,862

Table V-1: Annualized Costs, by Industry, for All General Industry and Maritime Entities Affected by the Silica Standard (continued)

NAICS	Industry	All Establishments	Small Entities (SBA-Defined)	Very Small Entities (<20 Employees)
335224	Household Laundry Equipment Manufacturing	$12,403	$157	$0
335228	Other Major Household Appliance Manufacturing	$26,829	$3,765	$0
336111	Automobile Manufacturing	$362,562	$20,482	$0
336112	Light Truck and Utility Vehicle Manufacturing	$324,735	$7,727	$0
336120	Heavy Duty Truck Manufacturing	$183,916	$36,819	$0
336211	Motor Vehicle Body Manufacturing	$260,377	$164,332	$0
336212	Truck Trailer Manufacturing	$180,129	$97,653	$0
336213	Motor Home Manufacturing	$45,680	$10,810	$0
336310	Motor Vehicle Gasoline Engine and Engine Parts Manufacturing	$334,051	$116,317	$0
336320	Motor Vehicle Electrical and Electronic Equipment Manufacturing	$315,816	$157,980	$0
336330	Motor Vehicle Steering and Suspension Components (except Spring) Manufacturing	$180,676	$58,720	$0
336340	Motor Vehicle Brake System Manufacturing	$140,620	$60,248	$0
336350	Motor Vehicle Transmission and Power Train Parts Manufacturing	$364,252	$129,753	$0
336370	Motor Vehicle Metal Stamping	$516,924	$310,283	$0
336390	Other Motor Vehicle Parts Manufacturing	$778,085	$366,093	$0
336611	Ship Building and Repairing	$9,586,384	$2,404,761	$110,154
336612	Boat Building	$2,566,768	$1,969,321	$156,109
336992	Military Armored Vehicle, Tank, and Tank Component Manufacturing	$69,849	$23,894	$0
337110	Wood Kitchen Cabinet and Countertop Manufacturing	$204,454	$155,433	$64,773
337215	Showcase, Partition, Shelving, and Locker Manufacturing	$215,675	$156,085	$0
339114	Dental Equipment and Supplies Manufacturing	$5,930,743	$4,331,589	$1,716,366
339116	Dental Laboratories	$6,857,347	$5,719,685	$4,641,195
339910	Jewelry and Silverware Manufacturing	$2,690,864	$2,065,825	$993,578
339950	Sign Manufacturing	$408,620	$354,823	$140,698
423840	Industrial Supplies Merchant Wholesalers	$2,292,917	$1,287,104	$528,996
444110	Home Centers	$110,386	$6,043	$1,681
482110	Rail transportation	$16,562,059	$0	$0
561730	Landscaping Services	$24,481,907	$18,249,100	$15,602,766
621210	Offices of Dentists	$2,592,207	$2,432,481	$2,094,401
	Totals	**$370,810,530**	**$186,093,853**	**$67,691,610**

[a] Not available. This estimate excludes NAICS 482110 (Railroad transportation) because the Census data did not include information sufficient for OSHA to identify the number of railroad establishments that are small firms and very small entities.

COSTS FOR GENERAL INDUSTRY AND MARITIME

Estimation of the costs of the final rule for general industry and maritime is broken out in this section for three categories of costs: (1) control costs to comply with the PEL of 50 μg/m^3; (2) respirator costs, in those cases where engineering controls are not sufficient to reduce worker exposures to the PEL; and (3) "program" and familiarization costs to comply with the ancillary provisions of the rule.

As discussed in Chapter III (and summarized in Table III-12) of this FEA, OSHA judged that there was no baseline compliance in the general industry or maritime sectors with any of the ancillary provisions (but 100 percent baseline compliance with the existing Hazard Communication training program); 50 percent baseline compliance with the respirator program requirements but no baseline compliance with the respirator use requirements; and 100 percent baseline compliance with the engineering control requirements for workers currently below the new PEL.

Engineering Control Costs

This section of the chapter covers OSHA's estimates of engineering control costs for general industry and maritime sectors. Oil and natural gas fracturing operations are addressed separately because OSHA used a different methodology to estimate engineering control costs for this application group. This section will address OSHA's overall methodology, the methodology for each category of costs (such as ventilation, housekeeping, conveyors), issues specific to small entities, and issues specific to the hydraulic fracturing industry. Within each of these discussions, this section summarizes the methodology used in the PEA to estimate engineering control costs, summarizes and responds to the comments on the PEA, and summarizes the changes made to the methodology used in the PEA for this FEA. Finally, the chapter presents OSHA's final estimates of engineering control costs.

Introduction

The PEA's technological feasibility analysis identified the types of engineering controls that affected industries or sectors would need in order to control worker exposures to at or below the proposed PEL of 50 μg/m^3. Through its contractor, Eastern Research Group (ERG), OSHA generated cost estimates for those controls using product and technical literature, equipment vendors, industrial engineers, industrial hygienists, and other sources, as relevant to each item. Wherever possible, objective cost estimates from recognized technical sources were used. Specific sources for each estimate were presented with the cost estimates.

Table V-4 of the PEA provided a list of possible controls on an industry-by-industry basis and included details on control specifications and costs. The basic information for the types of controls needed was taken from the PEA's technological feasibility analysis. The following discussion explains how OSHA developed and used these estimates to prepare the aggregate costs of engineering controls presented in the PEA.

In developing engineering control cost estimates for the PEA, OSHA made a variety of estimates about the size or scope of the engineering or work practice changes necessary to reduce silica exposures in accordance with the proposed rule. In some cases, OSHA estimated that employers would need to install all new engineering controls. In other cases, though, employers were expected to only need to add additional ventilation capacity or improve maintenance for existing equipment. In these cases, the costs were based on judgments of the amount of incremental change (either additional capacity or additional maintenance work) required per year. These estimates of the size or scope of the necessary engineering or work practice changes reflected representative conditions for the affected workers based on technical literature (including NIOSH Health Hazard Evaluations), judgments of knowledgeable consultants and industry observers, and site visits. A detailed list of the specific costing assumptions and information sources for each control, grouped by job category or industry sector, was shown in PEA Appendix V-A, Table V-A-1.

In order to estimate costs in a consistent manner, OSHA, in the PEA, estimated all costs on an annualized basis. For capital costs, OSHA calculated the annualized capital cost, using a three percent discount rate over the expected lifetime of the capital item. The capital costs for long-lasting capital items (such as ventilation system improvements) were annualized over ten years. OSHA estimated that, in the general industry and maritime sectors, any capital expenditure would also entail maintenance costs equal to ten percent of the value of the capital investment annually.

General Methodology

General Methodology: Per-Worker Basis and Treatment of Overexposures for Cost Calculations

PEA estimates

OSHA, in the PEA, estimated control costs on a per-worker basis. Costs were related directly to the estimates of the number of workers needing controls (i.e., workers exposed over 50 μg/m^3). OSHA divided engineering control costs into two categories: 1) those only needed by establishments with employees exposed to levels of silica that exceeded the preceding general industry PEL of 100 μg/m^3; and 2) those applicable to all establishments where workers were exposed to levels of silica above the proposed PEL (whether just above 50 μg/m^3 or also above 100 μg/m^3). It should be noted that the maritime sector has been subject to a different preceding PEL of 250 μg/m^3. The PEA estimates were presented in the PEA cost analysis tables. The overwhelming majority of the costs (90 percent of all engineering control costs and 85 percent of costs associated with meeting the preceding PEL of 100 μg/m^3) were associated with the second category (controls applicable to all establishments with exposures above the proposed or preceding PEL). Because OSHA is not accounting for the costs of controls necessary to reach the preceding PEL, the PEA focused on controls that may be needed to meet the new PEL. OSHA derived per-worker costs by examining the controls needed for each job category in each industry and dividing the cost of that control by the number of workers whose exposures would be reduced by that control. OSHA then multiplied the estimated per-worker control cost by the number of workers exposed between the proposed (new) PEL of 50 μg/m^3 and the preceding PEL of 100 μg/m^3. The numbers of workers in this category were based on the exposure profiles for at-risk occupations developed in the technological feasibility analysis in Chapter IV of the PEA and the estimates of the number of workers employed in these occupations developed in the industry profile in Chapter III of the PEA. The exposure profile information was determined to be the best available data for estimating the need for incremental controls on a per-worker basis.

In general, in the PEA, OSHA inferred the extent to which exposure controls were already in place from the distribution of overexposures among the affected workers. Thus, if most exposures in a facility were above the preceding PEL, OSHA broadly interpreted this as a sign of limited or no controls, and if most exposures were below the proposed (new) PEL of 50 μg/m^3, this would be indicative of having adequate controls in place. OSHA calculated the costs of controls per exposed worker in each job category and assigned this cost to the total number of employees exposed between the proposed (new) PEL and the preceding PEL. For example, if a control cost $1,000 per year and covered 4 employees, the cost per employee would be $250 per year. If 100 employees in the job category were exposed between the preceding and proposed (new) PEL, then the total costs would be $250 times 100 employees or $25,000. No costs were estimated for employees currently exposed above the preceding PEL or below the proposed (new) PEL.

OSHA determined that multiple controls would be needed for almost all jobs in general industry in order reduce exposures from baseline conditions to meeting the proposed (new) PEL of 50 μg/m^3. Some of these controls cover a group of workers, while others might be individualized (such as daily housekeeping by each individual worker).

Comments on the Per-Worker Basis and Proportionality of Costs

URS, speaking for the American Chemistry Council (ACC), argued that OSHA's approach underestimated the costs of controls because it based costs on controls per worker instead of controls per facility (Document ID 2307, Attachment 8, p. 4). Since OSHA did not provide a distribution of exposures by facility or provide facility-specific information, URS used data in the record to create its own models to account for facility size. URS described its approach as follows:

> URS created three statistical binomial distributions of overexposed workers, one for each of the three facility sizes, using OSHA's estimate of the percentage of over-exposed workers for that job. The result was a binomial distribution curve indicating the percentage of overexposed workers for each job category for each size-specific "model facility." For each binomial distribution, the peak of the distribution curve centers on the average number of overexposed workers per facility for that job description according to OSHA's estimate (Document ID 2307, Attachment 8, p. 7).

In taking this approach, URS erroneously assumed that the distribution of overexposed workers per facility was random, as evidenced by its use of a binomial distribution to approximate overexposures per facility within each of three facility sizes (Document ID 2307, Attachment 8, p. 7). Examination of the spreadsheet URS provided shows that this approach approximately doubles the number of controls needed and, and for this reason, doubles the total cost of engineering controls (Document ID 2307, Attachment 26, Table 2A, URS Summary Worksheet).

OSHA disagrees with URS's implicit conclusion that overexposures are random across facilities. It is not reasonable to assume that controls have no relation to exposure level as this approach assumes. As will be discussed later in the context of OSHA's treatment of the preceding PEL, the data underlying the exposure profile show that establishments with low exposures are much more likely to have controls in place than those with very high exposures.

URS then assumed that if one worker in a job category is overexposed, then all controls listed by OSHA will be needed (Document ID 2307, Attachment 25, Engineering Costs). URS did not dispute that multiple controls would be needed for almost all jobs in general industry in order reduce exposures from baseline conditions to meeting the proposed (new) PEL of 50 μg/m^3. The existence of multiple controls weakens the theory suggested by URS--that all controls are needed if even one worker is exposed at levels above the

PEL--because as explained above, some controls are individualized while some protect groups of workers.

The best possible approach to what engineering controls are needed might differ based on whether 1) there are no controls for a job category in place at all and most workers are overexposed by a large margin; or 2) only some workers in a job category are overexposed by a small margin (i.e., a set of controls is already in place).

In the first case, the most common approach would be to apply a relatively full set of controls, as explained in OSHA's technological feasibility analysis. This might start with enclosures and local exhaust ventilation (LEV), but, if exposures are high and the establishment is very dusty, it might also include initial cleaning or the introduction of ongoing routine housekeeping. In these situations, in which most employees are overexposed, OSHA estimated that the full set of controls listed in the technological feasibility analysis would be applied and, in these cases, there would be little difference in the results obtained using OSHA's approach and the results obtained using the approach suggested by URS.

However, the approach to controlling silica exposures that OSHA believes to be typical when establishments are faced with the second situation would be quite different, and therefore different from what URS expected. Commenters from both labor (Document ID 4204, p. 40) and industry (Document ID 1992, p. 6) pointed out that when there are controls in place or only some workers are overexposed, the first step is to examine work practices. The AFL-CIO noted that exposures can be controlled through work practices, repositioning ventilation systems, and controlling fugitive emissions (carryover from adjacent silica emitting processes) (Document ID 4204, p. 40). Implementing these types of changes can be inexpensive. The principal cost of improving work practices may only be training or retraining workers in appropriate work practices. OSHA's proportional cost approach in the PEA may therefore overestimate costs for situations in which overexposures can be corrected with work practice changes because the Agency will have included costs for engineering controls when, in fact, none will be needed. The URS approach will always include the costs of all controls for a job category in any facility where anyone in a job category is overexposed, and will thus yield even higher estimates.

As described in Chapter IV, Technological Feasibility, and summarized below, in situations in which there are LEV systems in place but the PEL is still not being met, employers would typically try many things short of removing the entire system and replacing it with a system with greater air flow velocities (and thus greater capacity and cost). The incremental solutions to controlling silica exposures include minor design modification of existing controls, better repair and maintenance of existing controls, adding additional LEV capacity to existing systems, improving housekeeping, modifying tools or machinery causing high levels of emissions, and reducing cross contamination. Some worksites might require a slightly different and readily modified design. For example, an OSHA special emphasis program inspection of a facility in the Concrete Products industry discovered that installing a more powerful fan motor, installing a new filter bag for the bag-filling machine LEV, and moving hoods closer to the packing operator's position reduced respirable dust exposure by 92 percent, to 11 $\mu g/m^3$ (Document ID 0126, pp. 7-8). In an assessment of the Asphalt Roofing industry, NIOSH recommended repair and servicing of existing process enclosures and ventilation systems to eliminate leaks and poor hood capture but did not indicate that entirely new systems would need to be installed (Document ID 0889, pp. 12-13; 0891, pp. 3 and 11; 0890, p. 14; 0893, p. 12).

In other cases, better equipment repair and maintenance procedures can be the key to meeting the PEL when there are already controls in place. For example, as described in Chapter IV of this FEA, in the Concrete Products industry, OSHA obtained a sample of 116 $\mu g/m^3$ for a material handler who operated a forklift to transport product between stations. The inspector noted that there were leaks in the silo bin chute and that some controls were not fully utilized. The report indicated that dust generated by various other processes in the facility was a contributing factor to the forklift operator's high level of exposure. In this case, the first course of action for the employer would be to correct the deficiencies in the existing systems. Similarly, at a site visit in the Paint and Coating industry, ERG monitored mixer operators' exposures and obtained results below the limit of detection while workers emptied 50-pound bags of powder into hoppers when dust control systems were working properly. These values are 95 percent lower than the 263 $\mu g/m^3$ obtained during another shift, at the same plant, when the dust control systems malfunctioned (Document ID 0199, p. 9).

In other cases, as pointed out by a foundry commenter, adding LEV capacity to existing systems for silica emissions not yet subject to any LEV control can be a good strategy for lowering exposures (Document ID 1992, p. 6). In one foundry, NIOSH investigators recommended installation of LEV over the coater and press areas, enclosure of the coating process, and/or repair and servicing of existing process enclosures and ventilation systems to eliminate leaks and poor hood capture (Document ID 0889, pp. 12-13; 0891, pp. 3 and 11; 0890, p. 14; 0893, p. 12).

Various combinations of improved housekeeping, initial cleaning, and switching to High-Efficiency Particulate Air (HEPA) vacuums can also help employers meet the PEL. In the Structural Clay industry, professional cleaning in a brick manufacturing facility removed "several inches" of dust from floors, structural surfaces and equipment (Document ID

1365, pp. 3-19-3-20; 0571). These changes alone led to a dramatic decrease in exposures, by as much as 90 percent, to below 50 μg/m^3, for materials handlers. Similar results were observed for grinding operators (Document ID 0571). In one NIOSH evaluation, operators in a grinding area where good housekeeping practices were being implemented had substantially lower exposures than operators in a grinding room where the housekeeping practices were poor. The grinding room referred to as the “C plant” had 2 to 3 inches of settled dust on the floor and had an exposure result of 144 μg/m^3. Grinding operators at the grinding room referred to as the “B plant,” where dust had been cleaned up, had substantially lower exposures (24 μg/m^3) (Document ID 0235, pp. 6-7).

Good housekeeping also increases the useful life of equipment. As discussed in Chapter IV of this FEA, dust clogs machines and reduces their useful life. As an example, regulating cotton dust was acknowledged to increase productivity by reducing down time. It also increased the useful life of looms (Document ID 2256, Attachment 4, p. 11). The Agency predicts that this is likely to be the case with silica controls as well. Dust being properly captured at the source can also result in cost savings in housekeeping activities because less dust needs to be cleaned up when it is captured at the source and not allowed to spread (Document ID 2256, Attachment 4, p. 11).

In specific situations, there are a variety of other controls that may be useful. As discussed in the technological feasibility chapter of this FEA, Simcox et al. (1999) (Document ID 1146) found that Fabricators in the Cut Stone industry had a mean exposure of 490 μg/m^3, which was reduced 88 percent to 60 μg/m^3 when dry grinding tools used on granite were replaced or modified to be water-fed. Similar reductions were found at other facilities when wet grinding, polishing, and cutting methods were adopted (Document ID 1365, p. 11-20; 1146, p. 579). In the technological feasibility chapter, OSHA examined the work practices of cut stone splitters and chippers and found that a combination of wetting the floor at appropriate times, modifying ventilation directly from the top of the saws, and retrofitting splitting stations with LEV reduced exposures from a mean of 117 μg/m^3 to a mean of 18 μg/m^3, an 85 percent reduction (Document ID 1365, p. 11-22; 0180).

Finally, in situations where there is cross contamination, employers may achieve the PEL for some workers without implementing any controls specific to that job category. As pointed out by the AFL-CIO, when this occurs, OSHA’s costs may be overestimated (Document ID 4204, Attachment 1, p. 105).

These examples show that in many situations, where there are already controls in place, or where exposures are only slightly above the PEL, the PEL can be met by a variety of mechanisms short of installing an entirely new set of controls. Since the record shows that, frequently, exposures can be controlled without installing new engineering controls, OSHA's approach of estimating costs based on the proportion of the workers exposed above the PEL is much more likely to be accurate than estimates based on URS's suggestion that all controls are needed whenever one worker is exposed above the PEL.

The URS facility-based approach would require taking the costs of newly installing a full set of controls even if only one worker is exposed above the PEL. This approach assumes that (1) the existing exposure levels in a given facility have been achieved without the use of any controls; and (2) existing controls cannot be improved upon for less than the cost of installing an entirely new system of controls. These assumptions are unsupported by the URS comments and the nature of exposure control, as discussed above.
OSHA therefore rejects URS's approach and is maintaining its per-worker basis for calculating costs for this FEA. Based on the evidence presented in this section, the Agency concludes that OSHA's proportional approach of assigning control costs to each worker based on the cost per worker of a complete set of controls is a better approach to commonly encountered exposure situations than to assume that any reading above the PEL triggers the need for a complete set of controls.

The AFL-CIO argued that OSHA's proportional approach resulted in an over-estimation of costs because it involved adding costs for the exposed occupation wherever there was an overexposure, even when the overexposure was primarily or solely the result of cross contamination. The AFL-CIO recommended that OSHA "identify operations which are unlikely to [generate] silica emissions, or background and bystander exposure measurements, and subtract those measured exposure levels from those operations which do emit silica" (Document ID 4204, Attachment 1, pp. 31-32). OSHA has routinely included the elimination of cross contamination as a component of the controls needed for some job categories. However, as discussed in Chapter IV of this FEA, OSHA also believes that other controls will still be needed for many job categories and as long as these additional controls are needed, overall costs will not decline as a result of controlling cross contamination.

General Methodological Issues—Comments on Costs Associated with Exposures Over the Preceding PEL

Many commenters argued that OSHA should have attributed the costs of reaching the preceding PEL of 100 μg/m^3 to this standard (Document ID 2307, Attachment 8b, p. 16; 2195, p. 33; 1819, p. 2; 2375, Attachment 2, p. 65; 2307, Attachment 1, p. 2; 2379, Attachment 2, p. 9). For example, Stuart Sessions of Environomics, Inc., (Environomics) commenting on behalf of the ACC, stated that of the workers currently exposed over 50 μg/m^3, two-thirds are exposed over 100 μg/m^3, and that OSHA erred in excluding the costs of reducing those exposures to 100 μg/m^3 (Document ID 2307, Attachment C, pp. 2-3).[6]

OSHA's preliminary initial regulatory flexibility analysis (PIRFA) for the 2003 Small Business Advocacy Review (SBAR) panel included benefits and costs associated with future compliance with existing silica requirements on the basis that the rule would help improve compliance with the existing silica rules (OSHA, 2003a and 2003b). Upon further consideration, OSHA determined that a more fair and accurate measure of the benefits and costs of the proposed rule was to begin the analysis with a baseline of full compliance with existing requirements; OSHA has retained this approach for the final rule. The Agency offers three reasons in support of this approach. First, the obligation to comply with the preceding silica PEL is independent of OSHA's actions in this rulemaking. The benefits and costs associated with achieving compliance with the preceding silica rules are a function of those rules and do not affect the choice of PEL. The question before the Agency was whether to adopt new rules, and its analysis focused on the benefits and costs of those new rules. Second, the Agency's longstanding policy is to assume 100 percent compliance for purposes of estimating the costs and benefits of new rules, and to assume less than full compliance with the existing OSHA rules would be inconsistent with that policy. Finally, assuming full compliance with the existing rules is in keeping with standard OSHA practice in measuring the incremental effects of a new rule against pre-existing legal obligations. Reliance on costs that assume full compliance with both the preceding and proposed (new) OSHA rules makes it easier to compare the two regulatory schemes.

Some commenters also disagreed with the way OSHA attributed costs to employers whose workers were being exposed to silica at levels greater than the preceding PEL of 100 μg/m^3 (Document ID 3251, p. 2; 3296, p. 2; 3333, p. 2; 3373, p. 2; 2503, p. 2; 2291, p. 16; 4209, p. 111). These commenters argued that OSHA did not attribute any costs of reaching 50 μg/m^3 to employers whose employees were exposed above 100 μg/m^3. They argued that OSHA instead assumed that the costs and controls necessary to reach 100 μg/m^3 would also be sufficient to reach a level of 50 μg/m^3 and, as discussed above, that OSHA did not account for those costs because reducing exposures to the preceding PEL of 100 μg/m^3 was already required before this rulemaking. The American Foundry Society (AFS) argued that OSHA reduced costs by two-thirds "under the logic that employers must comply with the current PEL and the proposal does not add any existing

[6] As this commenter pointed out, this is largely an issue with respect to engineering and respiratory protection costs. As the preceding PEL for silica has no required ancillary provisions, all employers affected by this rule—whether exposures in their facility are above the preceding PEL or above the new PEL—will be newly required to comply with the rule's ancillary provisions and OSHA has fully accounted for these costs.

obligation" (Document ID 2379, Appendix 1, p. 10). AFS added that OSHA's underestimation of costs in this manner was particularly severe because OSHA used outdated data that showed more employees with exposures over 100 μg/m^3, whereas more recent data would show fewer employees with exposures above 100 μg/m^3 and more with exposures between 50 and 100 μg/m^3. Had OSHA used these updated data, in AFS's estimation, the Agency would have identified more employers needing to install additional engineering controls and thus there would be additional costs that were not accounted for in the PEA (Document ID 2379, Attachment 3, pp. 9-10). ACC made a similar point, saying that, as a result of OSHA's methodology, "the exposure reduction costs for the estimated 81,000 workers now exposed above 100 μg/m^3 are not taken into account by OSHA on either a full cost basis or an incremental cost basis" (Document ID 2308, Attachment 9, pp. 2-3).

In addition, URS, among others, argued that "OSHA fails to account for the non-linear costs associated with each incremental reduction in silica concentrations," meaning that URS believed that it is more costly to achieve additional reductions in exposure as exposures are lowered. For example, according to URS's contention, it would be more costly to reduce exposures from 75 μg/m^3 to 50 μg/m^3 than from 125 μg/m^3 to 100 μg/m^3 (Document ID 2308, Attachment 8, p. 11; 2291, p. 16; 4209, p. 11; 2307, Attachment 2, pp. 181-182; 2379, Attachment 2, p. 9; 3487, p. 13).

OSHA has several responses to these criticisms. In response to the criticism that OSHA overestimated the number of workers with exposure levels above 100 μg/m^3 as a result of using outdated data, the Agency has updated the exposure profile used to develop the final analysis of costs. This update is described previously in Chapters III and IV of this FEA. As a result of this update, OSHA found that, in the aggregate, the percentage of workers in general industry exposed to silica levels between 50 μg/m^3 and 100 μg/m^3 rose from 33 percent as estimated in the PEA to 42 percent. And, as the commenters noted would be the case, the percentage exposed at levels above 100 μg/m^3 fell from 67 percent to 58 percent. OSHA has updated this analysis to incorporate these data and has estimated costs for these additional workers whose exposures fall between 50 μg/m^3 and 100 μg/m^3. The revised distribution also shows that of those workers with exposures above the new PEL, 41 percent are exposed between the new PEL and the preceding general industry PEL with an average exposure level of 70 μg/m^3, 29 percent are exposed between the preceding PEL and 250 μg/m^3 with an average exposure level of 156 μg/m^3, and 30 percent are exposed above 250 μg/m^3 with an average exposure level of 485 μg/m^3. Where an industry submitted more recent exposure data or information about exposure distributions within their industry, OSHA was able to show that its final exposure distribution was roughly equivalent (see Chapter IV of this FEA).

The technological feasibility analysis (presented in Chapter IV of this FEA) describes the controls necessary for reducing exposures from the highest levels observed in an industry's exposure profile to the new PEL. In all application groups except two (asphalt paving products and dental laboratories), the highest observed exposures were above the preceding PEL. With the exception of hydraulic fracturing,[7] the technological feasibility analysis did not distinguish between the controls necessary to meet the preceding general industry PEL of 100 μg/m^3 and those necessary to meet the new general industry PEL of 50 μg/m^3. Instead, the technological feasibility analysis simply listed the controls necessary for those employers whose employees had the highest baseline exposures to significantly reduce exposures and, in most operations, meet the new PEL.

It was not necessary for OSHA to distinguish between controls necessary to achieve the preceding PEL and those necessary to achieve the new PEL in order to demonstrate the technological feasibility of achieving a PEL of 50 μg/m^3. Such a distinction would have been difficult because, from a baseline of uncontrolled exposures, the controls necessary to meet the preceding and new PELs are difficult to distinguish. For example, if there are two different controls necessary to fully meet the new PEL, then it is logically possible that two different establishments may achieve an exposure level at or below the preceding PEL in different ways. One establishment may have excellent housekeeping but poorly maintained LEV. Another may have well maintained LEV but poor housekeeping. For individual cases, there is not a simple demarcation of which controls of the total set of controls are necessary to achieve the new PEL when only the exposure level and not the controls already in place are known. Nor, as discussed above, is it the case that a control, once installed, will always provide identical protection. Two otherwise equal facilities may have the same installed controls but different exposure levels because of the quality of the maintenance of the system.

For the purposes of costing engineering controls for general industry and maritime in the PEA, OSHA assigned all of the costs for meeting a PEL of 50 μg/m^3 – including the costs of controls necessary to meet the preceding PEL of 100 μg/m^3 – to all workers with exposure levels between 50 μg/m^3 and 100 μg/m^3. However, OSHA assigned no costs in the PEA to employees whose exposures exceeded the preceding PEL. This approach would be accurate for both those above and below the preceding PEL only if the exact same controls would be needed to control exposures in both situations and these controls would always yield an exposure level below the preceding PEL. However, as discussed in the previous section on proportionality of costs, OSHA has determined that this is not typically the case. There exist multiple kinds of controls and the actual application and

[7] Due to an unusually rich data set, and the great similarity of different fracturing operations, both with respect to the equipment used and the current levels of control, OSHA was able to estimate which controls are necessary to go from an uncontrolled situation to the preceding PEL and which are necessary to get from the preceding PEL to the new PEL in the hydraulic fracturing industry.

operation of the control can differ. The approach applied in the PEA applied more controls than will typically be needed where exposures are below the preceding PEL and thus overestimates costs in these situations, but then assigns no costs for achieving the new PEL where exposures are above the preceding PEL. In the latter situation, it can reasonably be expected that, in most cases, some costs would be incurred to meet the new PEL even after the preceding PEL is met and therefore the PEA methodology underestimated costs in those situations. Although these over- and under-estimates are partially offsetting, OSHA acknowledges that any over-estimates of cost do not necessarily offset the potential under-estimates of costs.

OSHA has therefore decided to adopt an approach to the estimation of costs different from that adopted in the PEA. In this FEA, OSHA relied on data available in the rulemaking record to both correct the overestimate of costs for those below the preceding PEL and, as many industry commenters urged, estimate the costs necessary to meet the preceding PEL as well as the new PEL for those above the preceding PEL.

To be clear, these data still do not enable OSHA to distinguish between the exact controls needed to get from uncontrolled exposures to the preceding PEL and those needed to get from the preceding PEL to the new PEL on an industry-by-industry and occupation-by-occupation basis. However, the data do enable OSHA to show that the majority of the costs of controlling silica exposures are incurred in order to reduce exposures from uncontrolled levels to the preceding PEL. OSHA will then assume that 50 percent of the costs incurred will be to implement the controls necessary to get from the uncontrolled situation to the preceding PEL and 50 percent to implement the controls necessary to go from the preceding PEL to meeting the new PEL. If, in fact, a majority of the costs are incurred in order to reduce exposures to the preceding PEL, the assumption that attributes 50 percent of costs to going from the preceding PEL to the new PEL will overestimate the true costs for establishments with exposures at the preceding PEL or between the preceding PEL and the new PEL.

In order to assess whether the majority of the costs are necessary to meet the preceding PEL, OSHA first examined what kinds of exposures are associated with the uncontrolled situations that served as the starting point for the estimates of needed controls in the technological feasibility analysis. The average level of exposure across all of general industry for employees with exposure exceeding the preceding PEL is over 300 $\mu g/m^3$. Thus, on average, across all industries the uncontrolled situation involves high levels of exposure, commonly more than 3 times the preceding PEL.[8]

[8] To check that this was not the result of a very high exposures for a small number of employees or industries, OSHA examined the exposure profile presented in Table III-9 and found that in only 4 industries

In general, to reduce exposures from over 2.5 times the preceding PEL to the preceding PEL, employers would have to implement some measure or measures and those measures would be the ones that provide the greatest reduction in silica exposures and therefore control most of the silica exposures in the facility. In most cases this will be a working LEV system or some form of worker isolation. Measures like improved housekeeping cannot reduce exposures from the levels observed in uncontrolled exposure situations to the preceding PEL. OSHA reviewed industry-by-industry and occupation-by-occupation cost estimates for engineering controls and found that, on average 63 percent of the costs were for LEV, 23 percent were for housekeeping, and 16 percent were for other controls, most commonly wet methods (based on OSHA, 2016). In many cases, where wet methods were applicable, wet methods represented the majority of the costs and there were not significant LEV costs. As a result, 79 percent of the costs of controls, on average, are attributable to either wet methods or LEV. The combination of LEV or wet methods with some improvement in housekeeping (though not the improvements necessary to meet the new PEL) will constitute the majority of costs for virtually all occupational categories. Some improvement in housekeeping will typically also be required to meet even the preceding PEL.[9] While employers can probably meet the preceding PEL with less than ideally maintained LEV systems, improvements in maintenance will not reverse the conclusion that the majority of the costs are incurred to meet the preceding PEL. This is the case because on average 63 percent of engineering control costs are necessary to reach the preceding PEL and some housekeeping costs will also be necessary, leaving a significant percentage of expenditures above 50 percent of the costs available for improved maintenance.

To confirm the findings of this cost-spreadsheet- based analysis of where the majority of the costs are incurred, OSHA reviewed industries where good data are available on controls in both uncontrolled situations and situations with exposures between the new and the preceding PEL. OSHA examined the exposures and controls in eight ferrous sand casting foundry facilities. In these eight facilities, four had relatively few workers exposed above 50 μg/m^3, and the other four had many exposures over 100 μg/m^3. OSHA found that those facilities with most exposures over 100 μg/m^3 generally had little or no

(with 1.1 percent of all employees exposed above the preceding PEL) were there no exposures above 250 μg/m^3.

[9] For example, in several industry sectors where workers are currently manually dumping silica-containing materials, the use of automated and ventilated dumping stations is needed to reduce exposures from over 250 μg/m^3 to below the preceding PEL. However, once these controls are installed and in use, final exposures are often below the limit of detection or less than 12 μg/m^3 -- well below the new PEL (see technological feasibility chapter for paint and coatings). However, to maintain these exposures below the new PEL, these industry sectors will need to ensure that ventilation systems are properly maintained and will need sufficient housekeeping to ensure against build-ups of dust.

LEV (relying instead on general ventilation), poor housekeeping, no enclosures for workers, and poor maintenance. The foundries where silica dust was better controlled generally had working LEV systems, good housekeeping that kept surfaces free of silica dust, and good maintenance practices. This indicates that LEV and some housekeeping are essential to meeting the preceding PEL. OSHA also examined data on all exposures with control descriptions. These data showed that exposures above 250 $\mu g/m^3$ occurred in uncontrolled situations or situations in which controls, though installed, were not in use. In situations where exposures were between the preceding and new PELs, most exposures showed some controls in place, normally LEV, but not all controls recommended. In some cases there were no controls in place. These generally represented situations in which exposures were much lower than the typical uncontrolled situations and such facilities would not normally need the full controls necessary to go from very high levels of exposure to the new PEL. (See Exhibit: Descriptions of Controls (2016).)

Based on these findings, OSHA determined that the majority of costs are incurred in order to implement controls necessary to get from an uncontrolled situation to the preceding PEL. However, OSHA developed cost estimates for engineering controls based on the conservative assumption that 50 percent of the total costs of going from an uncontrolled situation to the new PEL are incurred in order to reach the preceding PEL and the remaining 50 percent are incurred to reach the new PEL.[10] For example, in the cut stone industry 63 percent of those exposed above the new PEL are also above the preceding PEL, and 37 percent are below the preceding PEL but above the new PEL. Total cost to the cut stone industry of going from uncontrolled exposure to the new PEL is estimated, using the spreadsheets mentioned above, to be $17.7 million. With OSHA's assumption that half of the costs of going from an uncontrolled situation to the new PEL are incurred in order to reach the preceding PEL, then the cost for those employers with employees exposed above the preceding PEL would be 63 percent of $17.5 million times 0.5, which equals $5.5 million. The cost for those below the preceding PEL would be 37 percent of $17.7 million times 0.5, which equal $3.3 million. The total cost of going from the preceding PEL to the new PEL in the cut stone industry is therefore the sum of these two calculations: $8.9 million.) This will overestimate the costs of reaching the new PEL, given the majority of the costs are incurred to implement controls necessary to reach the preceding PEL.[11]

[10] This approach was not applied to the two industries, dental laboratories and asphalt paving materials, where the exposure profile showed that there were no exposures above the preceding PEL.

[11] OSHA also notes that this approach shows rising incremental costs of control, which is consistent with some comments. This is because 50 percent of the costs are estimated to be incurred to go from levels of over 250 $\mu g/m^3$ to 100 $\mu g/m^3$ and equal costs are estimated to be incurred to go from 100 $\mu g/m^3$ to 50 $\mu g/m^3$.

As presented in more detail below, this approach results in a total annualized cost estimate for general industry and maritime engineering controls of $225 million. Fortunately, this cost estimate is not highly sensitive to the percentage chosen. Each decrement of 5 percentage points changes the engineering control costs by approximately 5.5 percent. Thus, for example, if 65 percent of the costs are necessary to go from the preceding PEL to the new PEL, then the annualized cost estimate for engineering controls would rise to $261 million per year.[12]

Accounting for Costs of Downtime

Some commenters suggested that OSHA failed to account for the downtime that installing engineering controls or performing an initial through cleaning would require (e.g., Document ID 2368, p. 13 for engineering controls; Document ID 2379, Attachment 2, p. 16 for initial thorough cleaning).

Almost all firms need downtime occasionally in order to perform general maintenance, inventory, or other tasks. In the final rule, OSHA has extended the compliance date for general industry from one year to two years. This will allow almost all employers to schedule work that might require downtime to install, improve, or maintain controls that they determine are necessary to meet the new PEL or to perform the initial thorough cleaning at times when they would already need scheduled downtime for other purposes. Therefore, OSHA has determined that there will be no additional costs incurred for downtime in order for employers to install engineering controls or to perform the initial thorough cleaning.

Technological Change

One commenter, Dr. Ruth Ruttenberg, testifying for the AFL-CIO, argued that OSHA had overestimated costs by failing to consider technological change:

> Technological improvements – both engineering and scientific – are constantly occurring, especially when the pressure of a pending or existing regulation provide a strong incentive to find a way to comply at a lower cost. … These improvements are well-documented following the

[12] A value of 100 percent would be totally implausible as it would imply that all establishments currently far above the preceding PEL could achieve that PEL without cost. Put another way, this would be equivalent to saying that, if OSHA had decided to adopt the alternative PEL of 100 μg/m^3 (i.e., the same as the preceding general industry PEL), as some employer groups recommended, any employers currently above that PEL – regardless of how far above the PEL they were - would be able to meet a PEL of 100 μg/m^3 without implementing any new engineering controls.

> promulgation of rules for vinyl chloride, coke ovens, lead, asbestos, lock-out/tag-out, ethylene oxide, and a host of others (Document ID 2256, Attachment 4, p. 2).

She recognized that OSHA, in the PEA, already predicted some "technological and cost-saving advances with silica," such as expanding the use of automated processes and developing more effective bag seals, but criticized OSHA for not accounting for those cost savings in its analysis:

> Technological improvements are as sure a reality – based on past experience and academic research – as overestimation of cost and underestimate of benefits are in an OSHA regulatory analysis. More than 40 years of OSHA history bear this out (Document ID 2256, Attachment 4, p. 3).

When promulgating health standards, OSHA generally takes an approach in which cost estimates and economic feasibility analyses are based on the technologies specified in the technological feasibility analysis. This is a conservative approach to satisfying OSHA's legal obligations to show economic and technological feasibility. As a result, the Agency does not account for some factors that may reduce costs, such as technological changes that reduce the costs of controls over time and improvements in production that reduce the number of employees exposed. As pointed out in the PEA and from the examples described in the "Total Cost Summary" at the end of this chapter, some past experience suggests that these factors tend to result in OSHA's costs being overestimated.[13] OSHA considers the primary purpose of the cost estimate to be to provide a basis for evaluating the economic feasibility of the rule, and OSHA has determined that for this rulemaking, feasibility is most accurately demonstrated by using an approach that does not account for the potential impacts of future technological changes.

General Methodological Issues: Number of Workers Covered by a Control

<u>*PEA estimates*</u>

The cost calculations in the PEA included estimates of the number of workers whose exposures are controlled by each engineering control. Because working arrangements vary within occupations and across facilities of different sizes, there are no definitive data on how many workers are likely to be covered by a given set of controls. In many small facilities, especially those that might operate only one shift per day, some controls will

[13] On the other hand, there is supplemental evidence from Harrington et al. (2000) that OSHA does not systematically overestimate costs on a per-unit basis, and that the reason for overestimation of costs at the aggregate level has been a combination of difficulty with establishing baseline conditions and noncompliance. Nevertheless, several examples of OSHA's overestimation of costs reported in the article are due to technological improvements.

limit exposures for only a single worker. Also, small facilities might have only one worker in certain affected job categories. More commonly, however, and especially in the principal production operations, several workers are likely to derive exposure reductions from each engineering control.

The PEA relied on case-specific judgments of the number of workers whose exposures are controlled by each engineering control (see Table 3-3 in ERG, 2007b). The majority of controls were estimated to benefit four workers, based on the judgment that there is often multi-shift work and that many work stations are shared by at least two workers per shift. The costs of some types of equipment that protect multiple employees, such as HEPA vacuums, were spread over larger groups of employees (e.g., six to eight workers). In the PEA, the average number of workers affected represented an average across all establishments, large and small.

Comments and responses

Some commenters questioned OSHA's estimate of the number of workers whose exposures could be controlled per newly added or enhanced control. OSHA's PEA most commonly estimated that four workers would have their exposures reduced for each new or enhanced engineering control. Dr. Ronald Bird, testifying for the Chamber of Commerce, argued that OSHA's estimates were simply arbitrary assumptions (Document ID 2368, p. 14). Stuart Sessions, testifying for the ACC, argued that the use of a single standard crew size of four led OSHA to underestimate costs and economic impacts for smaller establishments, at which, he argued, "there are virtually never as many as four overexposed workers in any job category, and it is simply impossible that one application of a package of controls in this situation could protect as many as 4 overexposed workers on average" (Document ID 4231, Attachment 1, p. 6).

The approach OSHA used was intended to represent the average number of employees affected by a given set of controls. Larger establishments may have more than four workers whose exposures are reduced by a single control, and smaller establishments may have fewer than four. However, OSHA agrees that this approach may result in an underestimate of costs for the smallest establishments. Because it is particularly important to consider the costs to the smallest establishments, OSHA has reduced the number of employees whose exposures are reduced per control by half for establishments with fewer than twenty employees, so that in those small establishments a given control is assumed to reduce exposures for two workers instead of four as assumed in the PEA. Because larger establishments may have greater numbers of employees whose exposures are reduced per control, this change may result in an overall overestimation of costs. (In the PEA, the overestimation of costs for larger facilities was partially offset by the underestimation of costs for smaller establishments. This is no longer the case in this

FEA.) OSHA nevertheless believes the revised approach used in this FEA is better than the approach used in the PEA for purposes of capturing economic impacts on smaller establishments, even though it may result in aggregate costs being overestimated.

Variability

Some commenters argued that both OSHA's technological feasibility and cost analyses were flawed because OSHA neglected to address the day-to-day variability of exposure measurements. By failing to address the issue of variability, these commenters argued, OSHA grossly underestimated the costs of engineering controls. These commenters reported that silica exposures would have to be controlled to levels considerably lower than the proposed (new) PEL in order to account for the variation in exposures across jobs and from day to day (e.g., Document ID 2307, Attachment 2, p. 202; 2308, Attachment 7, p. 2; 2308, Attachment 8, p. 6; 2379, Attachment 4, p. 1; 2291, p. 11; 2195, pp. 26-27; 2503, p. 2; 2222, Attachment 1, p. 1). For example, in response to a written question about the activities in which employers were able to achieve the proposed (new) PEL "most of the time," AFS objected to the premise of the question, noting that "[s]everal foundries have received citations for exposures above the current PEL on operations or tasks for which the proposed PEL is achieved most of the time" (Document ID 2379, Appendix 1, p. 18). AFS argued that OSHA's non-compliance model of enforcement requires employers to reduce average exposures to half the PEL in order to have confidence that exposures will never exceed the PEL (Document ID 2379, Appendix 2, p. 29). The Asphalt Roofing Manufacturing Association (ARMA) made a similar point and said that the majority of asphalt roofing plants operated by its members have some exposures over the PEL of 50 $\mu g/m^3$, even if it's a "relatively small incidence" (Document ID 2291, p. 11).

Both AFS and ARMA offered estimates of the magnitude of this variability by measuring the statistical variance of exposures. AFS stated that to assure 84 percent confidence in compliance with the preceding PEL, the mean exposures in some specific jobs in specific foundries would need to be below half that PEL, and that the "mean level necessary to achieve the 95 percent confidence of compliance could not be determined but is significantly below one half the PEL" (Document ID 2379, Appendix 1, p. 23). ARMA examined the distribution of silica exposures in over 1,300 samples from 57 asphalt roofing facilities. These data showed that even though the median exposures for all jobs were below the new action level of 25 $\mu g/m^3$, a total of 9 percent of all samples were above the new PEL of 50 $\mu g/m^3$ (Document ID 2291, p. 5, Table 1). ARMA also provided an estimate of the "lowest strictly achievable level" (meaning a level not to be exceeded more than 5 percent of the time) which varied by job classification from 67 to 310 $\mu g/m^3$ (Document ID 2291, p. 9, Table 2).

One serious problem with the ARMA analysis is that the discussions of variability and the estimates of mathematical variance are based on results either from different facilities with potentially different levels of controls or from all job categories within one facility. The key issue for assessing the importance of variability is the variance within a given job category in a specific establishment with specific controls. The methodology employed is such that even if individual job categories or individual facilities had no variance, pooling data across facilities would create variance.

ARMA estimated that sufficiently controlling variation would require investment in capture vents, duct work, and dust collection systems costing up to $2.1 million each in initial costs per manufacturing line (Document ID 2291, p. 12). AFS did not provide a cost estimate solely for sufficiently controlling variation.

The AFL-CIO disagreed with industry's arguments and instead argued that the best way to reduce variance was not simply to add additional engineering controls because, as explained earlier in the discussion of URS's comments on the per-worker cost basis, overexposures are not random:

> The worker-to-worker variation is explainable and controllable: workers use different methods, they may take different positions relative to ventilation systems, they may use different work practices, and they may be subject to fugitive emissions (carryover from adjacent silica emitting processes). These differences in conditions can be observed by the industrial hygienist collecting the air sample, compared to exposure levels, and changed. Day-to-day variation for the same worker is caused by variation in materials, ventilation systems, production rate, and adjacent sources showing such variation. Sometimes these variations can be large, based on breakdowns of ventilation, process upsets and blowouts (Document ID 4204, p. 40).

OSHA's enforcement policies are discussed in Chapter IV of this FEA and in the preamble. Variability of exposures is potentially a cost issue when there are technologically feasible controls that have costs not otherwise accounted for that could further reduce environmental variability. If it is not technologically feasible to reduce variability then there will be no further costs. For example, if an employer has installed all feasible controls, there are no additional costs for engineering controls because there are no additional controls to purchase, regardless of variability. On the other hand, an employer who has a median exposure level of 80 percent of the PEL with frequent excursions above and who could feasibly reduce variability would be required to do so. As noted above, those (AFS, ARMA) who argued that OSHA had underestimated costs by failing to account for exposure variability, in general, assumed that the best approach to reducing variability would be to increase the levels of LEV to reduce the average exposure level to half of the PEL or less, without examining the origin of the variability.

OSHA agrees with the AFL-CIO that variability in exposure is likely controllable by examining the origins of the variability. One origin is poor work practices. To improve work practices, employers could observe work practices when monitoring takes place; determine which work practices are associated with high exposures; and modify those work practices found to lead to high exposures. Variability can also be the result of controls not functioning properly, either resulting from sudden failures or from gradual deterioration of performance over time. The latter can be prevented by good maintenance.

Both in its cost assessment for the proposal and in the modifications made for this final rule, OSHA has taken account of the costs necessary to reduce unusual and exceptionally high exposure levels and thus reduce some sources of variation. As discussed in the cost of ancillary provisions, OSHA has estimated costs for exposure monitoring that include the time for observation of the worker. OSHA has also estimated costs for training to assure good work practices, and has increased the estimated length of training in general industry to ensure that the time is sufficient for training on work practices. In this section, OSHA has costed LEV, LEV maintenance, and the need for replacement LEV to assure that the LEV will function properly. OSHA has therefore already accounted for a variety of costs associated with steps that can be taken to reduce variability in exposures.

Substitution of Low- or Non-Silica Inputs

PEA estimate

For several industries, employers might lower silica exposures by substituting low- or non-silica inputs for existing inputs. While this option can be an extremely effective method for controlling silica exposures in many industries, OSHA did not cost this option in the PEA. OSHA determined that there were often complicating factors that restricted the potential for broad substitution of non-silica-containing inputs for silica-containing inputs throughout the affected industries. It is possible that the same product quality cannot be maintained without using silica. Some products made with substitute ingredients were judged to be inferior in quality and potentially not viable in the market. In addition, a substitute silica ingredient might introduce adverse health risks of its own. Further, in several instances, the availability of reasonably inexpensive alternative non-silica ingredients was well known but the alternative was not selected as a control option by most firms. In light of these concerns, OSHA decided not to include the option of non-silica substitutes in estimating the cost of the proposed rule.[14]

Comments and Responses on Substitution

Some commenters complained that OSHA's analysis did not account for the costs of substitution (Document ID 2264, Attachment 1, p. 27; 2379, Attachment 2, p. 6; 3485, p. 25; 3487, p. 17).

OSHA considered the comments on the issue but has decided to adhere to the approach taken in the PEA. OSHA did not take account of the costs of substituting other substances for silica, because, while such substitution might have substantial benefits and avoid the need for engineering controls, OSHA determined that, in most situations, substitution is not the least costly method of achieving the proposed or new PEL (Document ID 2379, Attachment 2, p. 6). As a result, OSHA's final cost analyses do not account for the possibility that firms would choose to substitute for substances other than silica. To the extent that substitutes are the least costly solution in some situations, OSHA has overestimated the costs.

Cost of Air Quality Permit Notification

The Agency received comments suggesting that foundries and other manufacturing plants would be required by the Environmental Protection Agency (EPA), or other federal or state environmental authorities, to incur an administrative cost to ensure their systems are compliant with relevant EPA regulations. Commenters expressed concern that the permitting process itself could be a major undertaking, made worse by difficult compliance deadlines. Given that the final rule provides extra time for planning and permitting, OSHA has examined the potential impacts of the new rule and finds that the commenters are overstating the potential for such costs. The argument for significant permitting costs was typically combined (e.g., Document ID 2379, Appendix 3) with an argument that the Agency underestimated the amount of ventilation required to comply with the final rule; comments on ventilation requirements are dealt with in great detail elsewhere in this chapter.

---

[14] OSHA's analysis in the PEA recognized that some silica-free substitutes were already being used for some industrial activities. To the extent that the rule induces some firms that can easily switch to silica substitutes that may be less costly for them rather than undertaking more expensive control methods, OSHA will have overestimated the costs of the rule. Offsetting OSHA's potential overestimate of costs in this regard would be any negative adverse health effects associated with silica substitutes. Thus, affected firms switching to substitutes could potentially lower both the costs and the benefits of the rule.

Upon investigation, while OSHA agrees that it would be appropriate to recognize an administrative burden with respect to the interfacing environmental regulations, the Agency believes that many of the commenters' concerns were overstated. First, many control methods needed to comply with the final rule will not require alterations to existing ventilation systems. As discussed earlier in this chapter, work practices, housekeeping and maintenance are important components in controlling exposures; in many cases existing ventilation, as designed and permitted with the environmental authority, is adequate, but needs to be maintained better. In addition, most establishments, particularly smaller ones, will continue to have particulate emissions levels that fall below the level of EPA permit requirements. In the case of large facilities that do not, the changes will be on a sufficiently small scale that they will not require elaborate re-permitting, but will only require minor incremental costs for notifying the environmental authorities, or in some cases, submitting a "minor" permit. (*See* http://www2.epa.gov/nsr and http://www2.epa.gov/title-v-operating-permits.) Taking into account the preceding silica PEL and the estimate that baghouses will capture 99 percent of silica emissions (Document ID 3641, p. VII-19), OSHA concludes that it is unlikely that facilities will encounter a need for significant air permit modifications.

The Agency recognizes, however, that there will be minor incremental costs for notifying environmental authorities. While many establishments in the United States may have no requirement to do so, the Agency has conservatively assumed that all establishments with twenty or more employees in most industries will need to dedicate a certain amount of time to preparing a one-time notification to environmental authorities to ensure that their air permits accurately reflect current operating conditions. OSHA has determined that small establishments would generally lack the large scale industrial facilities requiring permits, and that the few that might require such permits would be balanced out by the likely inclusion of medium establishments that do not actually require permits for their emissions. The industries excluded were those that generally lack large scale industrial facilities or that do not produce a concentrated, as opposed to diverse or unconsolidated, emission source. The excluded industries were hydraulic fracturing, shipyards, dental equipment and labs, jewelry, railroads, and landscaping.

To allow for adequate administrative time for creating and submitting the notification, at those facilities that could potentially incur costs, OSHA allocated 20 hours to establishments with 20 to 499 employees and 40 hours to establishments with 500 or more employees. A manager's loaded hourly wage rate of $74.97 was applied to estimate the cost to employers (BLS, 2012b). The costs per establishment were estimated at approximately $1,500 per medium establishment and $3,000 per large establishment. Because both new permit applications and permit modifications are minor administrative chores, OSHA's cost estimates are sufficient to cover either case.

Costs for Specific Engineering Controls

Ventilation Costs

PEA estimates

In the PEA, OSHA determined that at many workstations, employers needed to improve ventilation to reduce silica exposures. The cost of ventilation enhancements estimated in the PEA generally reflected the expense of ductwork and other equipment for the immediate workstation or individual location and, potentially, the cost of incremental capacity system-wide enhancements and increased operating costs for the heating, ventilation, and air conditioning (HVAC) system for the facility.

In considering the specific ventilation enhancements for given job categories the PEA estimated the type of LEV and the approximate quantity in cubic feet per minute (cfm) of air flow required to reduce worker exposures.

To develop generally applicable ventilation cost estimates for the PEA, a set of workstation-specific and facility-wide ventilation estimates were defined using suggested ventilation approaches described in the American Conference of Governmental Industrial Hygienists (ACGIH) Industrial Ventilation Manual, 24th edition, 2001 (Document ID 1607). With the assistance of industrial hygienists and plant ventilation engineering specialists, workstation estimates of cfm were derived from the ACGIH Ventilation Manual, and where not covered in that source, from expert judgements for the purpose of costing LEV enhancements (Document ID 1608, p. 29).

Over a wide range of circumstances, ventilation enhancement costs, which included a cost factor for HEPA filters and baghouses, where needed, varied from roughly $9 per cfm to approximately $18 per cfm (Document ID 1608, p. 29). Because of a lack of detailed data to estimate the specific ventilation installation costs for a given facility, an estimate of the likely average capital cost per cfm was used and applied to all ventilation enhancements. Based on discussions with ventilation specialists, $12.83 per cfm was judged to be a reasonable overall estimate of the likely capital costs of ventilation enhancements (Document ID 3983, p. 1).[15]

OSHA applied the per-cfm capital cost estimate to estimated cfm requirements for each workstation. By using the unit value of $12.83 per cfm, the cost estimates for each ventilation enhancement included both the cost of the LEV enhancement at the

[15] This unit value ($12.83 per cfm) was derived by inflating ERG's 2003 estimate of $11 to 2009 dollars using the implicit price deflator of 1.167.

workstation and the contribution of the enhancement to the overall facility ventilation system requirements. That is, each ventilation enhancement at a workstation was expected to generate costs to the building's general ventilation system either by requiring increased capacity to make up for the air removed by the LEV system or to filter the air before returning it to the workplace.

For operating costs, engineering consultants analyzed the costs of heating and cooling system operation for 12 geographically (and therefore, climatologically) diverse U.S. cities. The analysis, presented in Table 3-2 in the ERG report (Document ID 1608, p. 30), showed the heating and cooling British Thermal Unit (BTU) requirements for 60-hours-a-week operation (12 hours a day, Monday through Friday) or for a continuous 24-hour-a-day, year-round operation, with and without recirculation of plant air. Facilities that recirculate air have much lower ventilation system operating costs because they do not need to heat or cool outside air to comfortable inside temperatures.

In the PEA, ventilation operating costs were based on a weighted average of the costs of four operating scenarios: 1) no recirculated air, continuous operation; 2) no recirculated air, operating 60 hours per week; 3) recirculated HEPA filtered air, continuous operation; and 4) recirculated HEPA filtered air, operating 60 hours per week. These scenarios were chosen to reflect the various types of operating system characteristics likely to be found among affected facilities. The weights (representing the share of total facilities falling into each category) and operating costs per cfm for each of these scenarios are shown below in Table V-3:

Table V-3: Ventilation Operating Cost Averaging Assumptions in the PEA

Type of system	Average Cost per CFM	Share of Total
No recirculated air, continuous operation	$15.55	5.0%
No recirculated air, operating 60 hours per week	$5.78	15.0%
Recirculated HEPA filtered air, continuous operation	$1.40	20.0%
Recirculated HEPA filtered air, operating 60 hours per week (cost proportional to the number of hours operated)	$0.50	60.0%
Weighted average operating cost per CFM	**$2.22**	

Source: Document ID 1781, Workbook #6 - GI Unit Costs_Active, Vent op costs

The national average annual operating cost per cfm was estimated to be $2.22. This estimate was a weighted average of the operating costs for facilities that recirculate air and those that require make-up air. The operating costs for HEPA-filter recirculated air were estimated at $0.50 per cfm for facilities operating 60 hours per week and $1.40 per cfm for those continuously operating 24 hours per day. The operating costs for facilities that do not recirculate air were $5.78 per cfm for those operating 60 hours per week and $15.55 per cfm for those operating continuously. In generating these estimates, it was judged that 80 percent of facilities would recirculate airflow and 20 percent would not, and that 75 percent within each group operate for 12 hours per day on weekdays, with the remainder operating continuously, year-round, for 24 hours a day.

OSHA also added a maintenance factor to the operating cost estimates, which was 10 percent of the capital cost investments of $12.83 per cfm for ventilation systems. As a result, the total annual costs per cfm, excluding annualized capital costs, were estimated to be $3.50 (weighted average operating costs of $2.22 plus annual maintenance costs of 10 percent of $12.83.)

Underlying the cost results was the assumption that, over the course of the proposed one-year compliance period for engineering controls, employers would schedule installation of ventilation to minimize disruption of production, just as they would with any modification to their plants.

Comments and responses on Local Exhaust Ventilation Issues: Need for a Complete New System

Local exhaust ventilation represents one of the major costs associated with engineering controls in both the PEA and in this FEA. Commenters raised issues both about OSHA's PEA estimates of the unit costs of LEV and about the adequacy of OSHA's estimates of the volume of LEV that would be needed to adequately control silica exposures.

URS, testifying on behalf of ACC, argued that any firm that would be utilizing LEV to meet a PEL of 50 μg/m^3 would need to remove any existing LEV and install an entirely new LEV system. Thus, in URS's estimation, there would be no incremental addition of LEV. In a discussion of the URS approach during OSHA's informal public hearings, OSHA asked the URS representative to confirm that his organization commented that when a majority of workers are exposed over the PEL, the existing controls must be replaced instead of enhanced:

> MR. BURT: I want to be sure I understand what that's saying. Let's say you encountered a situation in which there were four workers. Two were exposed at 35, two at 60. You would scrap all of the controls and start over again. That's what it seems to be saying.
>
> […]
>
> MR. WAGGENER: [Y]es, that they would need to be replaced with a more adequate system (Document ID 3582, Tr. 2109-2110).

OSHA's examination of the spreadsheets URS provided documenting its independently developed cost estimates shows that, in all cases where any employee in an establishment was exposed above 50 μg/m^3, URS assumed that the employer would need to install a complete new LEV system and included the costs for installing and operating this entirely new system (Document ID 2308, Attachment 8, pp. 13-14).

John Burke from OSCO Industries took a different approach to the question that better illustrates the options that OSHA believed to be available when it developed the PEA estimates:

> A single large dust collector is probably already handling the exhausting of the entire sand conditioning system. Most likely all the pick-up points referenced in the economic analysis already have suction being applied and yet there is still an overexposure. What do you do and how much is that going to cost? If the sand system operator is overexposed then you could first evaluate work practices controls. If work practice controls are unsuccessful and additional suction is needed, that suction is going to be very expensive! If your environmental operating permit allows it you may be able to tweak the performance of the dust collector. There may be some things you can do to tweak the capacity of your existing dust collector to bring it up to exactly its permitted air volume or you might have to enlarge your dust collector (Document ID 1992, p. 6).

OSHA agrees with Mr. Burke. As discussed above, there are usually a wide variety of ways to improve existing controls before removing and reinstalling an LEV system. As a result, OSHA finds the URS approach unrealistic and likely to significantly overestimate costs.

Comments and Responses on the Volume of Controls Needed

One commenter, URS, questioned OSHA's estimates of the volume of additional LEV that would be needed to comply with the standard. URS, testifying for ACC, reported that OSHA's estimates in the PEA were too low as compared to the recommendations in Table 6-2 of the ACGIH Ventilation Manual (28th Edition) (ACGIH, 2013). They criticized OSHA's estimates saying that OSHA routinely underestimated required capture velocities by at least a factor of two for particles with high (conveyor loading, crushing) or very high (grinding, abrasive blasting, tumbling) energies of dispersion (Document ID 2308, Attachment 8, pp. 12 and 14). URS said that "the capture velocities for LEV systems in OSHA's models were often based on the minimum recommended velocity," that OSHA's estimated additional LEV was too low because "the ACGIH capture velocity values used by OSHA were first developed and published many years ago" and were not sufficient to control dust to the levels OSHA is now proposing, and that "the velocity values used in OSHA's cost model are most likely undersized by a factor of 2 or more" (Document ID 2308, pp. 11-12). Other than its own supposition, URS did not identify an alternative source for OSHA to use as the basis for estimates of ventilation capacity necessary to control silica exposures.

In response to these comments, and in order to determine whether ACGIH recommendations had changed between the 24th edition (which OSHA used to develop estimates in the PEA) and the more recent 28th edition, OSHA checked its estimated volumes against those in the more recent ACGIH Ventilation Manual (Chapter 13 in the 28th edition (Document ID 3883)). In the 24th edition of the Manual, ACGIH provided a single recommendation for ventilation capacity rather than a range. In the PEA, OSHA adopted this recommendation and did not choose a value from within a range of values. The 28th edition of the Manual provides more flexibility in system design and specification and incorporates a recommended range. However, OSHA determined that the ventilation capacity estimates did not change between the 24th edition of the Manual and the 28th edition. In most cases, OSHA's estimated volumes were identical to those recommended by ACGIH. The exceptions were situations in which ACGIH provided no recommendation (in which case OSHA relied on recommendations of industrial hygienists), and situations in which the technological feasibility analysis recommended additional volumes of LEV capacity above what employers were typically using. In the latter situations, OSHA estimated that an additional 25 percent of the ACGIH specification would be necessary to adequately control silica exposures. (See Exhibit: Comparison of OSHA CFM Volumes to ACGIH Values (2016).)
URS argued that silica was different from other substances LEV might be applied to in ways that would call for higher volumes of ventilation (Document ID 2308, Attachment 8, p. 14). However, at least some of the volumes criticized by URS are listed in the ACGIH manual as being appropriate for situations that clearly involve silica, such as shake-out stations.

OSHA's estimates of the ventilation capacity necessary to control silica exposures relied on a detailed set of recommendations provided by ACGIH while URS simply asserted that these values are "most likely undersized by a factor of 2 or more" without providing additional evidence to support this (Document ID 2308, Attachment 8, p. 12). Based on these findings, OSHA has determined that the ACGIH recommendations constitute the best available evidence and has maintained the estimates of ventilation capacity from the PEA for this FEA.

Comments providing alternative ventilation system cost estimates

Other commenters provided much higher costs than OSHA's estimates but without providing any background to allow OSHA to put those costs in context. It is difficult for OSHA to evaluate a cost estimate without information on the size of the facility, the estimated volume of air, and the exposure levels before and after the LEV was installed.

The Interlocking Concrete Pavement Institute (ICPI) commented that OSHA underestimated compliance costs because "[o]ne ICP manufacturer reported that it could cost $150,000 to acquire and install highly efficient vacuum and water dust-control systems" and other manufacturers reported similarly high costs (Document ID 2246, p. 11). At the public hearings, OSHA sought clarification on the assumptions underlying the ICPI cost estimate, and the ICPI representative stated that $150,000 was a mid-range estimate. The representative also confirmed that this was the cost of an entirely new system:

> MR. BLICKSILVER: [D]oes this actually represent the incremental cost associated with complying with OSHA's proposed rule? … Or is this an overall cost for dust control in these manufacturing plants?
> MR. SMITH: The latter. (Document ID 3589, Tr. 4407-4409)

In a follow-up verbal exchange, OSHA requested that ICPI analyze their survey data to produce median values for the range of cost estimates and submit their analysis as a post-hearing comment (Document ID 3589, Tr. 4409). However, no ICPI comments appeared in the record following the Institute's testimony at the hearings.

Similarly, OSHA asked Mr. Tom Slavin, testifying for AFS, for additional information from AFS on the many cost estimates for individual foundries that they had included in their comments:

> MR. BURT: You provide many examples of cost to specific foundries of specific activities. I would like to suggest that those can be most useful if we have data on the size of the firm in question, the type of foundry if that's appropriate, and what they were trying to accomplish with this effort.
>
> Were they at 400 and trying to get to 100, at 100 trying to get lower? Something that puts it in context would again make these many, many helpful quotes much more useful.
>
> Size is just critical, just because of the fact that when we don't know whether we're talking about 20 or 200 people in a foundry really affects what you want to do with those cost estimates. And that one's relatively simple, size of firm, type of foundry if you have it, what they were trying to do with that effort. (Document ID 3584, Tr. 2773-2774)

Later in the exchange, OSHA requested information on "the components of [AFS's estimated cost per cfm of additional ventilation] that would be capital cost, installation cost, and then any other operating costs you have" (Document ID 3584, Tr. 2784). OSHA received no response to this request.

Unfortunately, it is almost impossible for OSHA to make use of commenters' estimates of costs or volume of LEV systems without information on the size of the facility and on what the resulting system accomplished in terms of reducing exposure levels. OSHA consistently requested this kind of information, but did not receive it. As shown in the discussion of alternative estimates of costs by small entity representatives during the SBAR Panel (discussed below), even estimates that appear higher than OSHA's average costs can be consistent with those costs when the full context for the estimates is examined.

Comments and Responses on Unit Cost per CFM

Many commenters thought that OSHA's unit costs for ventilation were too low. With respect to the annualized value of the capital costs plus operating and maintenance costs of $5.33 that OSHA used in the PEA, AFS stated:

> The PEA uses an annual cost factor of $5.33 for ventilation, including ducting and bag house operation [. . .] is far below foundry experience. A group of foundry ventilation managers and ventilation experts estimated the annual cost per CFM at $20 for exhaust alone and another $6-10 for makeup air critical to achieving the lower PEL. The cost to meet the new U.S. Environmental Protection Agency (EPA) dust loading criteria increases the exhaust annual cost to $25 per CFM. Any new installation would be expected to design to the new criteria even if not yet required to do so for that specific jurisdiction (Document ID 2379, Appendix 3, p. 9).

URS, commenting on behalf of ACC, estimated the annualized cost of LEV to be $27 per cfm, and increased OSHA's estimate of capital costs from $12.83 to $22 per cfm for the purpose of URS's cost estimate (Document ID 2308, Attachment 8, pp. 13-14).
Many other commenters from industry suggested unit costs for additional LEV. For example, AFS provided independent estimates of annualized costs of $20 to $25 per cfm and URS estimated $22 to $27 capital costs per cfm (Document ID 2379, Appendix 1, p. 45; 2308, Attachment 8, p. 14; 2379, Appendix 2, p. 13; 2503, p. 2; 2119, Attachment 3, p. 4; 2248, p. 8; 3490, p. 3; 3584, Tr. 2779).

OSHA agrees that there can be a wide range of both capital and operating costs associated with LEV. Capital costs will vary according to such factors as the exact nature of the ventilation (including the design of the slot, hood, or bagging station), the volume of materials to be handled by the ventilation, and the length of the ductwork necessary. OSHA also would like to clarify that, as shown in OSHA's spreadsheets (OSHA, 2016), where there are major structural changes associated with a control, such as automation, a new bagging station, or conveyor closure, these costs are estimated over and above the basic capital costs of LEV. Annual operating costs vary according to climate, hours of operation, and the extent to which air is recirculated. To examine these possible costs, OSHA reviewed the thoroughly documented LEV costs presented in its Final Economic Analysis for the Occupational Exposure to Hexavalent Chromium Standard (Document ID 3641). In that FEA, OSHA's estimates of the capital costs for LEV (updated to 2012 dollars) averaged more than $20 per cfm when major work station changes, such as automated bag slitting stations, were included in the cost of LEV. Ordinary additional LEV without major workstation changes was estimated to have an average capital cost of $9 per cfm in 2012 dollars. Operating costs in that rulemaking were estimated to be somewhat higher than estimated here, but combined annualized costs (capital plus operating costs) were approximately the same. (See Exhibit: Analysis of LEV Costs from Hex Chrome (2016).) OSHA agrees that the capital costs of some kinds of LEV that involve significant workstation modifications or even automation can exceed $20 per cfm, but finds an average of $12.83 per cfm in capital costs to be reasonable given that some kinds of LEV installation can cost as little as $3 to $5 per cfm. OSHA also finds the operating cost estimates used in this FEA to be a reasonable average across a very wide variety of circumstances.

Housekeeping and Dust Suppression Costs

PEA costs

For a number of occupations, the technological feasibility analysis in the PEA indicated that improved housekeeping practices were needed to reduce silica exposures. The degree of incremental housekeeping depended upon how dusty the operations were and the appropriate equipment for addressing the dust problem. The incremental costs for most such occupations reflected labor associated with additional housekeeping efforts. Because incremental housekeeping labor was required on virtually every work shift by most of the affected occupations, the costs of housekeeping in the PEA were significant. The PEA also estimated that employers would need to purchase HEPA vacuums and to incur the ongoing costs of HEPA vacuum filters. The time needed for such housekeeping varied from five to twenty minutes per affected worker per day. Appendix V-A in the PEA provided detailed specifications on the application of housekeeping and other dust-suppression controls in each occupational category and the sources of OSHA's unit cost data for such controls.

For some indoor dust suppression tasks, it was assumed that dust suppression mixes - often sawdust-based with oil or other material that adheres to dust and allows it to be swept up without becoming airborne - were spread over the areas to be swept. For these products, estimates were made of usage rates and the incremental times necessary to employ them in housekeeping tasks.

For outdoor dust suppression, the PEA determined that workers must often spray water over storage piles and raw material receiving areas. The methods by which water is provided for these tasks can vary widely, from water trucks to available hoses. It was judged that most facilities would make hoses available for spraying and that spraying requires a materials-handling worker to devote part of the workday to lightly spray the area for dust control.

The PEA did not include any costs for thorough cleaning designed to remove accumulated dust, either as a one-time cost or as an annual cost.

Comments and Responses on Costs of Routine Housekeeping and Initial Cleaning

Commenters had a number of issues with respect to how OSHA treated the costs of housekeeping, including the time and equipment needed for vacuuming, the need for professional floor to ceiling cleaning, and the costs of the ban on dry sweeping.

Comments and Responses on Costs of Routine Housekeeping

With respect to the use of HEPA vacuums, AFS commented that due to the volume of sand involved, foundries often use vacuums that cost $45,000 instead of the $3,500 estimated by OSHA in the PEA (Document ID 4229, Attachment 1, p. 23). Several commenters reported that HEPA semi-mobile central vacuum systems cost more than $40,000 to purchase and cost approximately $4,000 per year to maintain, and that sweeping compound costs approximately $4,000 per year (Document ID 2384, p. 7; 2114, Attachment 1, p. 4). Several others noted that acquiring HEPA vacuums and employee time for vacuuming would be expensive (Document ID 2301, Attachment 1, p. 74; 3300, pp. 4-5; 2114, Attachment 1, p. 4).

OSHA’s costs are for improved housekeeping, beyond the necessary tasks related to dealing with the large volumes of sand used in foundries. For this final rule, OSHA estimates the costs of additional housekeeping as those necessary for overexposed worker to spend ten minutes vacuuming their immediate work areas with a fifteen-gallon HEPA vacuum. It is possible that a large firm may find a dust handling system or a semi-mobile central vacuum system less expensive than having individual workers equipped with smaller capacity HEPA vacuums spend additional time performing housekeeping on each shift.

With respect to the shipbuilding sector, OSHA found that it had not accounted for the costs of HEPA vacuums for abrasive blasting helpers. OSHA has added costs for the vacuums, but not for the time spent performing housekeeping as the vacuums replace dry sweeping.

As to the possible costs of the ban on dry sweeping, OSHA has modified this prohibition in ways that should avoid significant costs in situations where dry sweeping is the only effective method of housekeeping.

Comments and Responses on Costs of Initial Cleaning

URS, testifying for ACC, questioned OSHA's omission of "professional cleaning" from its cost models for some industries, noting that professional cleaning was identified in the PEA as necessary for some industries to achieve the PEL (Document ID 2308, Attachment 8, p. 12). URS also provided estimates of the cost of professional cleaning:

> Based on communications with several industries, URS estimates that a thorough annual professional cleaning will cost about $1.00 per square foot of the facility process operations area.
> … A professional cleaning can take several days to accomplish […] For square footage, URS assumed 20,000 square feet for very small facilities, 50,000 square feet for small facilities, and 200,000 square feet for large facilities (Document ID 2308, Attachment 8, p. 24).

Initial thorough facility cleaning and rigorous housekeeping are supplemental controls and work practices addressed in the technological feasibility analysis for the following application groups: Concrete Products, Pottery, Structural Clay, Mineral Processing, Iron Foundries, Nonferrous Sand Foundries, and Captive Foundries. OSHA failed to include the costs of a thorough initial cleaning in the PEA, but has developed estimates of these costs for the FEA in response to the URS comment. The final standard sets the performance objective of achieving the PEL using engineering controls, work practices, and where necessary, respiratory protection, and, with respect to facility cleaning and housekeeping, the rule does not mandate that firms hire outside specialists. To estimate the final costs for initial thorough facility cleaning, OSHA first developed an analysis of average production floor space in square feet for two plant sizes based on data on plant floor space and employment for individual facilities reported in various NIOSH control technology and exposure assessment field studies (OSHA examined Document ID 215; 216; 268; 1373; 1383; 3786; 3996; and 4114. The analysis is in Exhibit: Analysis of Plant Floor Space (2016)). For the purpose of estimating cleaning costs, OSHA characterized establishments with fewer than twenty employees as very small establishments, and characterized establishments with twenty or more employees as larger establishments.

OSHA determined, based on a review of the data in the NIOSH field studies, that production floor space averages 725 square feet per employee (see Exhibit: Analysis of Plant Floor Space (2016)). For very small establishments with fewer than 20 employees, OSHA used an average of 7 employees per establishment. For larger establishments, OSHA used an average of 80 employees. (These estimates of the number of employees are based on OSHA (2016), which shows that the average number of employees for establishments with fewer than 20 employees is 7 employees and that the average number of employees for establishments with more than 20 employees is 80 employees.) Based on these parameters, OSHA's floor space model found that the typical floor space for very small establishments is 5,075 square feet and for larger establishments is 58,000 square feet.

ERG spoke with a representative of an upper-Midwestern firm specializing in the industrial cleaning of foundries and related facilities (Document ID 3817, p. 2). According to that representative, cleaning costs depend on numerous factors, such as the distance to the facility that needs to be cleaned, the size and number of machines and pieces of equipment present, the types of required cleaning activities, and the presence of confined spaces. The representative described one of his company's clients as a sand-casting foundry that produces 42,000 tons of gray and ductile iron castings per year in a 210,000 square foot facility. According to the representative, a crew of two technicians cleans the facility every 2 to 3 weeks at a cost of $2,200 to $3,500 per cleaning, which requires one day, or roughly $0.01 to $0.02 per square foot in 2014 dollars.

For the FEA, OSHA is estimating, based on data from the ERG field interviews, that it will take 4 to 5 days to perform a one-time initial cleaning (remove all visible silica dust) and that if the same facility is cleaned every 2 to 3 weeks it will take 1 day to clean it. At a cost of $0.02 per day per square foot, and using a cleaning duration of five days, OSHA calculated a cost of $0.15 per square foot in 2012 dollars for an initial thorough cleaning. This value is derived from inflating the 2003 estimate of $0.10 per square foot ($0.02 per day per square foot over 5 days) to 2012 dollars, which raised the cost to $0.12 per square foot. OSHA also allowed for an additional allotment of 25 percent of the estimated cost of $0.12 per square foot (in 2012 dollars) to ensure that the cleaning was sufficiently thorough to achieve compliance, increasing the total from $0.12 to $0.15. OSHA judges that this is a reasonable average for the range of facilities to be covered, especially given that some annual cleaning is probably already occurring at most facilities and therefore the full cost of cleaning would not be attributable to this rule. The costs here are applied to represent an incremental cleaning beyond that employed for normal business purposes.

As discussed earlier in this chapter, URS, an engineering consultant to ACC, estimated that a thorough annual professional cleaning will cost about $1.00 per square foot of a facility's process operations area. URS provided no specific reference for that unit estimate other than that it communicated with industry representatives (Document ID 2308, Attachment 8, p. 24). The data OSHA used to develop its cost estimates are based on interviews with companies that provide housekeeping services rather than companies that may or may not have purchased such services. OSHA's estimated costs for a thorough initial cleaning are over five times the costs of a thorough cleaning where there is just few weeks' worth of accumulated dust. Greater accumulations during an initial cleaning do not mean that the initial cleaning will cost 50 times the cost of a more basic/regular cleaning, as much of the cost of the initial cleaning will be due to the time spent going over the entire facility with the appropriate cleaning devices—a cost that is fixed by area and not by accumulation. OSHA therefore rejects the URS unit estimate of $1.00 per square foot as not representative of a typical cost for initial thorough facility cleaning, particularly for firms that choose to use in-house resources. Nonetheless, OSHA acknowledges that unique circumstances may create higher unit costs than the value OSHA is using in this FEA. OSHA also acknowledges that the cost of cleaning per square foot probably declines as facility size increases (Document ID 4231, p. 4). The paucity of data on square footage for the affected facilities, however, did not allow for further modeling of cleaning costs.

For this final analysis of costs for initial thorough facility cleaning, OSHA estimated that an upfront, one-time, extensive servicing (using vacuum and wash equipment) to rid the production area of respirable crystalline silica during plant turnaround or other downtime would cost $0.15 per square foot (including the additional allowance to ensure a sufficiently thorough cleaning) or $0.02 when annualized at 3 percent for 10 years, and OSHA applied that unit cost along with the average production floor space discussed above in OSHA's cost model (725 square feet per employee) to derive final costs for facility cleaning by application group. For the seven affected application groups, OSHA estimates that annualized initial thorough facility cleaning costs will range from just under $45,000 for Nonferrous Sand Foundries to $488,000 for Concrete Products. Across all seven affected application groups, OSHA estimates that annualized costs for initial thorough facility cleaning will total $2.8 million.

Conveyor Covers

The technological feasibility analysis in the PEA recommended reducing silica exposures by enclosing process equipment, such as conveyors, particularly where silica-containing materials were transferred (and notable quantities of dust can become airborne), or where dust is generated, such as in sawing or grinding operations. For the PEA, OSHA estimated the capital costs of conveyor covers as $20.73 (updated to 2012 dollars) per linear foot, based on Iandola (2003) (as summarized in footnote a in Table V-3 of the PEA). OSHA estimated that each work crew of four affected workers would require 100 linear feet of conveyors. OSHA, based on ERG's estimates, calculated maintenance costs as 10 percent of capital costs. Based on the technological feasibility analysis, OSHA also included the cost of LEV on the vents of the conveyors for the structural clay, foundry, asphalt roofing, and mineral processing application groups, but not for the glass and mineral wool application groups.

URS commented that OSHA underestimated the length of conveyors by using 100 linear feet in its estimate, and suggested that the estimate of 200 feet that it used as the basis for its estimates was still an underestimation for some foundries (Document ID 2307, Attachment 26, Control Basis and Control Changes tabs). URS maintained OSHA's estimate of $20.73 per linear foot in its own calculations. However, it appears that URS did not understand that OSHA estimated 100 linear feet of conveyors for every four workers, not 100 linear feet of conveyors for an entire affected establishment. Further, the URS comment indicated that 100 linear feet was an underestimate for "medium and large foundries." But because OSHA's estimate of 100 linear feet is for every four workers, OSHA actually estimated much longer conveyor lengths for larger facilities with more workers. OSHA has determined that its estimate of 100 linear feet for every four workers at a cost of $20.73 per linear foot is a reasonable approach for estimating the costs of conveyor covers.

Selected Control Options That Are Not Costed

Consistent with ERG's cost model, in the PEA OSHA chose not to estimate costs for some control options mentioned in the accompanying technological feasibility analysis in Chapter IV of the PEA. In these cases, OSHA judged that other control options for a specific at-risk occupation were sufficient to meet the PEL. AFS identified several control options for which OSHA did not estimate costs:

- Substitution of non-silica sand (V-A-51)
- Pneumatic sand handling systems (V-A-51)
- Didion drum to clean scrap for furnace operators (V-A-52)
- Non-silica cores and core coatings (V-A-52)
- Professional cleaning costs and associated downtime (V-A-52)
- Physical isolation of pouring areas (V-A-52)
- Modify ventilation system to reduce airflow from other areas (V-A-52)
- Automation of a knockout process (V-A-53)
- Automated abrasive blast pre-cleaning of castings for finishing operators (V-A-54)
- Wet methods (V-A-54)
- Low silica refractory (V-A-55) (Document ID 2379, p. 16)

Just because a control is mentioned in the technological feasibility analysis does not mean that OSHA has determined that its use is required – only that it represents a technologically feasible method for controlling exposures. The Agency developed cost estimates based on the lowest cost combination of controls that allows employers to move from an uncontrolled situation to meeting the new PEL. OSHA did not include the costs for possible controls that were either more expensive or were not necessary to achieve the PEL. OSHA (2016) describes in detail which controls were considered necessary to achieve the PEL. OSHA continues in this FEA to exclude costs for these kinds of more expensive possible controls.

Railroads

In its preliminary estimates, OSHA inadvertently applied the preceding general industry PEL of 100 μg/m^3 in its analysis of the railroad industry. Silica exposures among railroad employees, however, result from ballast dumping, which is track work that is generally subject to OSHA's construction standard and covered by the preceding construction PEL of 250 μg/m^3 (see discussion of railroads in Chapter III, Industry Profile). As a result, OSHA has changed its conclusion that there would be no incremental costs for railroads to meet the new PEL. OSHA has reassigned all costs previously assigned to meeting the preceding PEL to being incremental costs of meeting the new PEL. Although the railroad activities affected by the new silica rule will typically constitute construction work, OSHA has categorized all compliance costs for railroads with general industry costs under NAICS 482110 because the railroad industry is predominately engaged in non-construction work and its NAICs code is not typically classified as a construction code..

Costs of Engineering Controls for Hydraulic Fracturing in the PEA

Both in the PEA and in this FEA, OSHA presented the methods of estimating the costs of controlling silica exposures during hydraulic fracturing separately from the engineering control costs for all other portions of general industry because there are some fundamental differences in the methodology OSHA used, and thus in the comments OSHA received on that methodology. In the PEA, OSHA began its analysis of hydraulic fracturing in the standard way of examining the set of engineering controls available to control employee exposures to silica. Unlike the way OSHA handled the rest of general industry, however, for hydraulic fracturing OSHA identified precisely which controls were necessary to go from current levels of exposure to the preceding general industry PEL of 100 μg/m^3 and then what further controls would be necessary to go from the preceding general industry PEL of 100 μg/m^3 to the new PEL of 50 μg/m^3. OSHA took a different approach for this sector because the data available for this industry, as a result of an extensive set of site visits, were adequate to make this kind of determination. OSHA determined that a combination of wet methods, partial enclosure, and LEV controls would be sufficient to meet a PEL of 100 μg/m^3 for hydraulic fracturing. OSHA then determined that LEV controls at thief hatches and operator enclosures would be sufficient to reduce exposures during hydraulic fracturing from 100 μg/m^3 to 50 μg/m^3. The costs of these additional engineering controls were shown in Tables A-14, A-15, and A-16 for large, medium, and small fleets, respectively, in the PEA (the full derivation of the results in these tables can be found in ERG, 2013, Document ID 1712).

As discussed in the Industry Profile section of this FEA (Chapter III), the basic unit for analysis for this industry is the fleet rather than the establishment. Rather than allocating costs according to the proportion of workers above a given exposure level, as was done for the rest of general industry, for hydraulic fracturing the controls applied per fleet were judged to reduce the exposures of all workers associated with the fleet.

Public Comments on OSHA's Preliminary Cost Estimates for Engineering Controls in Hydraulic Fracturing

General methodology

Though there were extensive comments on OSHA's estimates of engineering control costs for hydraulic fracturing, no commenter objected to the differences in methodology compared to OSHA's treatment of the other general industry sectors (as outlined above). Halliburton Energy Services, Inc. commented that OSHA's analysis "lacks data" (Document ID 4211, p. 5). As discussed in Chapter IV Technological Feasibility, OSHA agrees that there is limited experience with many possible controls. For this reason, OSHA has allowed this industry an extended compliance deadline of five years before they have to meet the new PEL with engineering controls. However, OSHA does not agree that that this adds significant uncertainty to the costs analysis. The costs of the controls OSHA has examined, and especially those needed to go from the preceding general industry PEL to the new PEL can readily be ascertained. It is possible that the cost of some controls that have not yet been tested and that OSHA has not costed could be much lower than the costs OSHA estimated in the PEA and in this FEA.

<u>Compliance rate</u>

In the joint comments submitted by the American Petroleum Institute and the Independent Petroleum Association of America (API/IPAA or "the Associations"), the Associations disagreed with OSHA's estimated current compliance rate for the use of engineering controls. In the PEA, OSHA estimated a compliance rate of ten percent for engineering controls in this industry. In their comments the Associations said that "ERG assumed that 10% of all hydraulic fracturing firms already utilize: (1) baghouse controls; (2) caps on fill ports; (3) dust curtains; (4) wetting methods; and (5) conveyor skirting systems" (Document ID 2301, p. 40, fn. 148).

While OSHA used a compliance rate of ten percent for all of these controls, it is not meant to represent that all prescribed controls are used in ten percent of firms. OSHA's compliance rates take into account that some well sites, as documented in Chapter IV of the PEA, were observed to be using a variety of controls that reduce dust levels, and as a result, those firms will not need to implement as many additional controls in order to achieve the new PEL. Further, as noted in Chapter IV of the FEA, the industry is constantly installing additional controls to reduce silica exposures. Thus the Agency sees no reason to change its estimate of current compliance. In any case, removing the assumption would make only a ten percent difference to the cost estimates, which would not be a change of large enough magnitude to threaten OSHA's conclusion that compliance with the final rule is economically feasible for the hydraulic fracturing industry.

Maintenance costs

In the PEA, OSHA estimated that the life of most capital equipment would be ten years, and that maintenance and operating costs would range from ten to thirty percent of capital costs per year (ten percent being most common).

API/IPAA argued that the hostile, sandy environment of the well site shortens the useful life of equipment and increases maintenance costs. The Associations estimated that the useful life of equipment ranges from 5 years to 7.5 years and that annual operating and maintenance costs range from 10 percent to 25 percent of capital costs. While OSHA agrees that the oilfield environment is challenging and dusty, there is no evidence in the record that these environments are more challenging than other industrial settings where equipment lives of 10 years and operating and maintenance costs of 10 to 30 percent have been used as reasonable estimates.

Cost of Specific Controls

Dust Booths

In the PEA, OSHA estimated that there would need to be one dust booth for each sand moving machine, and that this would result in one dust booth for small fleets, three for medium fleets, and five for large fleets. In critiquing OSHA's cost analysis for hydraulic fracturing, API/IPAA disagreed with OSHA's estimates that only sand mover operators would need to utilize dust control booths in order to achieve the new PEL (Document ID 2301, p. 69). API/IPAA suggested that instead there would need to be one booth per affected worker and that only one worker could utilize a given booth. In the Associations' estimate this would mean that there would need to be 3, 8 and 12 booths for small, medium, and large fleets, respectively (Document ID 2301, Attachment 4, Dust Booths, row 9).

As discussed in the technological feasibility chapter of this FEA, OSHA agrees that workers other than sand mover operators will need to use dust booths. However, OSHA does not agree that a booth can only accommodate a single person. These booths are places of refuge and are not assigned to specific individuals. The technological feasibility chapter (Chapter IV) in this FEA determined that dust booths can accommodate more than one person per booth. Because OSHA agrees that more employees than sand mover operators will need booths, OSHA has raised its estimates of booths needed by size class from 1, 4, and 5 booths to 3, 6, and 8 booths. While this estimate of the number of booths is lower than that recommended by API/IPAA, OSHA finds that these booths can accommodate 2 persons per booth and thus can accommodate more workers than API/IPAA suggested.

In the PEA, OSHA estimated the transportation costs for booths as $37.25 per booth. API/IPAA disagreed. The Associations argued that a cost of $513 for a small fleet, which would have only one booth, would be more appropriate (Document ID 2301, p. 69). Most of the difference between API/IPAA's cost estimate for deploying dust control booths and OSHA's estimate is attributable to the fact that the Associations presented their cost per fleet and OSHA presented its cost per booth. API/IPAA applied their estimate of the number of booths necessary at these worksites when deriving their estimate and they estimated about six times as many booths being necessary as OSHA did. However, after further examination of this cost, OSHA determined that the standard per-mile shipping rate that it used to estimate transportation costs in the PEA was applied incorrectly. This resulted in an estimate of transportation costs for booths in the PEA that was too low. OSHA has determined that the cost to transport dust booths presented by the Associations more completely captured the costs associated with transporting these booths. For this FEA, OSHA has accepted the Associations' per-fleet transportation cost of $513 for each booth and applied the cost to the Agency's estimate of the number of booths necessary to control silica exposures on well sites.

Water misting

In the PEA, OSHA estimated that water misting system would be needed to control residual emissions from some releases from sand moving systems. These water misting systems were estimated to cost $60,000 per fleet to purchase and an additional 20 percent of the purchase cost for installation. API/IPAA incorrectly assumed that these water misting systems were intended to control all dust emission from truck traffic and other sources (Document ID 2301, pp. 69-70). This was not the case—dust suppression for truck and other traffic was costed at a much higher rate separately from water misting. OSHA's cost estimates for misting systems were based on conversations with a mining dust control specialist who indicated the price and efficacy of available water misting systems (Document ID 1571). While API/IPAA disagreed with OSHA's costs, they did not offer any data to show an alternative cost, instead simply carrying OSHA's estimate for water misting systems forward in their analysis to arrive at their cost estimate (Document ID 2301, Attachment 3, Water Misting, cells K:O6 and J8). OSHA has determined that the equipment that formed the basis for its cost estimates in the PEA may not be durable enough to stand up to the wear from frequent loading, unloading, and transportation. Therefore, the Agency, based on its own judgment, has increased the estimated cost of a water misting system by 33 percent in order to account for the need for a more durable system. Based on this, OSHA's final cost analysis for hydraulic fracturing includes costs of $79,800 per fleet to purchase the equipment plus installation costs of $15,960 for installation (20 percent of the purchase price) for water misting equipment to control residual dust emissions from sand moving systems.

Costs of Transportation

In developing the costs for hydraulic fracturing firms to comply with this rule in the PEA, it was determined that the baghouse controls that are commercially available are integrated into sandmover units and therefore should not present any logistical difficulties for transportation purposes. However, in examining the costs to transport, assemble, and disassemble the control equipment, API/IPAA noted potential difficulties in adding baghouse controls to sandmovers, which are often nearly at weight limits for road movement (Document ID 2301, p. 71).

OSHA's determination about integrated units has not changed since the PEA. The existence of integrated units is further discussed in Chapter IV of this FEA, Technological Feasibility. OSHA notes that sandmover units are not the heaviest items transported by hydraulic fracturing firms, so the additional weight associated with baghouse controls would be insignificant in this context. These firms are highly experienced in moving the heavy, bulky equipment needed on well sites and including additional controls on this equipment is not expected to create a situation that exceeds the capabilities of these firms.

Containerized systems

Commenting on OSHA's analysis of the cost of controls for hydraulic fracturing, API/IPAA expressed concern that OSHA was considering requiring the use of containerized systems. The Associations stated that these systems would be economically infeasible for small fleets and raised questions about whether these systems would be sufficient to allow fleets using them to achieve the PEL (Document ID 4222, p. 7). Neither in the PEA nor the FEA has OSHA's cost analysis reflected the use of containerized systems, nor does OSHA require their use. Instead, containerized systems represent a possible technological change that could potentially reduce the costs of silica control. OSHA has in no way quantitatively tried to estimate the effects of this possible reduction.

Conveyor skirting

In the PEA, OSHA found that conveyor skirting systems with appropriate LEV would be needed to meet the new PEL, and included the cost of such controls in the incremental costs associated with the new PEL. As discussed in Chapter IV of this FEA, Technological Feasibility, however, OSHA now finds that these conveyor skirting systems will be needed to meet the preceding PEL, but not to further lower exposures to the new PEL, so OSHA is not including costs for these controls as incremental costs associated with achieving the new PEL. As a result, this FEA does not include costs for conveyor skirting systems and LEV.

Dust Suppression – control of dust generated from traffic

On the other hand, dust suppression to control silica emissions generated by truck traffic, estimated in the PEA as necessary only to meet the preceding PEL, has now been determined to be necessary to meet the new PEL (See Chapter IV, Technological Feasibility). As a result, in this FEA OSHA added the costs of dust suppression to control silica dust generated by truck traffic to the estimated incremental costs of meeting the new PEL. OSHA estimates that dust suppression is more expensive in the aggregate than conveyor skirting systems with appropriate LEV.

OSHA made two additional changes to the costs of dust suppression from the PEA to the FEA. First, OSHA accepted the unit costs for dust suppression application provided by API/IPAA (Document ID 2301, Attachment 3, Dust Suppression). This unit cost is somewhat lower than the original estimate that OSHA adopted in the PEA (Document ID 1712). This seems reasonable to OSHA based on the costs of the most commonly used dust suppression materials. Second, OSHA has determined that these controls will be utilized to reduce exposures for ancillary support workers and remote/intermittent workers, 50 percent of whom work in situations that currently have exposures below the new PEL (as shown in the exposure profile in the section on hydraulic fracturing in Chapter IV, Technological Feasibility). As a result, instead of assigning dust suppression costs for all wells (as in the PEA), OSHA determined in the FEA that dust suppression costs would be incurred by 50 percent of wells. This aligns with a view that, in many cases, natural conditions (silica content of soils, dustiness, wetness and/or climate) are such that dust suppression is not needed.

Small Business Considerations

Small Business Regulatory Enforcement Fairness Act (SBREFA) Comments on Compliance Costs in General Industry and Maritime

Before publishing the NPRM, OSHA received comment on the accuracy of its unit costs through the Small Business Advocacy Review (SBAR) Panel process.
The Small Entity Representatives (SERs) who participated in the 2003 SBAR Panel process on OSHA's draft standards for silica provided many comments on the estimated compliance costs OSHA presented in the Preliminary Initial Regulatory Flexibility Analysis (PIRFA) for general industry and maritime (Document ID 0938).

In response to the SERs' comments, OSHA carefully reviewed its cost estimates and evaluated the alternative estimates and methodologies suggested by the SERs. OSHA updated all unit costs presented in the PIRFA to reflect the most recent cost data available and inflated all costs to 2009 dollars prior to publication of the proposed rule. However, the Agency generally determined that the control cost estimates in the PIRFA were based on sound methods and reliable data sources.

For the PEA, OSHA reviewed the SERs' cost estimates for small entities in the foundry and structural clay industries. Given that those SERs did not report their own sizes, the Agency could not compare their estimates to the estimates in the PEA. OSHA concluded that the compliance costs reported by the SERs in general industry that did provide size data were not incompatible with OSHA's own estimates of the costs of engineering controls to comply with the PEL. As discussed above, for the FEA, OSHA has halved the number of workers assumed to be covered by each control for most controls in establishments with fewer than twenty employees, which results in a doubling of the engineering control costs for these establishments.

Comments and Responses on Costs for Small Establishments

Stuart Sessions, testifying on behalf of ACC, argued that OSHA had underestimated costs to small establishments for two reasons: 1) small establishments may have higher exposures and therefore many need to spend more money installing controls to reduce those exposures; and 2) costs to small establishments may involve diseconomies of scale—whereby smaller facilities would have to pay more per unit to procure and install systems—that OSHA had not accounted for (Document ID 4231, Attachment 1, pp. 2-4).

With respect to the issue about small establishments having higher exposures—the commenter simply asserted that this is the case without providing any evidence to support the claim. Mr. Sessions speculated that smaller businesses have a "lesser ability to afford compliance expenditures and lesser ability to devote management attention to compliance responsibilities" (Document ID 4231, Attachment 1, p. 2). While it is possible that very small establishments may not have the same controls already in place as large establishments, as asserted by the commenter, this does not necessarily mean that very small establishments will have higher exposures. Small and very small establishments typically only have one shift per day, so fewer shifts are being worked where there is a potential for exposure. They also may spend more time on activities not involving silica exposures. For example, a small art foundry that produces one or two castings a week will simply spend proportionally less time on activities that lead to silica exposure than a large production foundry.

With respect to the issue of diseconomies of scale, OSHA has taken this phenomenon into account in its cost estimates in the FEA. First, in order to provide a conservative estimate of costs for the purposes of determining the impacts on very small employers, OSHA has revised what Mr. Sessions called "the most inappropriate of OSHA's assumptions" (Document ID 4231, Attachment 1, p. 6). In the PEA, OSHA estimated that a single control would reduce the exposures of four workers. For this FEA, OSHA has revised its estimates so that the number of workers whose exposures are reduced by a control are half that used in the PEA for establishments with fewer than 20 employees—reducing the number of workers covered by a control from four to two. OSHA made this adjustment even though there are ways in which small establishments may have lower costs per cfm than larger establishments. For capital costs, a major element of cost per cfm is the length of ductwork. Within the same industry, the length of ductwork will be much shorter in smaller establishments. For operating costs per cfm, length of operating time is a key element of costs.

OSHA has continued to estimate that the exposures of four employees whose exposures would be reduced per control for establishments with more than twenty employees (even though it is likely that more than four workers have their exposures reduced per control in the largest establishments). This effectively means that very large establishments with hundreds of employees have been modeled as if their costs were equivalent to that of several 20-40 person establishments combined. Far from neglecting diseconomies of scale, in an effort to be conservative and adequately account for the challenges faced by smaller establishments, OSHA has instead neglected to account for economies of scale in larger establishments.

Mr. Sessions calculated some higher overall costs for smaller establishments (Document ID 4231, Attachment 1, pp. 6-10). However, these costs are critically dependent on the assumptions already addressed and rejected by OSHA, such as that exposures are random and that any exposures require that all possible controls be installed to control those exposures.

Final Control Costs

Unit Control Costs

Methodology

For this FEA, OSHA used unit costs developed in the PEA for specific respirable crystalline silica control measures from product and technical literature, equipment vendors, industrial engineers, industrial hygienists, and other sources, as relevant to each item. Some PEA estimates were modified for this FEA based on comments in the record, and all costs were updated to 2012 dollars. Specific sources for each estimate are presented with the cost estimates. Wherever possible, objective cost estimates from recognized technical sources were used. Table V-4 provides details on control specifications and data sources underlying OSHA's unit cost estimates.

Table V-4:

Source Materials for Costs of Compliance Estimates for General Industry and Maritime

Control	Description	CFM (for	Capital Cost [a]	Operating Cost	Annualized Capital Cost	Comment
Local exhaust ventilation (LEV)	Average capital and operating cost assumptions; per cfm	N/A	$13.34	$3.70	$1.56	Estimated by industrial ventilation consultants, capital cost of $12.83 per cfm [a]; operating costs reflect current energy prices
Conveyor covers (unventilated)	Conveyor covers (2 ft. bed, including all hardware); per linear foot	N/A	$20.73	NA	$2.43	$17.10 per linear foot for 100 ft. (Iandola, 2003) [a]
Maintenance percentage	Standard rate for maintenance of capital equipment	N/A	NA	NA	NA	10% - estimated as a percentage of capital cost
Dust suppressants	Kleen Products 50lb poly bag green sweeping compound	N/A	NA	$676.47	$0.00	$0.28/lb, 2 lbs/day; 5 minutes/day (www.fastenal.com).
HEPA vacuum for housekeeping	NILFISK VT60 wet/dry hepa vac, 15 gal	N/A	$3,632.58	$511.20	$793.19	Nilfisk, HEPA vacuum (http://www.sylvane.com/nilfisk.html)
HEPA vacuum for housekeeping	NILFISK, large capacity	N/A	$8,002.49	$988.90	$1,747.38	Nilfisk, HEPA vacuum (McCarthy, 2003)
Saw enclosure	8x8x8 wood/plastic	N/A	$526.90	$52.69	$115.05	Fabrication costs estimated by ERG, assuming in-plant work. Five-year life.
Cab enclosures	Enclosed cabs	N/A	$15,762	$5,517	$3,441.81	ERG estimate based on vendor interviews.
LEV for hand held grinders	Shrouds + vacuum	N/A	$1,737.51	$608.13	$379.39	Vacuum plus shroud adapter (http://www.proventilation.com/products/productDetail.asp?id=15); 35% for
Upgraded abrasive blast cabinet	Improved maintenance and purchases for some	N/A	$4,850	$1,000	$568.57	Assumes addit.maint. (of up to $2,000) or new cabinets ($8,000) (Norton, 2003) [a]
Yard dust suppression	100 ft, 1" contractor hose and nozzle	N/A	$212.19	$0.00	$110.89	Contactor hose and nozzle; 2 year life; (www.pwmall.com) [a]
Wet methods to clean concrete mixing equip.	10 mins per day per operator	N/A	$0.00	$1,024.04	$0.00	10 mins per day per mixer operator
HEPA vacuum substitute for compressed air	Incremental time to remove dust by vacuum	N/A	NA	$536.47	$0.00	5 min per day per affected worker
Spray system for wet concrete finishing	Shop-built sprayer system	N/A	$213.42	$21.34	$111.54	Assumes $100 in materials and 4 hours to fabricate. Also 10% for maint.
Improved spray booth for pottery	Maintenance time & materials	N/A	$121.25	$118.42	$239.67	Annual: $100 materials plus 4 hours maintenance time [a]
Improved LEV for ceramics spray booth	Increased air flow; per cfm	N/A	$3.33	$0.92	$3.33	25% of installed CFM price

Table V-4: (continued)

Source Materials for Costs of Compliance Estimates for General Industry and Maritime

Control	Description	CFM (for Ventilation)	Capital Cost [a]	Operating Cost	Annualized Capital Cost	Comment
Exhaust for saw, cut stone industry	Based on saw LEV (e.g., pg. 10-158, 159, 160, ACGIH, 2001)	645	$8,602.67	$2,385.88	$1,008.50	Includes 545 cfm for saw base and 100 cfm for blade guard; updated to ACGIH 2013; VS-65-02, pg. 13-79
LEV for hand chipping in cut stone	Granite cutting and finishing; (pg. 10-94, ACGIH, 2001)	600	$8,002.49	$2,219.43	$938.14	ERG estimate of CFM requirements
Exhaust trimming machine	Based on abrasive cut-off saw; (pg. 10-134) (ACGIH, 2001)	500	$6,668.74	$1,849.52	$781.78	Opening of 2 sq ft assumed, with 250 cfm/sq.ft
Bag opening	Bag opening station; (pg. 10-19, ACGIH, 2001)	1,513	$20,179.60	$5,596.66	$2,365.66	3.5'x1.5' opening; with ventilated bag crusher (200 cfm)
Conveyor ventilation	Conveyor belt ventilation; (pg. 10-70, ACGIH, 2001)	700	$9,336.23	$2,589.33	$1,094.49	Per take-off point, 2' wide belt.
Bucket elevator ventilation	Bucket elevator ventilation (pg. 10-68; ACGIH,2001)	1,600	$21,339.96	$5,918.47	$2,501.69	2'x3'x30' casing; 4 take-offs @250 cfm; 100 cfm per sq ft of cross section
Bin and hopper ventilation	Bin and hopper ventilation (pg. 10-69; ACGIH, 2001)	1,050	$14,004.35	$3,884.00	$1,641.74	350 cfm per ft^2; 3' belt width
Screen ventilation	Ventilated screen (pg. 10-173, ACGIH, 2001)	1,200	$16,004.97	$4,438.86	$1,876.27	4'x6' screen; 50 cfm per ft^2
Batch operator workstation	Bin & hopper ventilation for unvented mixers (pg. 10-69, ACGIH, 2001)	1,050	$14,004.35	$3,884.00	$1,641.74	ERG estimate of CFM requirements
LEV for hand grinding operator (pottery)	Hand grinding bench (pg. 10-135, ACGIH, 2001)	3,750	$50,015.54	$13,871.42	$5,863.35	ERG estimate of CFM requirements
LEV, mixer and muller hood	Mixer & muller hood (pg. 10-87, ACGIH, 2001)	1,050	$14,004.35	$3,884.00	$1,641.74	ERG estimate of CFM requirements
LEV for bag filling stations	Bag filling station (pg. 10-15, ACGIH, 2001)	1,500	$20,006.21	$5,548.57	$2,345.34	Includes costs for air shower
Installed manual spray mister	Manual controls, system covers 100 ft of conveyor	N/A	$10,609.36	$1,060.94	$1,243.74	National Environmental Services Company (Kestner, 2003). [a]
Install cleaning hoses, reslope floor, drainage	Plumbing for hose installations, floor resloping and troughs	N/A	$36,412.40	$3,323.52	$4,268.64	ERG estimate. Includes cost of water and labor time.
Substitute alt., non-silica, blasting media	Alternative media estimated to cost 22 percent more	N/A	$0.00	$5,156.25	$0.00	Based on 220,000 square feet of coverage per year per crew
Shakeout conveyor enclosure	Ventilated shakeout conveyor enclosure	10,000	$133,374.76	$36,990.46	$15,635.59	ERG estimate
Shakeout side-draft ventilation	Shakeout double side-draft table (pg. 10-23, ACGIH, 2001)	28,800	$384,119.32	$106,532.52	$45,030.50	ERG estimate of CFM requirements
Shakeout enclosing hood	Ventilated enclosing hood (pg. 10-23, ACGIGH, 2001); 4'x4' openings	7,040	$93,895.83	$26,041.28	$11,007.46	ERG estimate of opening size required

Table V-4: (continued)

Source Materials for Costs of Compliance Estimates for General Industry and Maritime

Control	Description	CFM (for Ventilation)	Capital Cost [a]	Operating Cost	Annualized Capital Cost	Comment
Small knockout table	Portable grinding table pg. 10-136), ACGIH, 2001), 3'x3' opening	1,350	$18,005.59	$4,993.71	$2,110.80	ERG estimate of opening size required
Large knockout table	Hand grinding table (pg. 10-135), ACGIH, 2001), 4'x6' surface	4,800	$64,019.89	$17,755.42	$7,505.08	ERG estimate of bench surface area
Ventilated abrasive cutoff saw	Ventilated cut-off saw (pg. 10-134, ACGIH, 2001, 2'x3' opening	1,500	$20,006.21	$5,548.57	$2,345.34	ERG estimate of opening size required
Hand grinding bench (foundry)	Bench with LEV (pg. 10-135, ACGIH, 2001); 3'x5'	3,750	$50,016	$13,871.42	$5,863.35	ERG estimate of CFM requirements; 250 cfm/sq. ft.
Forming operator bench (pottery)	Bench with LEV (pg. 10-149, ACGIH, 2001), 3'x4'	1,400	$18,672	$5,178.66	$2,188.98	ERG estimate of CFM requirements; 125 cfm per linear foot
Hand grinding bench (pottery)	Bench with LEV (pg. 10-135, ACGIH, 2001); 3'x4'	2,400	$32,010	$8,877.71	$3,752.54	ERG estimate of CFM requirements; 200 cfm/sq. ft.
Hand tool hardware	Retrofit suction attachment	200	$464	$739.81	$54.42	ERG estimate of CFM requirements [a]
Clean air island	Clean air supplied directly to worker	2,500	$33,343.69	$9,247.61	$3,908.90	ERG estimate of CFM requirements; 125 cfm/sq. ft. for 20 square feet
Water fed chipping equipment drum cleaning	Shop-built water feed equipment	N/A	$242.50	$0.00	$242.50	ERG estimate. $200 in annual costs [a]
Ventilation for drum cleaning	Ventilation blower and ducting	N/A	$823.98	$205.99	$179.92	Electric blower (1,277 cfm) and 25 ft. of duct. Northern Safety Co. (p. 193) [a]
Control room	10'x10' ventilated control room with HEPA filter	200	$20,327.53	$739.81	$2,383.01	ERG estimate based on Means, 2003, ACGIH, 2001
Control room improvement	Repair and improve control room enclosure	N/A	$2,240	NA	$262.60	ERG estimate. Assumes repairs are 20% of new control room cost.
Improved bag valves	Bags with extended polyethylene valve, incremental cost per bag	N/A	$0.01	NA	NA	Cecala et al., 1986 [a]
Respirator	Half-mask respirator	N/A	NA	NA	$520.32	ERG, 2003 [Economic Analysis of APF rule], Updated to 2012
Improved maintenance on process equipment enclosures (concrete II)	Maintenance time & materials	N/A	$303.12	$250.59	$553.71	Annual: $250 materials plus 8 hours maintenance time [a]
Improved maintenance on process equipment enclosures (Mineral Proc)	Maintenance time & materials	N/A	$303.12	$257.08	$560.21	Annual: $250 materials plus 8 hours maintenance time [a]
Initial cleaning	Thorough initial cleaning, per square foot	N/A	$0.00	$0.15	$0.15	ERG estimate
Self-contained dust collection system			$800.00	$80.00	$93.78	Self-contained dust collection system. Darby Dental Lab Supply, 2005 (www.darbylab.com)

Summary of Control Costs

Table V-5 summarizes the estimated number of at-risk workers and the annualized silica control costs for each application group. Control costs in general industry and maritime for firms to achieve the PEL of 50 μg/m^3 level are expected to total $238.1 million annually. As shown, application group-level costs exceed $15.0 million annually for concrete products, hydraulic fracturing, iron foundries, railroads, and structural clay.

Table V-6 shows aggregate annual control costs in general industry and maritime by NAICS industry. These costs reflect the disaggregation of application group costs among the industries that comprise each group. (See Table III-1 in Chapter III of this FEA on the profile of affected industries.)

Table V-5: Annualized Control Costs in General Industry and Maritime Associated with the Final Silica Standard, PEL=50 μg/m³, by Application Group

Application Group	Total	Employees Exposed Above PEL=50 μg/m³		Control Costs [a]
		Number	Percent	
Asphalt Paving Products	14,353	48	0.3%	**$199,831**
Asphalt Roofing Materials	9,074	1,410	15.5%	**$1,789,474**

Respiratory Protection Costs

This section presents OSHA's estimate of the costs for general industry and maritime employers to comply with the respiratory protection requirements of the final rule. Contained below is an overview of the estimated costs associated with respirator use presented in the PEA, comments received on the preliminary estimates and OSHA's response to those comments, the changes made in this FEA, and finally the estimated costs associated with respirator use as required by the final rule.

PEA Estimate of Respiratory Protection Costs

In the PEA, OSHA's cost estimates assumed that implementation of the recommended controls prevented workers in general industry and maritime from being exposed over the proposed PEL in most cases. OSHA expected, based on the preliminary technological feasibility analysis, that engineering controls would be adequate to keep exposures at or below the alternative PEL of 100 $\mu g/m^3$ (examined for analytical purposes) and the proposed PEL of 50 $\mu g/m^3$ for most operations most of the time, but that these controls might not be adequate in all cases to ensure that worker exposures in all affected job categories are at or below 50 $\mu g/m^3$. OSHA's preliminary analysis determined that, with the exception of workers authorized to enter regulated areas, reusable respirators would be more cost-effective than disposable respirators. For workers in maritime, the preliminary exposure determination identified abrasive blasting as the only activity with silica exposures above 50 $\mu g/m^3$, and OSHA preliminarily determined that maritime workers engaged in abrasive blasting are already required to use respirators under existing OSHA standards. Therefore, OSHA estimated no additional costs for maritime workers to use respirators as a result of the proposed silica rule.

In the PEA, respirator cost information from a 2003 OSHA respirator study was used to estimate the annual, per-worker cost of $570.13 (in 2009 dollars) for a non-disposable half-mask, non-powered, air-purifying respirator (ERG, 2003). This unit cost includes expenses for accessories, training, fit testing, and cleaning. In the PEA, OSHA estimated that 10 percent of the workers in general industry and maritime with current silica exposures above 50 $\mu g/m^3$ would require respirators, at least occasionally, after the implementation of engineering controls, to achieve the proposed PEL. This translated into 11,992 workers needing respirators. Applying the annual unit cost of $570.13 to the workers required to wear a respirator under the proposed rule resulted in total costs for respirator use (not including programmatic costs) of $6.8 million annually.[16]

[16] Note that these respirator costs did not include the costs of disposable respirators used in regulated areas. Costs for these disposable respirators were estimated as part of regulated area costs.

The PEA also estimated the burden to employers to establish a respiratory protection program. OSHA projected that this expense would involve an initial 8 hours for establishments with 500 or more employees and 4 hours for all other establishments. After the first year, OSHA estimated that 20 percent of employers would revise the program in any given year, with the largest establishments (500 or more employees) expending 4 hours for program revision, and all other employers expending 2 hours for program revision. OSHA preliminarily estimated that, of the establishments that would require respirator use to achieve compliance, half of the establishments in general industry and all of the establishments in maritime already have a respiratory protection program. OSHA estimated that the combined costs of the respiratory protection program and the costs for respirator provision and use totaled $6.9 million annually in general industry and maritime.

Comments and Responses on PEA Estimate of Respiratory Protection Costs

OSHA received limited comment on the issue of respirator use and associated costs. A few commenters provided estimates of the costs for respiratory protection under the proposed rule. The Precast/Prestressed Concrete Institute (PCI)—in providing estimates of the costs for the types of controls and ancillary measures necessary to comply with the proposed standard, including respirators—noted, "[a] powered air-purifying respirator (PAPR) is expensive […]" (Document ID 2276, p. 10). A PAPR is not required by the standard, and OSHA expects that silica exposures can be controlled using disposable N95 respirators or reusable half-face elastomeric respirators, both of which have an assigned protection factor (APF) of 10.

The Society for Protective Coatings estimated annual costs for respirators ranging from $100 to $150 per worker (Document ID 2120, p. 2). However, this range did not include a detailed breakdown of how that cost was estimated, so OSHA cannot compare this range to OSHA's own estimates for per-worker annual respirator costs presented later in this section. In addition, in their post-hearing comments, PCI estimated that "[f]it testing and associated medical clearance for one worker costs between $75 and $400" (Document ID 4029, Attachment 1, p. 3). While OSHA included the cost of medical clearance to wear a respirator as part of the medical surveillance required by this standard, OSHA's estimated cost of fit testing alone appears to be in line with the estimate that PCI presented.

OSHA also received comment regarding the productivity impact of wearing respirators. For example, Peter Soyka, representing James Hardie Building Products, developed a model that included a productivity impact for "wearing respirators to account for fatigue and adverse impacts on employee-to-employee communication" (Document ID 2322, Appendix G, p. 32). OSHA does not believe it is appropriate to assign a productivity impact for respirator wear for the final silica rule. This is consistent with decades of OSHA rulemaking. To establish a relevant productivity effect for respirators, it needs to be compared against its prospective baseline, which in this case would involve inhaling substantial amounts of silica. As outlined also in the discussion of the productivity effects of engineering controls, there was ample comment to suggest the productivity loss from inhaling silica over an extended period of time, both physiologically and psychologically, is at least as problematic as wearing a respirator.

For example, Deven Johnson, testified about the human effect of controlling silica:

> Another thing is, an individual who is working in an environment where […] he or she is constantly bombarded with concrete dust all day long, your productivity drops as you get more and more miserable as the day goes on. Commonsense would dictate, if you're not blasting me in the face with dust and sand and silica for eight hours a day, that I'm going to feel physically better and I'm not going to be as tired and exhausted and pissed off as I normally would be at the end of the day. Your productivity goes up […]. (Document ID 3581, Tr. 1594-1595)

Further, Mr. Javier Garcia Hernandez, from National Council for Occupational Safety and Health/Equality State Policy Center/Laborsafe, testified on the cognitive factors that affect productivity and why engineering controls should aid productivity:

> …as a construction worker, I highly believe that we're more productive when we are protected […]. We spend less energy focusing on how to protect ourselves. Just imagine you're working in a roomful of dust and you're just trying to either close your eyes or cover your mouth so the less you breathe. So you're constantly thinking about how to breathe less dust but if you have the respirator or the wet, the controlled area, whether it is water or respiratory protection, you're much more productive because our mind is less occupied in how to protect ourselves and we spend that time that we would have spent protecting ourselves working (Document ID 3586, Tr. 3248-49).

Todd Ward, a bricklayer, testified that workers have some awareness of the hazards of dry cutting blocks and that:

> . . . when [workers] on the job [are] dry cutting they know – it affects morale as well when they know […] they have some safeguards and they're protecting their lungs. So there is an increased productivity when you have a good morale then on the job (Document ID 3585, Tr. 3057).

Based on these comments and reasoning, OSHA is not including a productivity cost for wearing respirators. This same reasoning applies for general industry and maritime as well as construction. Thus, OSHA has chosen not to repeat this discussion in the construction respirator cost section.

Some commenters disagreed with the number of workers that OSHA estimated would need respirators as a result of this rule. Alexandra Persichetti, representing Morgan Advanced Materials, North America, commented that this rule would greatly expand respirator use due to "the creation of a regulated area or implementation of an access control plan" (Document ID 2337, p. 2). In addition, the American Foundry Society disagreed with OSHA's estimate of the number of workers in respiratory protection programs as a result of the regulated area provision (Document ID 4035, Attachment 1, p. 9). OSHA discusses the relationship between respirator use and regulated areas in the regulated area cost section presented later in this chapter. The respiratory protection costs incurred only for entry into a regulated area (for a person not otherwise required to wear a respirator to comply with the PEL requirements of the final rule) are not included in the respiratory protection costs presented in this section; those respiratory protection costs are estimated as part of regulated area costs.

URS disagreed with OSHA's derivation of the number of workers who would require respirators:

> URS estimates that the percentage of silica-exposed workers likely to be exposed above the proposed 50 μg/m³ PEL following the installation of controls will be one-half the percentage of silica-exposed workers that OSHA estimates are now exposed above the current 100 μg/m³ PEL (Document ID 2308, Attachment 8, p. 22).

Two key analytical assumptions account for the difference between OSHA's estimate of the number of workers who will need respirators and the estimate presented by URS. First, OSHA does not consider the overexposures under the preceding PEL to be indicative of the exposures that employers will be able to achieve under the new PEL. OSHA's technological feasibility analysis determined that engineering controls are sufficient to achieve the new PEL for most operations most of the time. The residual 10 percent (or more, depending on the technological feasibility analysis for each particular industry) that OSHA estimated to need respirators in the PEA represented situations that are outside the norm.[17] Second, OSHA assumes that all employers are attempting to comply with the rule for the purpose of estimating costs, so OSHA's cost analysis does

[17] For this FEA, OSHA increased its estimate of the number of respirators needed in general industry and maritime in part by modifying its approach for estimating the number of needed respirators, as discussed later in this section.

not take potential non-compliance into account. OSHA's estimates recognize, however, that despite employers' best efforts, exposures may remain high in some workplaces if engineering controls are improperly used or maintained (and the residual 10 percent respirator use would account for these employees).

Mark de Bernardo, representing Halliburton, argued that OSHA did not "take account of ubiquitous respirator use" and therefore "inflated the number of workers at exposure levels above the proposed PEL and artificially inflated the number of avoided fatalities" (Document ID 2302, p. 10). OSHA discusses the estimates of workers exposed above the PEL in Chapter III of this FEA, but notes that, while overestimating baseline overexposures would, indeed, result in an overestimate of benefits, it would also mean that OSHA had overestimated the cost of respirator use necessary to comply with the new PEL.

Estimates of Respiratory Protection Costs for the Final Rule

The methodology OSHA used to estimate the costs to employers of respiratory protection in this FEA is largely similar to the methodology it employed in the PEA. OSHA has updated to 2012 the profile numbers that serve as input to the model (i.e., the number of employees, the number of establishments, and wage rates) and has updated all costs to reflect 2012 dollars. However, whereas the PEA estimated that, with the exception of workers who are entering regulated areas,[18] all workers in general industry who need respirators with an APF of 10 would use non-disposable, half-face respirators, the FEA estimates that half of the workers who need respirators will use half-face elastomeric respirators and half will use disposable N95 respirators. This is because, as clarified in the final rule,[19] both disposable and non-disposable respirators are available with an APF of 10, and, with each type of respirator offering certain advantages, OSHA accordingly estimates that about half of the employees in general industry and maritime will prefer the ease of use of disposable respirators while the other half will prefer the durability of non-disposable respirators. Similar to the PEA, this FEA identified abrasive blasting as the only maritime activity with silica exposures above the PEL of 50 $\mu g/m^3$. In the PEA, OSHA concluded that all maritime workers engaged in abrasive blasting were already required to use respirators under existing OSHA standards and, therefore, maritime

[18] In both the PEA and the FEA, OSHA estimated that any person entering a regulated area would use a disposable N95 respirator. For further discussion, see the regulated area cost section later in this chapter.

[19] The clarification is clearest in Table 1 for the construction rule, where in the proposal the stated requirement was for a "half-mask (10)" and "(10)" referred to the APF while in the final rule the stated requirement is simply for an "APF 10." As a result, in the PEA in support of the proposal, the OSHA economists erroneously assumed that disposable N95 respirators would not satisfy the "half-mask (10)" requirement and only estimated costs for non-disposable half-mask respirators.

establishments would incur no additional costs for maritime workers to use respirators as a result of this final rule. However, for this FEA, OSHA has determined from its earlier technological feasibility analysis that only abrasive blasting operators, but not abrasive blasting helpers, are already required to use respirators under existing OSHA standards. The Agency, therefore, has added respirator costs for abrasive blaster helpers in maritime (half of all the abrasive blaster workers) as a result of this final rule.

Paragraph (g) of this rule requires that, where respiratory protection is required, employers provide each employee with an appropriate respirator that complies with the requirements of paragraph (g) and also with 29 CFR 1910.134. This final rule requires respiratory protection during the installation or implementation of engineering and work practice controls when employees are exposed above the PEL; during tasks, such as certain maintenance and repair tasks, for which engineering and work practice controls are not feasible and employees are exposed above the PEL; in situations where all feasible engineering and work practice controls have been installed and such controls are not sufficient to reduce exposures to or below the PEL; and during periods when the employee is in a regulated area. The rule also requires, where respirator use is required, that the employer institute a respiratory protection program in accordance with 29 CFR 1910.134.

According to OSHA's Respiratory Protection standard, employers whose workers are required to wear respirators during the course of their job duties must establish a written respiratory protection program. A respiratory protection program must contain the following elements:

- Procedures for selecting respirators;
- Medical evaluations of employees required to use respirators;
- Fit testing procedures;
- Procedures for proper use of respirators in routine and reasonably foreseeable emergency situations;
- Procedures and schedules for cleaning, disinfecting, storing, inspecting, repairing, discarding, and otherwise maintaining respirators;
- Procedures to ensure adequate air quality, quantity, and flow of breathing air for atmosphere-supplying respirators;
- Training of employees in respiratory hazards and proper use of respirators; and
- Procedures for regularly evaluating the effectiveness of the program.

For this FEA, OSHA estimated the costs for developing a respiratory protection program, annual fit testing, the costs for equipment (which includes the cost for respirators, any necessary accessories, and cleaning (when non-disposable respirators are used)), and annual training. Costs for medical clearance are included as part of medical surveillance costs, and recordkeeping costs are included in the respirator program costs.

OSHA estimated that a human resources manager, or equivalent, with an hourly wage rate of $74.97, will be responsible for developing the respiratory protection program (BLS, 2012b). As in the PEA, the Agency estimated that it will take 4 hours for small employers (those with fewer than 20 employees) and medium employers (those with between 20 and 499 employees) and 8 hours for large employers (those with 500 or more employees) to develop the respiratory protection program and provide the appropriate recordkeeping. In addition, as in the PEA, OSHA estimated that it will take half as much time (2 hours for small and medium employers and 4 hours for large employers) to review and update the respiratory protection plan (including appropriate recordkeeping), and that 20 percent of establishments will do so in any given year. The unit costs for respiratory protection program development and updating in general industry and maritime is displayed in Table V-7 below. The table also shows the estimated baseline compliance rates in general industry and maritime, with separate, higher rates for hydraulic fracturing. These are the same baseline compliance rates that were used to estimate respiratory protection program costs in the PEA.

Table V-7: Respiratory Protection Program Unit Costs in General Industry and Maritime

	Establishment Size		
	Small (<20)	**Medium (20-499)**	**Large (500+)**
Respirator users per establishment with respirators	2	4	6
Program development			
Hours	4	4	8
Labor value	$300	$300	$600
Program Updates			
Hours	2	2	4
Labor value	$150	$150	$300
Establishments updating program			
Per year	20.0%	20.0%	20.0%
Compliance rate (GI & Maritime)	50.0%	50.0%	50.0%
Compliance rate (Hydraulic Fracturing)	70.0%	80.0%	95.0%

The Respiratory Protection Standard requires that, before a worker is required to use a respirator with a negative or positive pressure tight-fitting facepiece, the employee must be fit tested with the same make, model, style, and size of respirator that will be used (29

CFR 1910.134(f)). OSHA estimates that qualitative fit testing will be performed by a supervisor on groups of four employees simultaneously. This fit testing is estimated to take a total of one hour for each employee and fifteen minutes of a supervisor's time per-employee (one hour divided by the four employees in the group). The total cost per-employee for fit testing in general industry or maritime is shown below in Table V-8.

Table V-8: Cost of Qualitative Fit Testing in General Industry and Maritime	
Testing group size	4
Employee hours	1
Supervisor hours	0.25
Loaded employee hourly wage	$24.75
Loaded supervisor hourly wage	$40.38
Cost per employee	$34.85

As previously discussed, OSHA reevaluated the assumption used in the PEA that all workers in general industry and maritime needing respirators would use reusable half-face elastomeric respirators. The Agency determined that N95 disposable filtering facepiece respirators would be adequate to protect workers from respirable silica hazards and that these respirators could be used to comply with the requirements of the final rule when an APF of 10 is specified. For this FEA, OSHA has judged that half of workers in general industry and maritime who need respirators with an APF of 10 would use a disposable N95 respirator and that half would use an elastomeric reusable half-face respirator.

The unit equipment costs for each type of respirator are presented in Table V-9 below. OSHA estimates that, in general industry or maritime, an employee who needs respiratory protection will need such protection every workday. The employer could choose to supply disposable N95 respirators, which the employee would replace every day but which would need no cleaning or additional accessories, or reusable elastomeric half-mask respirators, which can be used for two years but which will require weekly cleaning and additional accessories[20] that will need to be replaced regularly.

[20] OSHA's respirator costs are based on estimates of the annual costs of respirator use derived in an earlier study (ERG, 2003). These costs include not only the purchase cost of the respirator itself, but the ancillary costs of accessories (e.g., filters) and other costs associated with respirator cleaning and required training and fit testing. The 2003 estimates were based on a unit cost of $3.57 for a replacement pair of filters for half-mask negative-pressure air-purifying respirators. These were extrapolated to an annual cost

Table V-9: Respirator Unit and Annualized Costs in General Industry and Maritime

Equipment	Disposable Filtering Face-Piece	Elastomeric Half-Mask Respirator	Elastomeric Full-Face Respirator
Equipment Cost (each)	$1.05	$32.74	$269.78
Equipment Service Life (years)	1	2	2
Annualized Equipment Cost	$1.05	$17.11	$140.99
Accessory Cost	0	$295.52	$295.52
Accessory Service Life (years)	1	1	1
Annualized Accessory Cost	$0.00	$295.52	$295.52
Total Annualized Equipment	$1.05	$312.63	$436.51
No. per year	250	1	1
Total Annualized Cost	**$262.92**	**$312.63**	**$436.51**

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA (2016).

Workers who are provided with reusable respirators will need to clean those respirators. OSHA estimates that this will happen weekly and take five minutes (0.08 hours) of the worker's time. On a yearly basis this will cost $103.14 for a worker in general industry or maritime who uses a non-disposable respirator. These costs are shown below in Table V-10.

---

of $285.52 per year, assuming that the filters would be changed 80 times a year.

In the PEA cost analysis, respirator costs from the 2003 study were used, but inflated from 2003 to 2009 dollars using the implicit price deflator for this period. For this FEA, those costs have again been adjusted for inflation to 2012 dollars resulting in an annual cost for filters of $295.52. Research conducted for the PEA showed that filter prices have not, in fact, increased since 2003, and might well have declined, at least for the N95 particulate filters used for silica protection. Thus, it is possible that OSHA has overestimated the cost for accessories for reusable respirators in this FEA.

Table V-10: Respirator Cleaning Costs in General Industry and Maritime（non-disposable

Cleaning Frequency per year	50
Time (hours)	0.08
Loaded employee wage	$24.75
Yearly cost	$103.14

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA (2016) and BLS (2012b).

The final cost component of a respiratory protection program is training workers in respiratory hazards and in the proper use of respiratory protection. OSHA estimates that this training will take two hours and that it will be provided by a supervisor to a group of four employees at a time. The total per-employee cost for training on respiratory hazards and respirator use will be equal to two hours of the worker's wage plus one half hour of the supervisor's wage (two hours of supervisor time total divided among four workers). The unit costs for this training are shown below in Table V-11.

Table V-11: Respirator Training Costs in General Industry and Maritime

Class size	4
Training hours	2
Loaded employee wage	$24.75
Loaded supervisor wage	$40.38
Cost per employee	**$69.70**

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA (2016) and BLS (2012b).

The total annualized costs for respirators in general industry are shown below in Table V-12.

Table V-12: Total Annualized Costs for Respirators (Excluding Programmatic Costs)
in General Industry and Maritime

	Disposable Filtering Facepiece	Elastomeric Half-Mask Respirator	Elastomeric Full-Face Respirator
Equipment	$262.92	$312.63	$436.51
Fit testing, training, & cleaning [a]	$104.55	$207.69	$207.69
Total	**$367.46**	**$520.32**	**$644.20**

[a] Cleaning applies to reusable elastomeric respirators only

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA (2016) and BLS (2012b).

For this FEA, OSHA estimates that respirators will be required: (1) for all workers that the Agency's technological feasibility analysis has determined will require respirator use; and (2) for ten percent of the remaining workers currently exposed above 50 μg/m^3 at covered workplaces.[21]

This is a change in methodology from the PEA, where OSHA estimated the percentage of workers requiring respirators in an industry as either (1) or (2), whichever was larger. The Agency believes that the FEA formula, which results in higher estimates of respirator usage, is more accurate in that it reflects the combined effects of (1) and (2) whereas the earlier methodology did not. The number of workers that this FEA estimates will need respirators is presented below in Table V-13.[22]

Table V-13 below also aggregates unit costs and the number of workers estimated to be wearing respirators and calculates the costs for providing equipment, the programmatic costs associated with respirator use, and the total costs to each industry for the respiratory protection requirements. The total cost for respiratory protection increased from about $6.9 million in the PEA to about $10.5 million in the FEA. While the number of workers estimated to be exposed over the PEL of 50 μg/m^3 decreased from the PEA to the FEA,

[21] This additional 10 percent is designed to cover circumstances in which engineering controls do not reduce exposure levels to the extent anticipated by the technological feasibility analysis (e.g., because controls are not selected, used, or maintained properly).

[22] Table V-13 denotes, in the "Required by Tech. Feas." column, the number of workers requiring respirators as indicated by the technological feasibility analysis and, in the "Others" column, the remaining workers OSHA estimates will need respirators (10 percent of remaining workers with exposures currently above the PEL of 50 μg/m^3). For example, if an industry has 100 at-risk workers, and the technological feasibility analysis indicates that 20 workers will require respirators, OSHA would estimate that 10 percent of the remaining 80 workers (or 8) would also require respirators, for a total of 28. The row for that industry would display 20 in the "Required by Tech. Feas." column and 8 in the "Others" column.

the number of workers estimated to be wearing respirators increased from about 12,000 to about 31,000 workers. This is due to the changes in the way OSHA estimated the extent of respirator use, as previously described. In fact, much of the increase in respirator use from the PEA to the FEA can be explained by an increase in OSHA's estimate of the number of employees using respirators in NAICS 327320 Ready-mix Concrete Manufacturing (as a result of longer-duration exposures estimated in the technological feasibility analysis).

Table V-13: Annualized Respirator and Program Costs for Employers in General Industry and Maritime Affected by OSHA's Silica Standard

NAICS	Industry	No. of Respirator Users: Currently Exposed Above 50 μg/m³	Required by Tech. Feas.	Others	Total	Annualized Respirator Costs [a]	Annualized Program Costs	Total Cost

Exposure Assessment Costs

Overview of regulatory requirement

Section 1910.1053 of the final standard applies to employers engaged in general industry or maritime activities, and paragraph (d) requires those employers to assess the exposure of each employee who "is or may reasonably be expected to be exposed to respirable crystalline silica at or above the action level." Employers may either follow a performance option (as specified in paragraph (d)(2)) or a scheduled monitoring option (as specified in paragraph (d)(3)). For the performance option, the employer must assess the 8-hour TWA exposure for each employee on the basis of any combination of air monitoring data or objective data sufficient to accurately characterize employee exposures to respirable crystalline silica. For the scheduled monitoring option (termed the "periodic" monitoring option in the proposal), the employer must perform initial monitoring to assess the 8-hour TWA exposure for each employee on the basis of one or more personal breathing zone (PBZ) air samples that reflect the exposures of employees on each shift, for each job classification, in each work area. Where several employees perform the same job tasks on the same shift and in the same work area, the employer may sample a representative fraction of these employees in order to meet this requirement. In representative sampling, the employer must sample the employee(s) who are expected to have the highest exposure to respirable crystalline silica.

Under the scheduled monitoring option, requirements for periodic monitoring depend on the results of initial monitoring. If the initial monitoring indicates that employee exposures are below the action level, no further monitoring is required. If the most recent exposure monitoring reveals employee exposures to be at or above the action level but at or below the PEL, the employer must repeat monitoring within six months of the most recent monitoring. If the most recent exposure monitoring reveals employee exposures to be above the PEL, the employer must repeat monitoring within three months of the most recent monitoring.

Under paragraph (d)(4), employers must reassess exposures whenever a change in the production, process, control equipment, personnel, or work practices may reasonably be expected to result in new or additional exposures at or above the action level, or when the employer has any reason to believe that new or additional exposures at or above the action level have occurred. Also, paragraph (d)(5) requires employers to ensure that samples taken are evaluated in accordance with the procedures in Appendix A of the final standard.

In addition, paragraph (d)(6) requires the employer to individually notify each affected employee in writing of the results of an exposure assessment conducted in accordance with paragraph (d) of this section or post the results in an appropriate location accessible to all affected employees. Paragraph (d)(7) provides for the right of an employee-designated representative to observe any exposure monitoring.

PEA cost estimates

In the PEA, OSHA estimated that establishments performing exposure monitoring would require the assistance of an outside consulting industrial hygienist (IH) to obtain accurate results because the testing protocols were judged to be too challenging for firms to adequately perform using their own staff. OSHA also estimated in the PEA that, on average, there are four workers per work area.

In the PEA, OSHA conservatively estimated exposure monitoring costs by assuming all employers would follow the scheduled monitoring option, rather than the performance option, to comply with proposed paragraph (d). While this likely resulted in an overestimation of costs because the scheduled monitoring option has more stringent requirements than the performance option, OSHA chose to be conservative because of insufficient data about how many employers would choose the performance option. OSHA's initial cost estimates in the PEA were based on the employer selecting the regularly scheduled exposure monitoring option and conducting the initial exposure assessment by testing one worker in each distinct job classification within each work area, who is, or may reasonably be expected to be, exposed to airborne concentrations of respirable crystalline silica at or above the action level.

In addition to the initial exposure monitoring, OSHA estimated, for costing purposes, that exposure monitoring would be conducted (a) twice a year where initial or subsequent exposure monitoring reveals that employee exposures are at or above the action level but at or below the PEL, and (b) four times a year where initial or subsequent exposure monitoring reveals that employee exposures are above the PEL. For the PEA, OSHA judged that approximately 15 percent of workers whose initial exposure or subsequent monitoring was at or above the action level would require resampling due to a change in production, process, control equipment, personnel, or work practices that may reasonably be expected to result in new or additional exposures at or above the action level.

Further, OSHA estimated in the PEA that an IH would spend one day, at a cost of $500, to obtain the following number of PBZ samples: 2 for establishments with fewer than 20 employees; 6 for establishments with 20-499 employees; and 8 for establishments with 500 or more employees. In addition, OSHA estimated that analysis of each sample would cost $133.38 in lab fees and shipping costs. When combined with the IH fee, the cost per PBZ sample was projected to range from $195.88 to $383.38 (depending on establishment size).

In the PEA, the Agency indicated that it was not aware of any published studies presenting data on the frequency with which employee-designated representatives observe exposure monitoring but stated its belief that in some cases union officials are given the opportunity to observe monitoring at no direct cost to the employer. For these reasons, in the PEA, OSHA included no additional cost for this provision.

Other costs taken in the PEA were unit costs stemming from lost productivity during exposure sampling. OSHA estimated a 30-minute loss in employee time while attaching the pump and a 15-minute loss for the time required for recordkeeping, which includes recording the sampling results and notifying the employee of the sampling results. The loss in employee time was multiplied by an average employee hourly wage rate, including fringe benefits, to estimate the associated cost. The recordkeeping time was multiplied by a manager's hourly wage rate, including fringe benefits, to estimate the associated costs. Overall, in the PEA, OSHA estimated that unit costs would range from approximately $224.94 to $412.44 per sample. The Agency also conservatively estimated that no establishments in general industry or maritime were currently conducting exposure monitoring and assumed no current compliance with the proposed exposure monitoring requirements, as OSHA had no data about the number of establishments in general industry or maritime currently conducting exposure monitoring for respirable crystalline silica.

Comments and responses on exposure monitoring

General Methodology

OSHA received a number of comments on the costs of exposure monitoring, with some commenters stating that OSHA had underestimated costs in the PEA and others stating that OSHA had overestimated costs.

Commenters disagreed with OSHA's estimate of 15 percent of workers requiring reassessment. In particular, in his testimony, Jack Waggener, speaking for URS, testified that:

> For the periodic monitoring, OSHA, who we believe is unrealistically low, assumed that 15 percent of the workers would be over the action level and that no worker would be over the PEL. We expect many

> people to be over the PEL and many more people to be over the action level (Document ID 3582, Tr. 2019).

OSHA believes that Mr. Waggener simply misunderstood the Agency's methodology here. OSHA estimated that there would be an additional 15 percent of those at or over the action level performing additional testing due to a change in production, process, control equipment, personnel, or work practices that may reasonably be expected to result in new or additional exposures at or above the action level. OSHA was not suggesting that only 15 percent of worker exposures would be over the action level and none over the PEL.

Additionally, the American Foundry Society (AFS) asserted that the percentage of exposure sampling should be increased by 25 percent for reassessment based on experience (Document ID 2379, Attachment 3, p. 35). OSHA does not have strong evidence to dispute the AFS estimate, so the Agency has adopted AFS's 25 percent estimate for this FEA.

Under paragraph (d)(7) of the final rule, the employer must provide any required PPE at no cost to the observer. One commenter, the Korte Company, asserted that OSHA had omitted the cost of PPE for an employee's designated representative during observation of monitoring "without regards to whether or not the representative is trained or qualified to be wearing the required PPE" (Document ID 3230, p.1). While the Korte Company is in construction, the Agency believes this issue could also arise in general industry and maritime and therefore will address it here as well as in the construction section of this chapter. In response, OSHA would like to make several points. The final rule contains requirements for regulated areas in general industry and maritime, and these requirements include the provision of an appropriate respirator to authorized persons—including persons present to observe monitoring—in a regulated area.

Therefore, OSHA has already included respirator costs for observation of monitoring as part of regulated area costs. In most cases, observation of monitoring is expected to occur during the set-up and at the end of the exposure monitoring—outside of the regulated area, where a respirator is not required. Furthermore, in most cases, designated representatives have experience in observing monitoring—often in the presence of chemicals for which respirators would be required; therefore, the designated representatives would be expected to be trained and qualified to wear a respirator. For these reasons, OSHA has not included additional exposure monitoring costs for PPE during observation of monitoring.

Alternatives to hiring an industrial hygienist

In the PEA, OSHA estimated that employers would incur the cost of hiring an industrial hygienist to perform all necessary sampling. However, some commenters noted that there were less costly alternatives to hiring an outside IH consultant to conduct exposure monitoring.

A number of commenters suggested that the silica sampling could instead be conducted by in-house personnel. Kellie Vazquez, from Holes, Incorporated (a construction contractor), testified that the company she represented has done exposure monitoring using in-house personnel for some tasks its workers perform (Document ID 3580, Tr. 1411), while Andrew O'Brien from the National Industrial Sand Association (NISA) reported that "many NISA member companies [have] found that it is more cost-effective for them to train particular staff, and acquire the relevant equipment, than it is to hire consultants" (Document ID 3414, p. 10-11). Dr. Franklin Mirer, from the AFL-CIO, reported that General Motors has "a union rep who does all the air sampling," that at Johnson Controls hourly workers are performing exposure monitoring, and that, in his opinion, "the regular kind of facility management safety rep can do [exposure monitoring] as well" (Document ID 3578, Tr. 985-986). Dr. Mirer noted that while OSHA's exposure monitoring costs are "correctly derived from estimates of traditional consultant IH measurements, paying professional wages," employers could reduce costs by having "trained production or maintenance personnel, employed at the production facility, collect the samples" (Document ID 2256, Attachment 3, p. 12).

NISA urged OSHA to model costs for firms that choose to perform exposure monitoring using in-house personnel (Document ID 2195, p. 24), noting that the cost of doing so was not significant:

> …even the two largest companies [that NISA surveyed on this issue], one of which is publicly-held, regard these costs as sufficiently minor that the companies, which rigorously track all elements of their operating costs, do not bother to track the employee costs associated with dust exposure monitoring (Document ID 2195, p. 23).

Mr. O'Brien stated that "some percentage of OSHA-regulated establishments can and will internalize the function [of air monitoring]" and that the ability of firms to perform monitoring in-house is not an issue of business or establishment size. Mr. O'Brien directed OSHA to a document on the NISA website that could assist firms in performing air monitoring in-house[23] (Document ID 3414, pp. 10-11). Mr. O'Brien also testified that NISA has a three-day program to train workers to become qualified to do exposure sampling (not restricted to silica sampling) (Document ID 3577, Tr. 609).

Some commenters also suggested that when conducting the sampling in-house, employers could further reduce costs by utilizing less-expensive dust monitoring, as opposed to exposure monitoring specifically for respirable crystalline silica. Under this approach, if the content of dust in the air was less than the action level, an employer could then conclude that the respirable crystalline silica content would also be below the action level. Dr. Mirer suggested that "real-time aerosol monitor[ing] combined with area samples for silica would enable source identification, real-time results, knowing the overexposure within minutes of when it happened rather than waiting for the lab results to come back" and that "rather than do full shift sampling at each station," employers can "take area samples for silica, and then … use a dust monitor at each position to look at what the mass [of dust] is, apply the silica content, and you've got [the content of respirable crystalline silica]" (Document ID 3578, Tr. 941-942, 1004).

Robert Scholz, from TRC Consulting, testified that respirable dust monitors are commercially available and that if the silica content of the dust was known, then one could calculate exposures. Mr. Scholz also noted that these methods have been used by the foundry industry for twenty years and have become more widely used in the last ten years (Document ID 3584, Tr. 2738-9), while Scott Schneider, from the Laborers' Health and Safety Fund of North America, testified that respirable dust monitors are "becoming more useful, easier, and less expensive, and could be used" for defining a regulated area or on a job site. (Document ID 3589, Tr. 4264).

OSHA acknowledges that it might be more cost effective for firms to comply with the exposure monitoring requirement by using in-house personnel or by following the performance option and using less expensive general respirable dust monitoring, and that the Agency's assumption that all affected firms will comply by following the scheduled monitoring option and hiring consulting industrial hygienists will likely result in an overestimation of the cost of compliance.[24] However, OSHA does not have sufficient data in the rulemaking record regarding how many employers may choose to perform

---

[23] The document referenced is "Occupational Health Program for Exposure to Crystalline Silica in the Industrial Sand Industry", submitted as Document ID 2195, Appendix B. The document was accessed by OSHA staff on April 21, 2015 and does contain instructions for collection of exposure samples.

[24] Employers may comply with the exposure monitoring requirements of the standard by utilizing dust monitoring instead of silica monitoring only if they are following the performance option under section (d)(2) and treating the result as objective data. If employers are following the scheduled monitoring option, as this cost section assumes, then under section (d)(5), they must follow Appendix A and utilize a method that tests for respirable crystalline silica content.

monitoring in-house, with or without the use of commercially available dust monitoring, or how much those alternatives would cost. For example, even if a significant number of employers attempted in-house monitoring, it is not clear how many of those would need to provide additional training to their employees who would conduct the sampling, or how often those conducting the less expensive dust monitoring would need to incur additional costs when the silica content of the dust was not already known. Thus, OSHA was not able to make an accurate determination regarding the share of firms that would comply using other methods, or the cost involved in doing so. Because of this, OSHA is taking the more conservative approach and assuming that employers will follow the scheduled monitoring option for exposure monitoring. It should be noted, however, that the final standard does not preclude employers from utilizing other methods in order to comply with this provision when following the performance option under paragraph (d)(2).

Cost of an industrial hygienist

Having concluded that the final estimates will be based on the use of an industrial hygienist, the Agency turns now to the cost of that service. OSHA received a large number of comments on its estimate in the PEA that an IH would spend one day, at a cost of $500, to set up and collect up to eight PBZ samples. Many of the commenters critical of OSHA's cost estimates provided alternative estimates of their own, but these estimates ranged widely, as did the assumptions underlying them. Most of the comments discussed below are from general industry, but relevant comments from construction have been included as well.

First of all, some commenters took issue with the assumption of establishments hiring outside IH consultants to conduct the exposure assessments. Andrew O'Brien, from the NISA, stated that "NISA's member companies conduct exposure assessments using in-house personnel" (Document ID 3414, p. 10). OSHA recognizes that establishments may employ an in-house IH or an in-house IH technician to conduct the monitoring. However, there will be other establishments that do not, and OSHA is attempting to estimate an average cost across all establishments while erring on the side of overestimating rather than underestimating costs. Kellie Vazquez, from Holes Incorporated, stated that OSHA's costs were too low and that she would need to hire an industrial hygienist and provide a company vehicle at a total cost over $100,000 per year (Document ID 2338, p. 4). OSHA notes that the final rule does not specify that the exposure monitoring be performed by employees of a regulated employer. An employer could choose the less expensive option between hiring an IH employee and contracting with an IH consultant.

In terms of using an IH consultant, Franklin Mirer of the AFL-CIO stated that "the monitoring costs are correctly derived from estimates of traditional consultant IH measurements, paying professional wages" (Document ID 2256, Attachment 3, p. 8). The Precast/Prestressed Concrete Institute (PCI), estimated:

> the cost of a single one-day monitoring visit by an industrial hygienist, assuming 8 hours on site, 3 hours for preparation, 5 hours for report writing, and 4 hours for travel, would be at least $1,000 plus $100-$150 for the laboratory costs[25] (Document ID 2276, p. 9).

The American Foundry Society (AFS) commented that "[t]he industrial hygienist cost is closer to $1700 per day rather than $500 as estimated by OSHA in the PEA" (Document ID 2379, Appendix 3, p. 22). The AFS included consultant fees, travel time, and pump rental in its estimate. Christopher Norch, from Denison Industries and testifying on behalf of the AFS, noted that it cost one foundry $3,000 for one day of sampling by a consultant (Document ID 3584, Tr. 2678).

The American Subcontractors Association, a national trade association representing subcontractors, specialty trade contractors, and suppliers in the construction industry, reported that "retaining an industrial hygienist to conduct such monitoring would cost between $1,500 and $2,500 per day (Document ID 2187, p. 5).

The Asphalt Roofing Manufacturers Association asserted that OSHA's estimate of the costs to comply with this provision was unreasonably low because, among other things:

- The estimate includes only the cost of a base level IH technician to collect the samples. It does not take into account oversight costs and project planning or project management by a consultant CIH [certified industrial hygienist].
- The costs for travel and other reasonable project expenses are not included.
- The costs for IH consultant reports are not included.
- The costs for developing IH employee letters for those who participated in sampling were not included (Document ID 2291, p. 19).

Dr. Ronald Bird, on behalf of the Chamber of Commerce, similarly commented that OSHA omitted:

---

[25] OSHA notes that laboratory costs have been separately estimated, so they should not be included in estimates of IH costs.

> . . . costs of preparation for sampling, including research regarding past monitoring results, if any, and qualitative inspection of the facility, processes and materials used to identify work areas susceptible to exposure, analyzing workers task similarities and other factors relevant to grouping workers for air sampling purposes . . . (Document ID 2368, p. 12).

These criticisms of OSHA's estimates were echoed by the Independent Petroleum Association of America, which estimated a cost of $2,500 per day for a visit by an IH to conduct sampling, including the IH's travel, salary, equipment, and report-preparation costs. These estimates were based on "[average] survey response by hydraulic fracturing companies for per day cost of IH visit to [hydraulic fracturing] site (remoteness premium)" (Document ID 2301, Attachment 3, tab Exposure Assessment Factors and Exposure Assessment Costs). The IPAA further noted that:

> Where a static industry may be expected to be located within reasonable proximity to infrastructure and services required to comply with the ancillary provisions, hydraulic fracturing operations typically are not. Members of the Associations have reported that hiring an industrial hygienist to conduct exposure monitoring at a hydraulic fracturing site has four to six times as much per day [$2,000 to $3,000] as OSHA has estimated [$500] would be required for a stationary industry within a reasonable distance to a metropolitan area (Document ID 2301, p. 73).[26]

URS Corporation, on behalf of ACC, commented that OSHA underestimated costs of a CIH because the Agency omitted additional time "for the CIH to draw conclusions based on the sampling and to write reports," which URS Corporation estimated would take an additional day (Document ID 2307, Attachment 8, p. 20).

OSHA has interpreted URS's cost model to yield an IH exposure monitoring cost of $3,200, consisting of two days at $1,600 a day (including $100 a day for travel). Relatedly, in post-hearing comments on behalf of the ACC, Environomics reported that it had

> increased the estimated costs for exposure assessment by increasing the unit cost estimate for an industrial hygienist to visit a site for exposure sampling, and by reducing the average number of overexposed employees that would likely be sampled during a single site sampling visit (thus projecting more sampling visits as necessary to assess exposure for all

[26] The bracketed costs were added by OSHA for clarity.

> General Industry employees suspected of being exposed above the PEL) (Document ID 4015, p. 52).

To summarize, the Agency received IH cost estimates from commenters of $500 or less (AFL-CIO and NISA), $1,000 (PCI), $1,700 (AFS, with $3,000 reported by one foundry), $2,000 (an average calculated for ASA-reported range), $2,500 (an average calculated for IPAA), and $3,200 (URS/ACC). These various cost estimates reflect important differences in assumptions concerning IH qualifications and expertise (from an IH technician to an IH to a CIH); the duration of IH exposure monitoring to obtain up to eight samples, including report writing (1 day versus more than 1 day); and possible related IH expenses (particularly travel-related costs).

In addition, during the comment period, OSHA had its contractor, ERG, conduct telephone interviews with seven industrial hygiene consultants to obtain better estimates of the costs associated with exposure monitoring.[27] In a memorandum from ERG to OSHA, dated May 28, 2014, summarizing the interview results, ERG concluded from the interviewee comments that written reports may be needed to identify potential sources of exposure, that IH labor costs would apply to the preparation of sampling reports, and that it is common practice for a single IH (or field technician) to collect up to 8 full-shift samples and prepare a report in a single day (Document ID 3767). Averaging over the seven IH consultant interviewees, ERG reported that they estimated a minimum labor cost of $1,813 and a maximum labor cost of $2,411—or an average labor cost of $2,112 per day of sampling, including report writing. In addition to these summary costs, OSHA found two statements in the ERG report to be critical:

> One of the consultants stated that sampling costs are typically highest during the "discovery phase," such as characterization of a new site or facility or compliance with a new rulemaking, and that sampling costs are generally lower for routine periodic monitoring (Document ID 3767, p. 2).

Along the same lines, ERG also reported that an IH technician is often used "to perform routine sampling at well characterized sites; however, for new or complex operations, a certified industrial hygienist (CIH) might be needed" (Document ID 3767, p. 2).

These two statements help explain the wide variation in cost estimates submitted by commenters. In effect, commenters appear to be estimating costs for exposure

[27] Interview questions included the price range for a typical sampling project and report, labor costs for sample collection and report, other costs such as sample analysis and equipment rental, and regional differences in costs, for example for firms with office locations in different parts of the country, among others.

monitoring under two entirely different sets of circumstances: (1) initial monitoring during the "discovery phase" or for sites that have not previously been well characterized (in terms of being evaluated for purposes of exposure monitoring); and (2) routine periodic monitoring at sites that have previously been well characterized. Accordingly, OSHA has concluded that the best way to categorize the estimates provided in the comments is to provide two estimates of exposure monitoring costs in this FEA: one for initial monitoring and one for periodic monitoring.

Based on the comments received in the record, and recognizing that the highest estimate may be worst case estimates and not representative of average costs, OSHA has decided to significantly increase its estimate from $500 (in the PEA) to $2,500 for an IH consultant to perform initial exposure monitoring or to perform at sites that have not previously been well characterized. OSHA derived this cost estimate by taking ERG's estimate (developed from its interviews) of approximately $2,100 for sampling and report-writing and adding to it approximately $400 to cover IH travel time and travel expenses. To estimate travel time, because this was not accounted for in the PEA, OSHA obtained supplemental information on the General Service Administration (GSA) government-consulting hourly rate schedule for CIHs and other IH professionals.[28] The GSA hourly consulting rate for CIHs in 2012 was $144.20, and GSA mileage and lodging reimbursement rates in 2012 were $0.56 per mile and $77 per night.[29] Assuming two hours of travel time at $288.40, $56 for 100 miles of travel, and one night in a hotel at $77, these travel costs amount to approximately $421. This is likely an overestimate because many CIHs will not have to travel as far as 100 miles roundtrip or stay in a hotel, so OSHA rounded down from $421 to $400 for travel costs. To corroborate the $2,100 amount for sampling and report-writing, OSHA divided $2,100 by the CIH hourly rate of $144.20, resulting in approximately 14.5 hours, which OSHA judges to be a reasonable estimate of the time a CIH would spend on these activities. Thus, this estimated IH cost would include necessary IH travel time, travel expenses, and report preparation and would cover 2, 6, and 8 PBZ samples per day for small, medium, and large establishments, respectively. This estimate is broadly within the range of estimates from commenters when the lowest ones have been excluded. Again, this cost represents an average, and the Agency expects that some establishments' costs will be higher, but others lower (including those employers that have IH staff).

[28] Values reported here are for 2012 and are loaded for IH compensation and overhead. https://www.gsaadvantage.gov/ref_text/GS10F0091T/0K3PG4.2DOSEL_GS-10F-0091T_GSAWEBDOC12262011UPDATEFINAL.PDF

[29] Values reported here are for 2012 and available at http://www.gsa.gov/portal/content/103969 and http://www.gsa.gov/portal/category/100120.

To estimate the cost of routine periodic monitoring at sites that have previously been well characterized, OSHA judged that the IH labor time required would be approximately 75 percent of the time required for initial monitoring, or approximately 11 hours, since the sampling protocol would have already been established and that the daily rate for an IH or IH technician would be approximately 2/3 of the CIH hourly rate.[30] Based on these judgments, OSHA estimates that the IH periodic exposure monitoring costs would be approximately $1,250, or half of the $2,500 estimate.[31] This cost would cover 2, 6, and 8 PBZ samples per day for small, medium, and large establishments, respectively. This estimate is broadly within the range of estimates from commenters when the highest ones have been excluded.

OSHA notes that the cost estimates per sample under both circumstances reflect the fact that there are some economies of scale in obtaining exposure samples.

For purposes of estimating exposure monitoring unit costs in general industry and maritime, OSHA has applied the $2,500 cost estimate for IH services to all exposure monitoring at hydraulic fracturing sites (where the worksite is not fixed and has not been previously characterized) and to all initial monitoring. OSHA has applied the $1,250 cost estimate for IH services to scheduled or repeated exposure monitoring at fixed sites in general industry and maritime (thus, excluding hydraulic fracturing sites). In the construction sector, the $2,500 cost estimate for IH services applies to all exposure monitoring since the worksite is not fixed and has not been previously characterized.

Laboratory fees

Based on the 2000 EMSL Laboratory Testing Catalog, which was the source used for the PEA, OSHA estimated that analysis of each sample will cost $140.27 (adjusted to 2012 dollars by OSHA (2016)) in lab fees and shipping costs. This is roughly consistent with the laboratory costs estimate of $100-$150 offered by the Precast/Prestressed Concrete Institute (Document ID 2276, p. 9). NISA also submitted cost estimates from five NISA member companies that showed a cost per sample ranging from $49 to $129 for "analytics," which is lower than OSHA's estimate (Document ID 4008, Attachment 3, p. 1). Given these fairly consistent ranges of cost, OSHA is again using the same cost in

[30] This latter judgment is buttressed by the supplemental information on GSA rates that OSHA obtained. The GSA hourly rates in 2012 for an IH and for an IH technician II are 74 percent and 48 percent, respectively, of the corresponding rate for a CIH. https://www.gsaadvantage.gov/ref_text/GS10F0091T/0K3PG4.2DOSEL_GS-10F-0091T_GSAWEBDOC12262011UPDATEFINAL.PDF

[31] This is based on 75 percent of the time, or 3/4, times 2/3 of the hourly rate. (3/4)*(2/3) = 1/2.

constant dollars that it did in the PEA because the EMSL catalog represents a published cost from a widely used laboratory.[32]

OSHA also again notes the comments promoting the use of commercially available dust-monitoring equipment discussed above. While the use of this equipment in practice would likely reduce the number of samples that would be sent to laboratories, meaning that OSHA's estimate of the laboratory fee costs is an overestimate, any cost reductions would result from a combination of factors such as whether the silica content of the dust is known and how many employers would use these devices. OSHA did not find sufficient information in the record to determine what the reduction in laboratory expenses would be if some employers used dust-monitoring equipment. Furthermore, under the scheduled monitoring option, employers would need to comply with the laboratory requirements in Appendix A. OSHA is therefore, for cost purposes, taking a conservative approach and assuming that employers would follow the scheduled monitoring option instead of the performance option and pay the laboratory fee for each sample.

When the laboratory fee is combined with the IH fee, the direct cost per PBZ sample in general industry and maritime is projected to range from $296.52 to $1,390.27—depending on establishment size, purpose of exposure monitoring (initial or periodic), and industry type (hydraulic fracturing or not). This is an increase from the range of $195.88 to $383.38 estimated in the PEA.

Other unit costs

OSHA did not receive comment on the other exposure monitoring unit costs in the PEA and has retained them in the FEA. These include the costs to reflect a 30-minute loss in employee time while attaching the pump and the 15 minutes required for recordkeeping, including recording the sampling results and notifying the employee of the sampling results. The only difference was that these costs were updated to 2012 dollars. The loss in employee time was multiplied by the employee's hourly wage rate, including fringe benefits, to estimate the associated cost. The recordkeeping time was multiplied by a manager's hourly wage rate, including fringe benefits, to estimate the associated costs.

Summary of updated unit costs

[32] Because of the age of the original data source, ERG obtained supplemental information by contacting EMSL Laboratory, Galson Labs, and Analytics Corporation (all AIHA-accredited). ERG found the current cost estimates to average close to the original estimates in constant dollars, while noting that shipping costs per sample will vary with the number of samples and with the urgency of delivery.

For this FEA, OSHA developed separate cost estimates for (1) initial monitoring or any exposure monitoring at hydraulic fracturing sites and (2) scheduled monitoring at fixed sites (which excludes hydraulic fracturing). Costs under (2) were estimated to be lower because the exposure monitoring is expected to be of shorter duration (possibly obviating an overnight stay) and could be conducted by a lower-cost IH or IH technician rather than by a CIH. For initial monitoring or any exposure monitoring at hydraulic fracturing sites, the total unit cost of an exposure sample is estimated to range from $483.89 to $1,421.39 (depending on establishment size). For periodic monitoring in general industry and maritime, excluding hydraulic fracturing sites, the total unit cost of an exposure sample is estimated to range from $327.64 to $796.39 (depending on establishment size).

Overall, in the FEA, OSHA estimated that the total unit costs[33] of an exposure sample in general industry and maritime would range from approximately $327.64 to $1,421.39—depending on establishment size, purpose of exposure monitoring (initial or periodic), and industry type (hydraulic fracturing or not). This is an increase from the range of $224.94 to $412.44 estimated in the PEA.

Aside from updating the costs to reflect 2012 dollars, the only changes to the unit costs of exposure monitoring in general industry and maritime are due to the increased unit cost of a PBZ sample based on the increased cost to hire an IH consultant, as explained above. Table V-14 shows the unit costs and associated assumptions used to estimate the cost of an exposure assessment in general industry and maritime.

Table V-14
Exposure Assessment - General Industry and Maritime
Assumptions and Unit Costs
Coverage: All employees exposed above action level

Costs and Parameters	Comments/Assumptions

[33] Total unit costs include the direct costs (lab fee plus industrial hygienist fee) plus recordkeeping costs and worker productivity loss.

Direct Costs by Establishment Size	Small (<20)	Medium (20-499)	Large (500+)	
Initial Monitoring				
IH fees/PBZ sample	$1,250.00	$416.67	$312.50	Consulting CIH - cost per sample. Assumes IH fee of $2,500 for 2, 6, and 8 samples for small, medium, and large
Scheduled Monitoring - HF sites (also construction)				
	$1,250.00	$416.67	$312.50	Consulting CIH - cost per sample. Assumes IH fee of $2,500 for 2, 6, and 8 samples for small, medium, and large
Scheduled Monitoring - Fixed sites: General Industry & Maritime (HF excluded)				
	$625.00	$208.33	$156.25	Fee per sample. Assumes IH charges for periodic monitoring at fixed sites of one-half of the cost for initial monitoring ($1,250); for 2, 6, and 8 samples for small, medium, and large
Lab Fees and shipping cost	$140.27	$140.27	$140.27	Lab fees per sample (EMSL Laboratory, 2000) and OSHA estimates. Inflated to 2012 values.
Total - per PBZ sample - Initial	$1,390.27	$556.94	$452.77	
Total - per PBZ sample - HF	$1,390.27	$556.94	$452.77	
Total - per PBZ sample - Scheduled, fixed sites (Gen Ind and Maritime, except	$765.27	$348.60	$296.52

Number of Exposure Samples Taken Annually

For costing purposes, based on OSHA (2016) and as estimated in the PEA, OSHA estimated that, on average, there are four workers per work area. OSHA interpreted the initial exposure assessment as requiring initial testing of at least one worker in each distinct job classification and work area who is, or may reasonably be expected to be, exposed to airborne concentrations of respirable crystalline silica. In the FEA, as in the PEA, OSHA used the scheduled monitoring option under the exposure monitoring requirements to estimate, for costing purposes, that exposure monitoring will be conducted (a) twice a year where initial or subsequent exposure monitoring reveals that employee exposures are at or above the action level but at or below the PEL, and (b) four times a year where initial or subsequent exposure monitoring reveals that employee exposures are above the PEL.

As required under paragraph (d)(4) of the rule, whenever there is a change in the production, process, control equipment, personnel, or work practices that may result in new or additional exposures at or above the action level or when the employer has any reason to suspect that a change may result in new or additional exposures at or above the action level, the employer must conduct additional monitoring. As previously addressed in this section, OSHA has estimated in this FEA that for workers whose initial exposure or subsequent monitoring was at or above the action level, 25 percent annually would require an additional sample under section (d)(4) because of a change in work conditions.

To summarize OSHA's estimate of exposure monitoring frequency in general industry and maritime, each "representative" worker will receive initial monitoring. If the initial sampling results are below the action level, then no more exposure monitoring for that representative worker is estimated to take place in the initial year or in subsequent years. If the initial sampling results are not below the action level or above the PEL, then the representative worker will receive exposure monitoring an average of 2 times every year starting with the initial year, and 25 percent of these workers, on average, will require an additional sample be taken annually because of changing work conditions. If the initial sampling results are above the PEL, then the representative worker will receive exposure monitoring an average of 4 times every year starting with the initial year, and 25 percent of these workers, on average, will require an additional sample be taken annually because of changing work conditions.[34]

[34] This may be an overestimate in that, under the performance option, an employer may decide that continued monitoring does not serve to better characterize employee exposure. In these cases, as long as the air monitoring data continues to accurately characterize employee exposure, employers can use the existing data to meet their exposure assessment obligations without collecting more recent data.

OSHA notes that the National Association of Manufacturers (NAM) argued that in order to "demonstrate results meeting the 95 percent confidence limit […] it would be necessary to take 20 or more samples under substantially identical conditions" (Document ID 2380, Attachment 2, p. 17). OSHA disagrees with NAM's justification for the extensive sampling and has discussed the 95-percent-confidence-interval issue in greater detail in the Summary and Explanation section of the preamble concerning general industry and maritime compliance with the PEL. OSHA therefore retained its determination from the PEA that employers would not need to repeat sampling in order to achieve any particular confidence level.

Current Compliance

The AFL-CIO commented that OSHA's costs for exposure monitoring assumed that employers are not already conducting exposure monitoring, and contended that OSHA thus overestimated the costs of compliance because those employers would not need to spend the estimated amount to comply with the new exposure monitoring requirements (Document ID 2256, Attachment 4, pp. 1 and 5). Dr. Ruth Ruttenberg, speaking on behalf of the AFL-CIO, noted that the preliminary initial regulatory flexibility analysis (PIRFA) included an existing compliance assumption of 32.6 percent that was removed in the PEA (Document ID 2256, Attachment 4, p. 5). The PIRFA compliance assumption was based on 1988 National Occupational Exposure Survey (NOES) data, which presented a wide range of percentages and which OSHA concluded were somewhat unreliable. After weighing comment from the SBAR panel, OSHA determined it was prudent not to include baseline compliance estimates in the PEA based on NOES data and instead to await evidence to be submitted on this issue. Unfortunately, such evidence was not submitted to the record. The Agency agrees that it is very likely that some employers already conduct exposure monitoring, but concludes that there is not sufficient evidence in the record as to how many establishments currently conduct exposure monitoring. Therefore, for costing purposes for the FEA, as in the PEA, OSHA has conservatively assumed no current compliance with the exposure monitoring requirements.

Conclusion

Based on the unit costs of exposure monitoring presented in Table V-14, OSHA provides, in Table V-15, the estimated annual exposure monitoring costs for general industry and maritime, by NAICS industry and size of establishment, for the final rule. As shown, the combined costs of the exposure monitoring requirements for general industry and maritime are an estimated $79.8 million annually.

Medical Surveillance Costs

OSHA requested comments on the estimated costs in the PEA, but the comments, which are addressed in the following discussion, did not provide a persuasive argument that the Agency should use alternative costs in its final estimates. Accordingly, based on the rationale provided in the PEA and consideration of the issues identified in the following discussion and the record as a whole, OSHA has decided to maintain the same unit cost structure and time requirements used in the PEA. The only change from the PEA to the FEA was to update unit costs from 2009 to 2012 dollars.

Explanation of Medical Surveillance Provision

Paragraph (i) of the final standard requires the employer to make medical surveillance available for each employee occupationally exposed to respirable crystalline silica at or above the action level of 25 $\mu g/m^3$ for 30 days or more per year. This is a change from the proposed standard, which required that employers make medical surveillance available only for workers exposed to respirable crystalline silica above the PEL of 50 $\mu g/m^3$. The Summary and Explanation section of the preamble on medical surveillance provides a discussion of the rationale for this change.

Medical surveillance will include an initial (baseline) medical examination and periodic examinations. The initial medical examination must be made available to the employee within 30 days after initial assignment, unless the employee has received an equivalent medical examination within the last three years. The periodic medical examination must be made available to the employee at least every three years, or more frequently if recommended by the physician or licensed health care professional (PLHCP).

In accordance with paragraph (i)(2) of the final standard, the initial medical examination will consist of (1) a medical and work history, (2) a physical examination with special emphasis on the respiratory system, (3) a chest x-ray interpreted and classified according to the International Labour Office (ILO) International Classification of Radiographs of Pneumoconioses by a NIOSH-certified B Reader, (4) a pulmonary function test administered by a spirometry technician with a current certificate from a NIOSH-approved course, (5) testing for latent tuberculosis (TB) infection, and (6) any other tests deemed appropriate by the PLHCP. In accordance with paragraph (i)(3) of the final standard, the contents of the periodic medical examinations are the same as those for the initial examination, with the exception that testing for latent tuberculosis infection is not required. However, consistent with what was done in the PEA (without subsequent comment), OSHA medical experts in the Office of Occupational Medicine and Nursing estimated that the PLHCP will recommend testing for latent tuberculosis during the periodic medical examination for 15 percent of workers in general industry and maritime (Document ID 1720, p. V-54).

Note that the relevant language in both the proposed and final rule requires "the employer to make medical surveillance available to each employee…" For costing purposes, in both the PEA and FEA, OSHA assumed that all eligible employees would take advantage of the medical surveillance made available by the employer. In fact, to the extent that this is not true, OSHA will have overestimated the cost to employers of the medical surveillance provision. As evidence illustrating less than 100 percent employee participation, the record includes a study of miner participation rates in medical surveillance programs indicating that participation over the time span of the study ranged from 25 percent to 41.7 percent (Document ID 3998, Attachment 15; see also Document ID 3587, Tr. 3616-3617).

PEA Estimates

As presented in the PEA (and shown in Table V-10 in the PEA), OSHA's medical experts in its Office of Occupational Medicine and Nursing provided estimates (in 2009 dollars) of the following medical costs: a complete medical and work history, a triennial review and updating of health history, a physical examination by a PLHCP, a chest x-ray, the classification of a chest x-ray by a NIOSH-certified B Reader, a pulmonary function test, an examination by a specialist (defined in the standard as an American Board Certified Pulmonary Disease or Occupational Medicine Specialist), other necessary tests (the medical experts estimated that these would likely be required by 10 percent of examined workers), and a latent TB test (Document ID 1720, p. V-51). OSHA also used the research and expertise of staff from its Office of Occupational Medicine and Nursing and from OSHA's contractor, ERG, to provide preliminary estimates in the PEA of how much time each medical activity would take. These estimates included, for the employee, 120 minutes for the health history survey and exam, including x-ray; 30 minutes to review and update the health history; 60 minutes for the physical exam and tests (including pulmonary function but excluding x-ray); 30 minutes for the chest x-ray; 5 minutes for the reading of the latent TB test (return visit to receive results); and 60 minutes for an examination by a specialist (Document ID 1720, pp. V-51-V-54).

The PEA also accounted for round-trip travel costs necessary to see an off-site physician. Off-site travel time for a worker in general industry or maritime was estimated to be 60 minutes for medical surveillance at any off-site location. OSHA further enumerated in the PEA the percentage of employees seeing an off-site physician by establishment size. For the initial examination, it was estimated that 80 percent of employees in small establishments (with fewer than 20 employees), 25 percent in medium-sized establishments (with 20 – 499 employees), and 0 percent in large establishments (with 500 or more employees) would see an off-site physician. For new hires, the percentages increase slightly to 90 percent of employees in small establishments, 50 percent in medium establishments, and 10 percent in large establishments. For general industry and maritime, OSHA also estimated a hiring rate[35] of 27.2 percent (utilizing 2008 data from the Bureau of Labor Statistics Job Openings and Labor Turnover Survey) and judged that 75 percent of new hires would require an initial health screening (the other 25 percent of new hires would have previous job experience covered by either silica standard such they would have had a compliant health screening within the prior three years). OSHA did not receive comment on this 75 percent estimate, other than from commenters questioning whether it accounted for persons who would not need to be re-screened, which it does). The initial screening for current employees was estimated to range in cost from $389.38 to $424.94 per employee, depending on establishment size, and the initial screening for new hires was estimated to range in cost from $393.82 to $429.38 per employee, again, depending on establishment size. The slightly higher initial screening costs for new hires relative to current employees is due, in the former case, to the larger percentage of off-site physician visits, which has associated added costs for travel time.

Comments and Responses on Medical Surveillance

Underestimation of Costs

A frequent criticism expressed by commenters was that OSHA had underestimated the costs associated with the medical surveillance provision. Some commenters, such as the National Precast Concrete Association, only asserted that OSHA's cost estimates for various provisions, including medical surveillance, were underestimated, without specifying any particular element of those costs or providing any alternative cost estimates (Document ID 2067, p. 4). Some commenters were more specific. John Burke, from OSCO Industries, Inc., commented that the "local cost of the required medical surveillance procedures [at] $185/annually is approximately one-half of the cost required to conduct the medical surveillance on one employee" (Document ID 1992, p. 7). The cost Mr. Burke was referring to was for a single worker (per small entity in NAICS 331511) in Table IX-1 of the PEA, but that was the *annualized* medical surveillance cost *for 2.2 workers* in a small foundry, not the unit cost for a single worker. The comparable OSHA cost estimate for an initial medical screening for a single current employee in a small (20-499 employee) establishment, as shown in Table V-10 (page V-53) of the PEA, was $384—which is larger than Mr. Burke's estimate of $370 (since $185 is one-half of

[35] In the PEA, OSHA in some cases referred to this rate as the separations rate, but in fact the Agency was using the hiring rate reported by BLS. Because the regulatory analysis is based on steady-state economic conditions, the separations rate, the hiring rate, and the turnover rate are effectively identical.

the required cost, according to Mr. Burke). George Kennedy, from the National Utility Contractors Association, commented that "the cost of a medical evaluation that meets the NPRM requirements ranges from $300 to $500 per employee plus hourly wages and travel costs" (Document ID 2171, p. 5).

The Portland Cement Association (PCA) provided detailed cost information on the components of the medical exam:

> The total minimum cost for the four medical tests is more than twice the estimated cost in the proposal; the average national cost to comply with the medical testing provisions for employees in a medical surveillance program contained in the proposed rule is more than five times the estimate provided to OSHA (Document ID 2284, p. 7).

The PCA utilized http://health.costhelper.com and www.newchoicehealth.com to source its estimates. Both sites appear to be privately-held information providers and not necessarily subject to public data standards for validity. OSHA disagrees with PCA's estimates based on a review of these sites by ERG, an OSHA contractor, which produced significantly different results, with low-end costs substantially less than the low end cited by PCA (ERG, 2015). Furthermore, the PCA comment seems to have drawn many of its cost estimates not from the "typical" costs given by the CostHelper website but from site user-submitted comments about what they had been billed for similar procedures. Characterizing these as if they capture nationally-representative ranges of costs is inaccurate.[36] It is noteworthy that PCA's estimates for medical surveillance were above the range put forward by all other commenters in both general industry (as discussed above) and in construction (as discussed in the construction medical surveillance cost section later in this chapter). Also, while a number of commenters argued that costs within a certain range were typical of their members or employees, PCA did not make that claim.

[36] From ERG (May 1, 2015): For example, the page for "X-Ray Cost" gives two different ranges for those without insurance and 19 different costs, including one for a chest x-ray. The costs that are cited are drawn from NewChoiceHealth.com, Berger Health System in Ohio, Baptist Memorial Health Care in Memphis, as well as user-submitted comments regarding what the user paid for a foot/hip/ankle X-ray and "CT abdomen with contrast." The estimate given by PCA as an "average national cost" ($370) appears to be the cost from NewChoiceHealth.com for a chest x-ray; it is not clear how the "minimum national cost" ($190) was derived, as this figure is not currently listed on the site. The "maximum national cost" ($5,300) might be based on the $5,200 cost submitted by user "Budde in Booneville, MS" for a CT abdomen with contrast, which is a significantly different (and more expensive) test than a chest x-ray.

For a pulmonary function test, CostHelper estimates the cost as "$40-$800 total," whereas the PCA comment gives the minimum as $490 and maximum as $4,500. The "maximum national cost" listed by PCA appears to have been derived from a comment by the user "SecondBreath in Boston, MA," who estimated the costs at $4,445.00, and went on to say "Gross charges before insurance discount. Same tests two months ago were $2,155. At an affiliated regional hospital same tests were around $800."

The Asphalt Roof Manufacturers Association (ARMA) commented that OSHA's costs in the PEA substantially underestimated the full cost for:

> (i) the exam, (ii) the time away from work for the employee to have the exam performed, (iii) backfill of the job position while the exam is performed, and (iv) recordkeeping. The cost for just the exam may approach as much as $500 to $700 per exam, depending on the region of the country. Of course, larger employers may be able to negotiate lower costs based on volume of exams needed [footnote reference added by OSHA] (Document ID 2291, p. 26).[37]

Similarly, Stephanie Salmon, from the American Foundry Society (AFS), submitted a table comparing the estimates presented in the PEA for medical surveillance to estimates from the AFS, stating that "[t]hose [medical surveillance costs] estimated by AFS are higher than those estimated by OSHA in the PEA" (Document ID 2379 Appendix 3, p. 23). OSHA is unable to comment on the individual ARMA and AFS estimates as they did not contain source or reference material. While OSHA cannot address the validity of the ARMA and AFS estimates, OSHA recognizes that there is a wide range of costs and fees per service. The cost estimates included in this FEA represent a midpoint in the range, as derived from a national database of Medicare reimbursement, plus 30 percent to compensate for the effect of Medicare discounts that are unlikely to apply to occupational medicine environments. While it is possible that costs in particular geographic areas (or as ARMA notes, for different-sized employers) may run higher or lower than the national average, no evidence was presented to suggest that OSHA's methodology for deriving a national estimate for workers and industries affected by the silica rule as a whole was flawed.

In addition, the National Rural Electric Cooperative Association (NRECA) submitted a cost estimate for initial health screenings for its members, arguing that "in the absence of objective air monitoring data, all employees may be subject to the establishment of an initial baseline examination" (Document ID 2365, p. 17). OSHA acknowledges that there will be many workers who meet the trigger for medical surveillance and will need initial medical examinations in the first year. However, employers in general industry or maritime excluded from the scope of the final rule based on objective data or whose employees' exposures will not meet or exceed the action level of 25 μg/m^3 for 30 or more days a year will not be subject to the medical surveillance requirements at all.

<u>Travel Time Estimates</u>

[37] OSHA notes that ARMA provided no cost information for the items (ii) through (iv) and that item (iii) is already reflected in item (ii). To see this latter point, consider that without the medical surveillance the employer would pay one employee for the work to be completed; with medical surveillance, the result is the same except that one more worker would have to be paid (not two more).

OSHA included an estimate in the PEA of 60 minutes of worker time for off-site travel to have a medical examination when required by the general industry and maritime standard. NRECA commented that:

> "[g]iven the rural nature of our members, the range used in OSHA's estimate is likely understated. More travel time and fewer medical personnel in rural area will increase this estimate in the case of rural electric cooperatives" (Document ID 2365, pp. 3 and 17).

The Agency's analysis examines the economic impact on all affected industries. The NRECA represents employers who comprise only a fraction of the energy generation and supply industry. While the Agency recognizes that there will be instances where the travel time for a particular worker at a rural worksite will be greater than the 60 minutes that OSHA has estimated in its unit costs, this estimate represents a national average for workers in general industry or maritime. Logically, more rural, geographically dispersed jobs are likely to require more travel time; this additional travel time is already offset in the average by the concentration of jobs in other areas with nearby medical services available where the travel time would be significantly less than 60 minutes. The commenter did not identify any other deficiencies in the estimate. Additionally, OSHA compared the travel estimate to that in previous rules. For example, OSHA's chromium rule did not have the travel component broken out but an initial medical exam was estimated at 3 hours which includes the exam, written opinion, and travel time. For silica, the estimate is 2 hours for the exam and 15 minutes for recordkeeping. Applying the same breakdown to chromium would leave 45 minutes for travel time. Given this review of the chromium rulemaking, OSHA concludes that it is likely being conservative and overestimating the amount of travel time necessary and will revisit the issue in future rulemakings. However, because the record was not further developed in this rulemaking, OSHA is not now reducing its estimate from the PEA.

OSHA also notes that one commenter, the National Federation of Independent Business (NFIB), said that one member reported that "his company requires workers to go to the doctor in pairs" (Document ID 2210, p. 8), which would increase lost worktime costs. However, the Agency believes this example is so unusual and unrepresentative of most business practices that lost worktime costs have not been revised to reflect this single example.

Current Compliance and Overlap with Respiratory Protection

Although OSHA believes that some affected establishments currently provide some medical testing to their silica-exposed employees (as evidenced by the comments from firms and industry associations on their current medical surveillance costs), the Agency doubts that many provide the comprehensive health screening required under the rule. For example, Dal-Tile commented that:

> Other OSHA regulations already require the facility to implement and maintain a Respiratory Protection Program (RPP). One component of an RPP is the requirement for every person who uses a respirator at any time during the year to ensure that they are physically capable of safely wearing the respirator. This is accomplished by requiring the employee to complete OSHA's Medical Questionnaire and submit it to a Doctor or other qualified occupational health care provider (Document ID 2147, p. 3).

The Dal-Tile comment notes the potential overlap of the respirator fitness evaluation required by OSHA's existing RPP requirement with the medical surveillance requirements of the final rule. In fact, the medical and work history required by the medical surveillance provisions of the final rule would also satisfy the respirator medical clearance required by the RPP, and a PLHCP report to the employer of the worker's fitness to wear a respirator. However, the Agency has conservatively ignored, in both the PEA and the FEA, any cost reduction for medical surveillance in the final rule arising from baseline compliance with the medical clearance requirement for respirator use.

Employee Turnover

In the PEA, OSHA estimated a hiring rate of 27.2 percent (utilizing 2008 data from the Bureau of Labor Statistics Job Openings and Labor Turnover Survey) and judged that 75 percent of new hires would require an initial health screening. As specified in paragraph (i)(2) of the rule, employees who had received a medical examination that meets the requirements of the rule within the previous three years will be exempt from the initial medical examination, so not all new hires will require initial medical testing. As noted earlier, OSHA estimated that 25 percent of new hires in general industry and maritime will be exempt from the initial medical examination.

A number of commenters noted that job turnover would affect the costs attributable to the medical surveillance requirement, because the final rule states that employees will not need an initial exam within 30 days of initial assignment if they have received a medical examination that meets the requirements of the rule within the last three years. For example, Dr. Ruth Ruttenberg, on behalf of the AFL-CIO, suggested that if no portability of medical records is assumed, "then there is an overestimation of cost for …medical surveillance" (Document ID 2256, Attachment 4, p. 5). Dr. Ruttenberg continued by stating that "when individuals leave their jobs, it does not mean that they leave their industry…Portability of training and medical surveillance will help avoid duplication of services" and reduce compliance costs to employers (Document ID 2256, Attachment 4,

p. 6). OSHA agrees that if an employee receives the required medical screening at one job, and then moves to a second job at which the employee would be covered by an OSHA silica standard, the second employer would not need to incur expenses for re-screening if it is within the time period specified in the standard. OSHA's cost estimates for medical surveillance in the FEA (and previously in the PEA) do avoid "duplication of services," consistent with the final rule. As noted earlier, OSHA did not receive comment on the accuracy of the 75 percent estimate. Hence, the Agency is retaining its estimate that 100 percent of current affected employees and 75 percent of new hires (based on the share of turnover associated with new hires to the industry) who meet the criteria for receiving medical surveillance, will be tested in the initial year after promulgation of this final rule.

Updated Unit Costs for FEA

Based on the preceding comments and the Agency's responses, OSHA has decided to maintain the same unit cost structure and time requirements used in the PEA, with the only changes being to update unit costs from 2009 to 2012 dollars.

With the assistance of its contractor, ERG, the Agency updated the information on representative unit costs of initial and periodic medical surveillance to 2012 dollars. Separate costs were estimated for current employees and for new hires as a function of employment size (i.e., 1-19, 20-499, or 500+) of affected establishments. Table V-16 presents the unit cost data and modeling assumptions used by OSHA to estimate medical surveillance costs.

As shown in Table V-16, the estimated unit cost of the initial health screening for current employees in general industry and maritime ranges from $414.97 to $434.78 and includes direct medical costs, the opportunity cost of worker time (i.e., lost work time, evaluated at the worker's 2012 hourly wage, including fringe benefits) for offsite travel and for the initial health screening itself, and recordkeeping costs. The variation in the unit cost of the initial health screening by establishment size is due entirely to differences in the percentage of workers expected to travel offsite for the health screening. In OSHA's experience, the larger the establishment, the more likely it is that the selected PLHCP would provide the health screening services at the establishment's worksite. As was done in the PEA, OSHA estimates that, on average, 20 percent of establishments with fewer than 20 employees, 75 percent of establishments with 20-499 employees, and 100 percent of establishments with 500 or more employees will have the initial health screening for current employees conducted onsite.

The unit cost components of the initial health screening for new hires in general industry and maritime are identical to those for existing employees with the exception that the percentage of workers expected to travel offsite for the health screening will be somewhat larger (due to fewer workers being screened annually, in the case of new hires, and therefore yielding fewer economies of onsite screening). OSHA estimates, on average, that 10 percent of establishments with fewer than 20 employees, 50 percent of establishments with 20-499 employees, and 90 percent of establishments with 500 or more employees will have the initial health screening for new hires conducted onsite. As shown in Table V-16, the estimated unit cost of the initial health screening for new hires in general industry and maritime ranges from $417.45 to $437.25.

Table V-16:
Medical Surveillance and TB Testing - General Industry
Assumptions and Unit Costs
Coverage: All employees exposed above action level

Screening Tool	Cost	Initial Screening	Periodic Screening	Comments/Assumptions
Direct Costs				
Complete medical and work history	$36.94	Yes	Yes	Assumed one third of physical exam cost
Periodic review and updating of health history	$36.94	NA	NA	Assumed one third of physical exam cost
Physical examination by knowledgeable PLHCP [a]	$110.83	Yes	Yes	Evaluation and office consultation including detailed examination ($100, inflated to 2012).
Chest X-ray [a]	$88.24	Yes	Triennial	Radiologic examination (a single posteroanterior radiographic projection) ($62.97; inflated to 2012). Costs include consultation and written report
Chest X-ray classified by a NIOSH-certified B Reader [a]	$43.44	Yes	Triennial	Average of three estimates made by B Readers to ERG, inflated to 2012
Pulmonary function test [a]	$60.62	Yes	Triennial	Spirometry, including reports showing graphical displays and numerical results for measurements of Forced Vital Capacity (FVC), Forced Expiratory Volume in One Second (FEV1), and FEV1/FVC ($43.26; inflated to 2012)
Examination by a specialist [b]	$210.89	Yes	NA	Office consultation and evaluation by a specialist ($158.07; inflated to 2012)
Other necessary tests	$66.50	Yes	Yes	Assumed required by 10 percent of workers ($60; inflated to 2012)

Table V-16: (continued)
Medical Surveillance and TB Testing - General Industry
Assumptions and Unit Costs
Coverage: All employees exposed above action level

Screening Tool	Cost	Initial Screening	Periodic Screening		Comments/ Assumptions
Latent TB Test [a]	$16.63				$15; inflated to 2012
Time Requirements for Medical Examinations (minutes)					
Travel time for off-site exam	60				
Complete medical and work history and exam, including x-ray	120				Per survey and exam
Health history review and update	30				Per review
Physical exam and tests (without x-ray)	60				Per exam
Chest x-ray	30				Per x-ray
Examination by a specialist	60				
Recordkeeping (initial and periodic screenings)	15				Average per screening
Recordkeeping (specialist referrals and recordkeeping)	60				Includes time for referrals
Percentage of employees seeing off-site physician by establishment size		-	-		
		Small (<20)	Medium (20-499)	Large (500+)	
Initial examination		80.0%	25.0%	0.0	
New hires		90.0%	50.0%	10.0	
Time requirements for TB Testing (minutes)					
Initial test	NA				Included in initial exam
Return for reading	5				
Travel Times (minutes) - off-site location					
Initial test	NA				Included in initial exam
Return for reading	60

Percentage of employees tested in initial year

Table V-16: (continued)
Medical Surveillance and TB Testing - General Industry
Assumptions and Unit Costs
Coverage: All employees exposed above action level

Screening Tool	Cost	Initial Screening	Periodic Screening	Comments/ Assumptions
Current Employees			100.0%	
New Hires			75.0%	
Percentage of employees recommended for periodic TB testing [c]			15.0%	

[a] Typical charge based on ERG contacts with occupational health providers.
[b] Mean expense per office-based physician visit to a specialist for diagnosis and treatment, based on data from the 2004 MEPS. Inflated to 2012 levels using the consumer price index.
[c] The corresponding table in the PEA erroneously referred to this as annual TB testing. This typographical error did not impact the costs in the PEA.
Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA (2016).

The periodic medical examination will occur at least every three years, or more frequently if recommended by the PLHCP. As previously noted, the contents of the periodic medical examination are identical to those for the initial examination, with the exception that testing for latent tuberculosis infection is not required.

The estimated unit cost of periodic health screening also includes direct medical costs, the opportunity cost of worker time, and recordkeeping costs. As shown in Table V-16, these unit costs vary from $414.97 to $434.78 every third year. The variation in the unit cost is due entirely to differences in the percentage of workers expected to travel offsite for the periodic health screening. OSHA estimated that the share of workers traveling offsite, as a function of establishment size, will be the same for the periodic health screening as for the initial health screening for existing employees.

For general industry, the key change from the PEA relates to the scope of medical surveillance coverage. For the final standard, medical surveillance is triggered when an employee is expected to be exposed at or above the action level for 30 or more days per year, while in the proposal it was triggered when an employee was expected to be exposed above the PEL for 30 or more days per year. This rule change has increased the number of workers who must be offered medical surveillance. The Summary and Explanation section of the preamble on medical surveillance contains a thorough discussion of the explanation for the change in the medical surveillance trigger.
The Agency applied the expanded scope (due to the new trigger) to the unit costs to estimate total health screening costs. Based on a ten-year time horizon, OSHA estimated the total annualized costs in general industry and maritime for health screenings, including initial health screenings for existing employees and new hires and periodic health screenings, required by the final rule. These estimates, disaggregated by affected NAICS industry, are presented in Table V-17.

Finally, as in the PEA, OSHA estimated the unit cost of a medical examination by a specialist for those employees with a chest x-ray classified as 1/0 or higher on the ILO scale or who are otherwise referred by the PLHCP. As shown in Table V-16, the estimated unit cost of a medical examination by a specialist is $335.37. This cost includes direct medical costs, the opportunity cost of worker time, and recordkeeping costs, including the cost of the employer’s time to make a referral to a specialist. In all cases regardless of establishment size, OSHA anticipates that the worker will travel offsite to receive the medical examination by a specialist and so has also included the standard 60 minutes in travel time costs for employees in general industry or maritime.

Based on Buchanan et al. (2003), OSHA estimated that, for those workers in general industry and maritime under medical surveillance (with exposures at or above the action level), there would be 544 new cases of silicosis a year (all expected to be identified by medical surveillance), based on x-rays of silica-exposed employees classified as 1/0 or higher. For the purpose of estimating costs, OSHA assumes that the PLHCP would refer the employee to a specialist only if the employee was diagnosed with silicosis. ERG distributed the cost of a specialist visit for these disease cases among industries in proportion to the number of workers exposed at or above the action level. Table V-18, which multiplies the unit cost by the number of referred workers, shows the total annualized cost in general industry and maritime of medical examinations by a specialist. Table V-19, which combines total health screening costs and the total costs of medical examinations by a specialist, shows aggregate annualized costs in general industry and maritime, by NAICS industry, for the medical surveillance requirements in the rule. For general industry and maritime, combined over all affected NAICS industries, the estimated cost of these medical surveillance requirements is $29.7 million annually.

Table V-17: Annualized Medical Surveillance Costs for General Industry and Maritime

NAICS	Industry	At-Risk (25 μg/m³)	Initial Screening	Screening for New	Triennial Screening	Total Examinations	Total TB Testing	Total
213112	Support Activities for Oil and Gas Operations	13,819	$683,962	$1,109,234	$991,503	$2,784,699	$66,627	$2,851,326

Familiarization Costs and Costs of Communication of Silica Hazards to Employees

In this section, OSHA presents its cost estimates for two employer information activities arising from the silica final rule: (1) employer familiarization with the final rule, and (2) communication of respirable crystalline silica hazards to employees as required by the final rule.

Familiarization Costs

OSHA did not estimate any employer familiarization costs in the PEA. OSHA's rationale for not including familiarization costs in the PEA was that there was already an existing silica standard in place and, therefore, the Agency expected that any familiarization costs for a revised silica standard would be negligible. However, several commenters on the proposed rule argued that employers will need to spend time to become familiar with the requirements of the final rule; that the employer time spent is the direct result of the final rule itself; and, therefore, that OSHA should include employer familiarization costs as part of the costs of the final rule.

For example, James Hardie Building Products, Inc. (Document ID 2322, p. 175) stated that:

> [T]he newly (or more extensively) regulated firm will almost certainly carry out the following activities, none of which have been accounted for or included in OSHA's analysis.
>
> - Obtaining, reviewing, and developing an understanding of rule provisions and how they apply to the affected business
> - Receiving review, analysis, and consultation by legal counsel (internal or outside) to identify the precise obligations imposed by the rule
> - Consultation with insurance carrier(s) and possible revisions to policies and terms
> - Developing or revising existing policies and procedures (e.g., code of conduct, EHS, employee development, training, performance evaluation, and procurement)
> - Making adjustments to job scheduling and employee deployment to job sites
> - Management monitoring of regulatory compliance and new/revised program success
> - Initiation/expansion of employee health tracking
> - Referrals to a pulmonologist, as required, and
> - Records management for all of the above.

Ronald Bird, on behalf of the United States Chamber of Commerce, also commented on familiarization costs:

> Familiarization covers at least the basic “initial” screening analysis to determine the likelihood that the regulation contains any applicable requirements or exposes the employer to any legal liabilities that merit further examination. For employers who are unable to conclude from an initial screening review whether a new or revised rule applies, there would be “extended familiarization” effort required to fully review the regulation to determine in detail what elements of the regulation apply and to plan organizational adjustments to comply with the rules (Document ID 2368, p. 9).

In addition, Stuart Sessions, of Environomics, Inc., in characterizing OSHA’s cost estimates as being too low in general, included the following as an example of such costs that OSHA had omitted from its cost analysis: “Cost to read the rule, become familiar with it and plan a compliance strategy for the facility or business” (Document ID 4231, Attachment 1, p. 11).

OSHA finds the comments in support of including *some* familiarization costs persuasive—along the lines recommended by Stuart Sessions above— and the Agency has now concluded that employers will need to spend some time to understand the ancillary provisions and the other new and revised components of the final rule and to determine what actions they must take in order to comply. OSHA notes that, in addition to its other purposes, the familiarization time will help supervisors to prepare/select training to provide to other supervisors and to other employees of the firm. The issue that remains is to estimate the magnitude of these familiarization costs.

To provide some context, the Agency notes that there is an existing OSHA PEL for respirable crystalline silica that covers the same group of employers, and an existing OSHA hazard communication standard that covers all workplace exposures, including respirable crystalline silica. Therefore, OSHA expects that the vast majority of employers will already know whether they are going to be covered by the final rule and will be familiar with the types of processes and controls available to reduce their employees’ exposure to silica.

The Agency further notes that it is offering various materials to assist employers in understanding and complying with the final rule. These include guidance materials such as fact sheets and other summary materials on the final rule; an OSHA dedicated silica webpage that will contain outreach and compliance assistance products; and, as required by Section 212 of the Small Business Regulatory Enforcement Fairness Act,[38] the release and dissemination of a small business compliance guide (not limited for use to small businesses) to provide additional guidance and ease familiarization and compliance with the final rule. In addition, OSHA has developed guidance to educate stakeholders on new Agency approaches taken in the respirable crystalline silica rule such as the requirements for the PLHCP's written medical opinion for the employer. Furthermore, OSHA expects that industry associations will be providing additional support materials and services to their members covered by the rule. For example, such materials are already provided by the Marble Industry of America (MIA) including "videos, handouts, and training guidelines on awareness and prevention to minimize the risk of silicosis" which are provided "free-of-charge to stone companies online" (Document ID 1722, p. 1). OSHA also intends to work with individual employers and industry groups to address specific compliance questions as necessary.

One commenter, Dr. Ronald Bird, on behalf of the United States Chamber of Commerce, offered an example of 8 hours as an amount of familiarization time that was a "composite of several persons' inputs" into Dr. Bird's review of OSHA's proposal, while adding: "It is difficult to imagine that the requisite review time would be much less, and for larger firms and complex operations the time could be much more" (Document ID 2368, p. 10). An 8-hour estimate is the same that OSHA used in its most recent estimate of familiarization time in its 2012 update to the Hazard Communication Standard (see 77 FR 17637-17638 (March 26, 2012)). OSHA believes that this is a reasonable estimate of familiarization time for a typical firm for this final silica rule.

For purposes of estimating familiarization costs associated with this final silica rule, OSHA expects that the employer will assign responsibility for investigating the details of the final rule, and for determining how to implement it, to one or more supervisors. How many supervisors will be assigned such responsibility and how the responsibility will be delegated among supervisors will presumably depend on a number of factors, such as the number of respirable crystalline silica-generating activities within the employer's facilities, which OSHA has estimated would be correlated with the size of the facility (as measured by the number of employees), and other employer-specific factors. OSHA's estimate of familiarization costs therefore reflects the total supervisor familiarization time (costed at a supervisory wage) for each covered employer, with the number of employees at each establishment also serving as a proxy to represent the diversity of silica activities. OSHA made a similar adjustment to distinguish different amounts of familiarization time for different entities when it conducted its analysis of its Hazard Communications Standard. In that analysis, OSHA distinguished between manufacturers and non-manufacturers to determine different amounts of time for familiarization, and used the

[38] P.L. 104-121, March 29, 1996 (as amended by P.L. 110-28, May 25, 2007)

presence or absence of safety directors in non-manufacturing firms as a proxy for the size of the establishment and the number of chemicals likely to be present (77 FR 17637-17638). For the silica rule, the requirements are not broken out separately for manufacturers and non-manufacturers, and the number of employees seems to be a more appropriate proxy for the level of familiarization that would be needed. Accordingly, OSHA has reduced the average of 8 hours of familiarization time for establishments with fewer employees and increased it significantly for establishments with a larger number of employees: 4 hours per covered employer with fewer than 20 employees; 8 hours per covered employer with 20 to 499 employees; and 40 hours per covered employer with 500 or more employees. These estimates represent average familiarization times; it is expected that some establishments will spend less time on familiarization than estimated here (e.g., if worker exposure never meets or exceeds the action level) and some will spend more time on familiarization than estimated here.

OSHA has not included any additional costs for legal expenses. OSHA crafted the rule to be clear to employers, and is providing additional materials explaining the requirements of the final rule and guidance from the Agency on how to comply with the final rule. The general industry requirements do not present any novel legal issues: the rule's structure and most of the included provisions are generally consistent with previous OSHA health standards, such as those protecting employees from exposure to lead (29 CFR 1910.1025) and hexavalent chromium (29 CFR 1910.1026). Thus, the Agency believes that employers would not choose to undertake review of the final rule by legal counsel or insurance providers and that such review would be unnecessary. OSHA has not previously included legal fees in other rulemakings, and the record does not include any persuasive argument for departing from this longstanding practice.

Table V-20 shows the unit cost by establishment size for employers to become familiar with the final rule. These costs will likely be one-time costs incurred during the first year in which the rule is effective, but the aggregate costs are annualized for consistency with the other cost estimates for the rule. Table V-21, which incorporates the unit familiarization costs in Table V-20, therefore displays OSHA's estimate of the annualized familiarization costs of the final rule for general industry and maritime, by NAICS industry. For general industry and maritime, the total annualized familiarization cost of the final rule is $2.1 million.

Table V-20:
Familiarization - General Industry and Maritime
Assumptions and Unit Costs

	Small (<20)	Medium (20-499)	Large (500+)	
Hours per establishment	4.0	8.0	40.0

Training Costs for Employees in General Industry and Maritime

Communication and Training Requirements

The final standard requires two forms of hazard communication to employees: paragraph (j)(1) notes that employers must include respirable crystalline silica in their existing hazard communication programs required by the hazard communication standard (HCS) (29 CFR 1910.1200), and paragraph (j)(3) requires that employers must provide employees with specific information and training. Because the silica hazard communication under paragraph (j)(1) is already required by, and costed under, the HCS, OSHA has estimated no costs for compliance with this paragraph of the final silica rule. The costs for employers to comply with the training requirements of paragraph (j)(3) are discussed below.[39]

Under subparagraph (j)(3)(i), employers must ensure that each employee who is covered by this section can demonstrate knowledge and understanding of at least the following: (A) the health hazards associated with exposure to respirable crystalline silica; (B) specific tasks in the workplace that could result in exposure to respirable crystalline silica; (C) specific measures the employer has implemented to protect employees from exposure to respirable crystalline silica, including engineering controls, work practices, and respirators to be used; (D) the contents of this section; and (E) the purpose and a description of the silica medical surveillance program. There is no specified hours-of-training requirement; the amount of silica training an employee receives will depend on what is required for employees to demonstrate knowledge and understanding of the subjects listed under paragraphs (j)(3)(i)(A)-(E).

As specified in subparagraph (j)(3)(i) of the final rule and the HCS, training is required for all employees in general industry and maritime are covered by the standard. This requirement applies to newly hired workers who would require training before starting work, workers who change jobs within their current workplace or are assigned new tasks or exposure protection, and any covered worker an employer believes needs additional training. Thus OSHA has estimated a one-time training cost for existing employees as well as recurring training costs to account for new hires.

PEA estimates

In both the PEA and this FEA, OSHA divided the employer costs for training employees under the new standard into two categories: training materials and training time.

[39] Paragraph (j)(2) requires the posting of signs at all entrances to regulated areas, and the costs associated with this activity are estimated and discussed in the cost section on regulated areas.

In the PEA OSHA estimated the cost of training based on several key cost judgments. First, OSHA judged, for costing purposes, that employers will conduct the training in-house, relying predominately on free materials from OSHA and industry associations in order to develop and deliver the training. Second, the Agency estimated that the training materials that would need to be purchased would cost, on average, $2.00 per worker, encompassing the cost of handouts, video presentations, training manuals and exercises. Third, the training required by this standard, excluding the information-sharing already mandated by the hazardous communication standard, would last, on average, 45 minutes. Fourth, OSHA estimated that new hires would require the same amount of training as other employees. Fifth, in order to identify the number of trainers (and hence the amount of trainer time) necessary to conduct the trainings, OSHA estimated the number of employees for each training class based on the size of the establishment. Finally, OSHA used the hires rate[40] in manufacturing, which was 27.2 percent in 2008 (BLS Job Openings and Labor Turnover Survey, 2008), to estimate the amount of new hire training in general industry and maritime.

OSHA used these parameters to calculate the estimated cost of training, including the cost of instructor time, employee time, and materials.

Comments and responses on training

Training materials

In the PEA, OSHA based the training material cost estimate on ERG's judgment that $2.00 per worker could purchase sufficient training materials such as handouts, video presentations, and training manuals and exercises (Document ID 1608, p. 3-78). A number of commenters misinterpreted this figure as being OSHA's estimate of the total per-worker cost to provide training. For example, the Motor & Equipment Manufacturers Association commented that "[b]ased on the collective experience of our member companies, OSHA's training cost estimate of $2.00 per employee is considerably undervalued" (Document ID 2326, p. 3). This misinterpretation was reiterated by other commenters as well (e.g., Document ID 3391, pp. 1-2; 2370, p. 2; and 2130, p. 2). OSHA is therefore clarifying that this average per-worker cost of $2.00 is solely for training materials and is included in both the annualized training costs for employees as well as the annual cost for new-hire training.

[40] In the PEA, OSHA in some cases referred to this rate as the separations rate, but in fact the Agency was using the hiring rate reported by BLS. Because the regulatory analysis is based on steady-state economic conditions, the separations rate, the hiring rate, and the turnover rate are effectively identical.

While OSHA included costs to account for the purchase of training materials by covered employers, industry associations also have training materials that are available. For instance, James Hieb, from the Marble Institute of America (MIA), commented that “the MIA has produced videos, handouts, and training guidelines on awareness and prevention to minimize the risk of silicosis and is providing many of those resources free-of-charge to stone companies online” (Document ID 1722, p. 1).The National Ready Mix Concrete Association (NRMCA) commented that many of its members use the NRMCA’s Mixer Drum Cleaning guide (available for a fee on its website) or a guide developed by Georgia Tech’s Safety and Health Consultation Program titled “Chipping Out the Drum,” which is also available free online (Document ID 2305, p. 9). The National Precast Concrete Association (NPCA) reported that NPCA provides a Guide to Plant Safety that “includes policies and procedures for respiratory protection and a training plan” and can be downloaded for free from its website (Document ID 2067, p. 2). The International Union of Operating Engineers submitted a list of free online silica training tools. This list included the following resources:

> training materials produced by OSHA; [the National Institute of Occupational Safety and Health] NIOSH; [Center for Protection of Workers' Right] CPWR; Arizona Division of Occupational Safety and Health (ADOSH); NJ Public Health Services Branch, Division of Epidemiology, Environmental and Occupational Health Service, Occupational Health Surveillance Program; and Georgia Tech’s Safety and Health Consultation Program: Preventing Silicosis Among Masons (Document ID 4025, Attachment 1, p. 6).

Additionally, under the Small Business Regulatory Enforcement Flexibility Act, OSHA is required to provide to small businesses compliance guides that can be obtained and used by businesses of any size. These will include for this final rule a model training program and other training and compliance materials—all offered at no cost by OSHA. While OSHA does not typically endorse training products other than its own materials, and the Agency is not now endorsing any of these materials or even suggesting that following these training guides would alone bring anyone into compliance with OSHA’s training requirements, the point is that there are already a number of materials available from which employers can draw and it is likely that new training materials will be created in response to the new standards. Employers will not need to create their silica training materials from scratch.

Based on ERG’s expert judgment, OSHA’s compliance guides, the evidence of existing training materials and other guidance from industry groups and other sources, and the fact that much of the criticism of this estimate stemmed from misunderstanding, OSHA has decided to maintain the estimate of $2.00 per worker for the cost of training materials as measured in 2008 dollars, which has been updated to $2.10 per worker in 2012 dollars.

In-house training

As a threshold matter, OSHA based its estimates in the PEA on a model in which employers would use existing in-house personnel to train their employees. Several commenters nevertheless assumed, without further explanation, that employers would hire professional trainers (presumably from outside the organization) for this purpose (see, e.g., Document ID 2171, p. 5). Several commenters representing covered industries disagreed that companies have the resources to conduct training in-house. The Institute of Makers of Explosives asserted:

> Many of our member companies are small businesses that do not have adequate in-house expertise to provide the training […] that would be required under this rule. [. . .] OSHA's assumption that employers will be able to perform these tasks on their own […] is not realistic (Document ID 2213, pp. 4-5).

Justin Dyer, from Superior Graphite, and others echoed this concern, all writing in their comments that "OSHA has further made assumptions that are without foundation, such as its assumption that training […can be] performed by an organization's own staff" (Document ID 2383, p. 2; 2355, p. 2; 3391, p. 2; 2222, p. 1; 2241, p. 2; and 2130, p. 2). In criticizing OSHA's cost estimates, none of the commenters seemed to account for the availability of existing training and guidance materials or materials that would be produced prior to the effective date of the rule. Therefore, OSHA is not persuaded that the training costs would be as high as suggested by some commenters.

In this FEA, as discussed above, OSHA has introduced costs for the additional time needed for employer familiarization with the final standard—some of which the Agency expects will be spent by a supervisor learning the details of the standard and the training requirements, selecting training materials, and preparing to deliver the training. This additional time, along with the materials the employer purchases, the free training and guidance materials provided by OSHA, and other previously discussed materials developed by industry associations, will help ensure that supervisors, or those acting as trainers, understand how the rule applies to their particular establishment and will allow them to provide training to covered workers. The Agency has therefore decided, for the purpose of determining the costs of the training requirement, to maintain its assumption that training will be conducted in-house rather than contracted to outside trainers at additional cost.

Training time: employee time

In the PEA and the FEA, OSHA has accounted for the cost of the time spent in training by both the trainers (discussed later) and the employees. These training times only cover any newly required incremental training that an employer may find necessary in order to comply with the provisions of the final silica standard and do not include time spent in training that is already required by OSHA's hazard communication standard.
In the PEA, OSHA judged that a full training session for employees would last, on average, one hour. This estimate was based on the experience and expertise of both OSHA and OSHA's contractor, ERG. However, OSHA also estimated in the PEA that 50 percent of affected establishments already provide their workers, including new hires, with training that would comply with approximately 50 percent of the proposed new training requirements, so that half of covered employers would take 60 minutes to train their workers and the other half of covered employers would take 30 minutes to train their workers. This resulted in an overall average training time of 45 minutes per worker. OSHA used this 45 minute average in the PEA as the basis for costing the training time for employees.

Several commenters provided specific time estimates for employee training, but did not provide any specific support for their belief that their estimates were more accurate than OSHA's. For example, the American Fuel and Petrochemical Manufacturers commented, without further support, that it was "assuming [that] it would take an hour to train [an employee on the silica standard] and then thirty minutes to test and review the test with each employee" (Document ID 2350, p. 7). Underlying those time estimates, however, is the commenter's assertion that OSHA is requiring employers to provide "unusually rigorous" training that would inform employees of all the silica generating operations in their workplaces, all the procedures implemented to protect employees from exposure "whether or not they specifically relate to them", the entire rule text, and a description of the medical surveillance program (Document ID 2350, p. 7). First of all, OSHA disagrees because employees outside the scope of the rule do not require training. OSHA further disagrees that it is being "unusually rigorous" by ensuring that employees can "demonstrate knowledge and understanding" of the subjects on which they are trained. That is the purpose of all training. Moreover, the commenter's estimates were also based on criticism of OSHA's estimate as relying too heavily on the existing training required to comply with OSHA's hazard communication standard:

> This misguided assumption, however, ignores the many other topics outlined in the proposed rule's training requirements: (1) RCS exposure operations, (2) specific procedures implemented to reduce RCS exposure, and (3) every other provision of the rule outside of training and medical surveillance (Document ID 2350, p. 8).

The commenter apparently did not understand that OSHA's hazard communication standard already requires employers to train their employees on the health hazards of workplace exposures, the methods that can detect silica exposures, and the specific procedures in place to protect employees from silica exposures at their workplace (see 29 CFR 1910.1200(h)(3)(i) through (iii)). The Agency therefore disagrees with the commenter's assessment of the impact of the existing hazard communication requirements and believes the commenter's 90-minute estimate for new training is inflated. The Agency agrees with the commenter that some of the training time is normally allocated to an employee's demonstration of knowledge, and the Agency believes that the time allocated for training in this FEA is adequate to provide employees with both training and knowledge assessment as required by the final standard.

A different commenter, Thermcraft Inc., suggested that an even longer training session would be necessary, commenting without further explanation that "[t]he minimum time for a training session of the complexity of the silica standard will be at least 8 hours per person" (Document ID 2370, p. 2). While an employer might devote more than an hour to training per worker in some establishments, OSHA believes 8 hours per employee is well beyond the additional time the average employer would need to comply with the new training requirements of the final rule. OSHA has thus maintained its estimate that the additional training required by the final rule will take one hour per employee.

In the PEA, however, OSHA preliminarily determined that not all employees would need the full hour of training because half would have received some silica training already. Thus, based on the existing compliance rate of half of all employees, OSHA estimated an average of 45 minutes per employee for training. Some commenters agreed with OSHA that some silica training is already being provided. Angus E. Crane, from the North American Insulation Manufacturers Association (NAIMA), testified that NAIMA itself does not do any training on silica, but the member companies do (Document ID 3588, Tr. 3976). Larry Foreman, of Grede Holdings LLC, states that employees at his firm receive specific training regarding silica during HCS training (Document ID 2298, p. 4). In his testimony, William Mann, of Verallia/Saint-Gobain Containers, commented that the training program at his establishment "currently discuss[es] silica in terms of hazard communication and in terms of [the] respiratory program" (Document ID 3584, Tr. 2864). James Boland, from The International Union of Bricklayers and Allied Craftworkers (BAC), commented that it would not be difficult to mix new training into the existing training on silica:

> Silica safety is a regular topic of BAC communications with its affiliate officers and members. In many areas, the apprenticeship and training our

> members receive includes education on the use of engineered and work process controls, silica safety and silica risks (Document ID 2329, p. 5).

Other commenters, however, disagreed with OSHA's estimate of the percentage of employees who are already receiving some silica training or the amount of training those employees receive relative to the training requirements in the proposed rule. For example, James Hardie Building Products, Inc. commented that while larger companies may have comprehensive and sophisticated training programs, smaller companies such as homebuilders and their subcontractors may not (Document ID 2322, Attachment 1, p. 171). As noted above, the AFPM asserted that OSHA had improperly assumed a 50 percent baseline compliance rate based on an overestimate of the number of requirements in the new standard that could be addressed by the employers' existing training plans (Document ID 2350, pp. 7-8).

The Agency has reviewed its baseline training estimates in light of these comments and has decided to take a more conservative approach to estimating current compliance with the training provisions in the final rule. Therefore, for this FEA, OSHA is assuming no baseline respirable crystalline silica training (other than that already required under the HCS) and that a full hour of training, on average, will be required for all covered workers. This removal of baseline respirable crystalline silica training in estimating training costs has the effect, by itself, of increasing the effective training costs in the FEA relative to the PEA by 33 percent (from an average training time, per employee, of 45 minutes to 60 minutes). OSHA recognizes that this change may lead to an overestimation of training costs for some employers.

Training time: new hires

In the PEA, OSHA assumed that all new hires would receive the full silica training from their new employer. Dr. Ruth Ruttenberg, of the AFL-CIO, asserted that the cost of training as estimated by OSHA in the PEA may be overstated because of this assumption (Document ID 2256, Attachment 4, p. 5). OSHA acknowledges that many new hires in general industry and maritime may have been previously employed in the same industry and in some cases by the same establishment, so that they might have already received respirable crystalline silica training sufficient to comply with part or all of the training requirements specified in the final rule. However, the precise number of new employees who were previously trained would be difficult to ascertain for many reasons. Employer-run training programs are unlikely to come with certificates that workers can take with them to subsequent employment. Training is also based on achieving employee knowledge and understanding, and therefore cannot be completely standardized because the standard does not specify required elements of a training program. Training would depend on the employer's facility, the tasks performed, and the equipment used. OSHA has therefore decided to maintain the assumption that all new hires will receive the full hour of silica training from their new employer, while acknowledging that this may lead to an overestimation of costs.

Training time: trainers

Whereas the total training time for existing employees can be determined by multiplying the average training time (one hour) by the number of employees, it is slightly more complicated to calculate the amount of time required for the trainers to conduct the training. There are several other factors that must be accounted for. The same unit of time for the training class (45 minutes in the PEA, and 1 hour in the FEA) also applies to the amount of time each trainer needs to teach, but OSHA also had to determine the average class size for training classes in order to determine how many trainers would be required. For the PEA, OSHA enlisted ERG's expertise to develop estimates of average class sizes as a function of establishment size. For training of current employees (i.e., initial training), ERG identified an average class size of 5 workers for establishments with fewer than 20 employees; 10 workers for establishments with 20 to 499 employees; and 20 workers for establishments with 500 or more employees. For new-hire training, ERG identified an average class size of 2 workers for establishments with fewer than 20 employees; 5 workers for establishments with 20 to 499 employees; and 10 workers for establishments with 500 or more employees. OSHA did not receive comments on these estimated class sizes and has therefore retained them for this FEA.

Other potential training costs not included

OSHA also received comments on the "fixed costs" of establishing a training program. The Institute of Makers of Explosives, Superior Graphite, and others questioned whether the training could be provided for a fixed cost (e.g., Document ID 2355, p. 2; 3391, p. 2; 2222, p. 1; 2241, p. 2; and 2130, p. 2). Thermcraft Inc. stated that the fixed cost of implementing a training program is a minimum of $5,000 (Document ID 2370, p. 2) and Lapp Insulators commented that the fixed cost of implementing a training program is a minimum of $800 (Document ID 2130, p. 2). OSHA did not assume a fixed cost for implementing a training program because the training requirements are performance-driven: the employer complies with paragraph (j)(3) of the rule when its employees can demonstrate sufficient knowledge and understanding of the silica hazards and other information specified in that standard. The actual cost for each employer will vary, which is why OSHA's estimated cost is an average. Employers are already required to have training programs under the HCS, so the costs for the additional training required by the silica final rule—which will be influenced by the employer's operations and existing training programs—are unlikely to include the cost of establishing an entire training program from scratch.

Many commenters expressed a general belief that the estimated cost of training in the PEA was too low. For example, the Leading Builders of America expressed general concern in its written comments that “the costs of activities such as training, […] were materially underestimated based upon current costs of these activities” (Document ID 2269, p. 18). This concern was echoed by other commenters (e.g., Document ID 2303, p. 12; 2384, p. 12; 1992, p. 7; 2315, p. 8; and 2023, p. 6).

OSHA has reviewed the comments generally discussing the possibility that the training provision cost is underestimated. Many of the comments provide no support for their assertions, and some appeared to be based on a lack of understanding of OSHA’s economic analysis. A comment from OSCO Industries, for example, asserted that OSHA’s training cost was underestimated because it did not include the costs of a trainer, training materials, the facility, and refreshments (Document ID 1992, p. 7). While it is true that OSHA did not factor refreshments into its costs because refreshments are not essential to the training or required by the rule, the Agency did include the costs of a trainer and the training materials. OSHA also judged that training would be conducted on-site, negating the need to pay for a separate facility. Therefore, OSHA is not increasing its training cost estimate in response to these general comments. As discussed earlier, however, OSHA is increasing the average training time per worker from 45 minutes to 60 minutes, which represents a 33 percent increase from the PEA to the FEA in the time allocated for workers to receive training. Aside from increasing the per-worker training time, the only other unit cost difference between the PEA and the FEA is that the estimated unit training costs have either been inflated from 2009 to 2012 dollars or been updated to incorporate 2012 data from data sources.

Total cost estimates

The unit costs of worker training in general industry and maritime for this FEA are summarized below in Table V-22. As shown, OSHA has estimated the annualized cost (annualized over 10 years) of initial training to be between $3.39 and $4.10 per employee and the annual cost of new- hire training as between $30.90 and $47.05 per employee, depending on establishment size. OSHA updated the hiring rate in manufacturing, used to estimate the amount of new hire training in general industry and maritime, from 2008 data to 2012 data. Based on the 2012 BLS survey data cited in Table V-22, the hiring rate used in the FEA is 25.0 percent.

Table V-23 summarizes OSHA’s estimate of the annualized costs, by NAICS industry, of the training requirements in the final standard for general industry and maritime. This estimate is based on the assumption that all workers in general industry or maritime who are within the scope of the final standard would receive the required silica training. For general industry and maritime, combined over all NAICS industries, the annualized cost to provide training as required by this paragraph is estimated to be $3.9 million annually. Table V-24 summarizes for general industry and maritime, by NAICS industry, the annualized costs of employer familiarization and employee training for the final rule. For general industry and maritime, combined over all NAICS industries, the annualized cost of employer familiarization and employee training for the final rule is $6.0 million annually.

Table V-22:
Training - General Industry and Maritime
Assumptions and Unit Costs

Cost Category	Cost			Comments/Assumptions
Instructor cost per hour	$40.38			Based on supervisor wage, adjusted for fringe benefits (BLS, 2012b)
Materials for class per attendee	$2.10			Estimated cost of $2 per worker for the training/reading materials; Inflated to 2012.
Labor Costs				
Time spent in class (min)	60			Estimated average training session time
Class size by Establishment Size Class				
	Small (<20)	Medium (20-499)	Large (500+)	
Initial training	5	10	20	
New hire training	2	5	10	
Average value of worker time spent in class	$24.75	$24.75	$24.75	Based on worker wage, adjusted for fringe benefits (BLS, 2012b)

Table V-22: (continued)
Training - General Industry and Maritime
Assumptions and Unit Costs

Annualized Training Cost per Employee by Establishment Size

	Small (<20)	Medium (20-499)	Large (500+)	
Initial training				
Value of instructor's time	$8.08	$4.04	$2.02	
Value of employee's time	$24.75	$24.75	$24.75	
Cost of materials	$2.10	$2.10	$2.10	
Total	$34.93	$30.90	$28.88	
Annualized total	$4.10	$3.62	$3.39	
New hire training				
Value of instructor's time	$20.19	$8.08	$4.04	
Value of employee's time	$24.75	$24.75	$24.75	
Cost of materials	$2.10	$2.10	$2.10	
Total	$47.05	$34.93	$30.90	
Hiring rate	25.0%			2012 annual hires rate for the manufacturing industry (BLS, 2012a)

Regulated Areas

Paragraph (e)(1) of the final standard requires employers in general industry and maritime to establish a regulated area wherever an employee's exposure to airborne concentrations of respirable crystalline silica is, or can reasonably be expected to be, in excess of the PEL.[41] Paragraph (e)(2)(i) requires employers to demarcate regulated areas from the rest of the workplace in a manner that minimizes the number of employees exposed to respirable crystalline silica within the regulated area. Paragraph (e)(2)(ii) requires employers to post signs at all entrances to regulated areas that bear the following legend (specified in paragraph (j)(2) of the standard): DANGER; RESPIRABLE CRYSTALLINE SILICA; MAY CAUSE CANCER; CAUSES DAMAGE TO LUNGS; WEAR RESPIRATORY PROTECTION IN THIS AREA; AUTHORIZED PERSONNEL ONLY. Under paragraph (e)(3), employers must limit access to regulated areas to: (A) persons authorized by the employer and required by work duties to be present in the regulated area; (B) designated employee representatives present to observe monitoring; and (C) persons authorized by the OSH Act or regulations issued under it to be in a regulated area. Under paragraph (e)(4), employers must provide each employee and designated employee representative entering a regulated area with an appropriate respirator (in accordance with paragraph (g) of the standard) and require each employee and designated employee representative to use the respirator while in a regulated area.

In this section, OSHA first explains the unit cost estimates for regulated areas in the PEA. Then, the Agency addresses and responds to comments on unit cost estimates. Next, the Agency addresses general comments about regulated area costs. Finally, the Agency explains its methodology for estimating costs in this FEA and provides cost tables.

PEA Estimates

In the PEA, OSHA estimated that one regulated area would be necessary for every eight workers in general industry and maritime exposed or expected to be exposed above the PEL. Unit costs included planning time, estimated at an initial seven hours of supervisor time (annualized at $238.63 in 2009 dollars) and one hour annually for changes (at $34.09 a year in 2009 dollars); material costs for signs and boundary markers (annualized at $63.64 in 2009 dollars); and costs of $500 annually for two disposable respirators per

[41] In the silica proposal, employers in construction would have been required either to establish a regulated area or a written access control plan whenever an employee was exposed above the PEL. This requirement for construction employers was removed from the final rule. Although OSHA received comments from the construction sector on the merits of this proposed provision, these comments are generally discussed in the Summary and Explanation section of the preamble, not in the FEA, except where the Agency judged that they may have some bearing on general industry or maritime regulated area costs.

day to be used by authorized persons (other than those who regularly work in the regulated area) who might need to enter the area in the course of their job duties.[42]

In addition, with respect to the proposed protective work clothing requirements in regulated areas, OSHA estimated annual clothing costs of $1,100 per regulated area. The protective clothing provision was deleted in the final rule, and the associated clothing costs are not included in OSHA's estimate of costs for the regulated area provision in the final rule.

Comments and Responses on PEA Unit Cost Estimates

One commenter, the American Foundry Society (AFS), was critical of OSHA's estimate in the PEA of seven hours of planning time to set up a regulated area:

> This activity may change throughout the year as exposure monitoring requires ongoing redefinition of areas. Unless the entire facility is designated as a regulated area (in which case OSHA's application numbers must be greatly increased) the area will evolve as exposures and controls change. Administration, notification and enforcement tasks may bring the set-up time to 10 days per year (Document ID 2379, Appendix 3, pp. 36-37).

Additionally, the National Federation of Independent Business (NFIB) commented:

> In practicality, small business owners will make their entire job sites regulated areas. The threshold for what could be considered a regulated area is a low one and to be safe small businesses will err on the side of caution. In OSHA's PEA, it derived lower costs by assuming small businesses would have the omniscience to know exactly what areas of a job site should be regulated areas. This assumption is disconnected from the reality of the workplace, particularly given the vaguely worded definition of regulated area included in the proposed rule (Document ID 2210, p. 7).

OSHA does not agree that AFS's estimate of 10 days for establishing regulated areas reflects a more accurate assessment of the amount of time required for establishing regulated areas, and disagrees with the assumption that the regulated area will encompass entire job sites. First, the silica exposure areas in many general industry and maritime worksites are relatively fixed and limited. Because most exposures are generated by processes utilizing fixed machinery, the entire facility need not be designated as a regulated area. Moreover, if engineering controls are applied consistently, changes in the

[42] See Table V-16 of the PEA.

designated regulated area should be infrequent. Second, as the commenters subsequently noted, posting signs or otherwise demarcating the regulated area is a relatively simple task; removing or moving some signage should be even simpler. Third, regarding the specific time estimates, AFS never explained how they derived the estimate of 10 days a year. Fourth, as engineering controls are added or improved, reducing worker exposures overall, one would expect exposures above the PEL to decline, possibly decreasing the size and number of regulated areas or eliminating the need for regulated areas entirely. Finally, OSHA accounted for the possibility that employers will need to modify regulated areas over time by including costs of one hour annually to cover such changes.

Other commenters had additional concerns about perceived costs associated with the regulated area provision, including the cost of garments, the cost for purchasing HEPA filter vacuums for cleaning regulated areas, the cost of air showers or vacuums for “de-dusting” workers exiting a regulated area, and the cost of respiratory protection associated with regulated areas. For example, John Burke, from OSCO Industries, Inc., stated:

> Currently, OSCO does not administer such "regulated" areas so the cost of compliance is largely speculative. Simply, [we] do not know how many such areas there might be and how many employees would be affected. Based on the proposed requirements anyone entering the "regulated" area is going to require respiratory protection, possibly uniform service or disposable outer garments and/or decontaminat[ion] might be required, periodic "de-dusting" of the regulated area and use of HEPA filter vacuums for cleanup. We are estimating the operational cost of a regulated area to be $25,000 to $35,000 per "regulated" area per year (Document ID 1992, p. 7).

Similarly, Wayne D’Angelo, from the American Petroleum Institute and the Independent Petroleum Association of America, commented:

> This proposed requirement will likely mean that hydraulic fracturing companies will need to provide multiple HEPA vacuum stations or air showers or something similar for workers exiting a regulated area. Such equipment would entail a considerable cost to purchase and then continually transport, unload, install, disassemble, and reinstall at site after site (Document ID 2301, p. 74).

Additionally, AFS disagreed with OSHA’s estimate of the number of workers in respiratory protection programs as a result of the regulated area provision, stating that the regulated area provision is unworkable:

> [M]ovement of affected employees could dictate designation of the entire foundry as a regulated area. Requiring visitors and employees with minimal exposure to respirable crystalline silica to be part of the respiratory control program is not reasonable. Furthermore, the PEA does not include costs associated with all workers being part of the respiratory protection program, which this provision would demand (Document ID 4035, Attachment 1, p. 9).

Alexandra Persichetti, representing Morgan Advanced Materials, North America, similarly commented that this rule would greatly expand respirator use due to “the creation of a regulated area or implementation of an access control plan” in every department where any employees would be exposed over the PEL (Document ID 2337, pp. 2-3). The regulated area provision requires the provision and use of respirators for workers entering a regulated area as well as demarcation of the regulated area. Regarding the comments from the AFS and Ms. Persichetti, the regulated area provision does not require all workers and visitors to be part of the respiratory protection program—only workers or persons who are authorized to enter or work in a regulated area. The regulated area provision in the final rule does not require employers to provide protective clothing, vacuum stations, or air showers or to decontaminate, de-dust, or clean the regulated areas with a HEPA filter vacuum. Protective clothing was required in the proposed rule, but the Agency has deleted that requirement in the final rule (as discussed in the Summary and Explanation of this provision in the preamble). While an employer might want to keep employees from inadvertently carrying silica dust from a regulated area to other parts of the workplace, the cost of any such action taken by the employer is already included in the costs of complying with the PEL through housekeeping and is not a cost attributable to the regulated area provision.

Finally, URS provided comments arguing for higher regulated area costs because: (1) OSHA had underestimated the number of visitors a day to each regulated area and, therefore, disposable respirator costs; and (2) OSHA had underestimated the number of regulated areas (Document 2307, Attachment 8, p. 23). Regarding (1), URS commented,

> OSHA had assumed two visitors each day to each regulated area. URS assumed very small facilities would have one visitor, small facilities would have five visitors, and large facilities would have 20 visitors each day to each regulated area. … All of these categories would greatly increase as the size of the facility gets larger. URS actually decreased the number of visitors to regulated areas for very small facilities from the OSHA estimate (Document 2307, Attachment 8, p. 23).

The Agency believes that URS has misunderstood how OSHA estimated unit costs, including respirator costs, for regulated areas. URS seems to believe that each establishment with at least one worker exposed above the PEL will have one regulated area with two visitors each day. However, OSHA's estimate reflects one regulated area for every eight workers, not for every establishment. For example, if a large establishment has 80 workers exposed above the PEL, OSHA estimated there to be ten regulated areas (80 workers/8 workers per regulated area). As URS stated, OSHA estimated there to be two visitors each day to each regulated area. In a facility with ten regulated areas, this amounts to 20 visitors each day to regulated areas at that large establishment, just as URS estimated. Thus, the Agency does not believe that URS's adjustment is significantly different from OSHA's estimate in the PEA. OSHA did not adopt URS's visitor adjustment because OSHA's costing unit is the regulated area, not the establishment.

Regarding (2), URS asserted that many more workers would exceed the PEL of 50 $\mu g/m^3$ than OSHA estimated in the PEA. The Agency has already addressed, and rejected, this URS assertion in the technological feasibility, industry profile, and engineering control cost sections of this FEA. Furthermore, in its cost model, URS applied regulated area costs to every facility in an industrial sector whenever more than 25 percent of the workers in any job were initially found to be above the PEL. OSHA rejects this modification because initial overexposures may not persist after engineering controls are applied. However, as explained in the section in this chapter of the FEA on respiratory protection costs and below in the presentation of estimated regulated area costs for this FEA, OSHA increased its estimates of the number of respirators, and proportionately the number of regulated areas, needed in general industry and maritime to reflect changes in the technological feasibility analysis (in Chapter IV of this FEA). Also, as described below, OSHA's approach to estimating the number of respirators needed under the final rule—from, in the PEA, all workers that the Agency's technological feasibility analysis has determined will require respirator use *or* 10 percent of workers currently exposed above 50 $\mu g/m^3$ whichever is larger, to, in this FEA, all workers that the Agency's technological feasibility analysis has determined will require respirator use *and* 10 percent of the remaining workers currently exposed above 50 $\mu g/m^3$—further increased the estimated number of regulated areas.

<u>Comments on methods of demarcation</u>

Some commenters expressed concern that employers would be required to undertake extensive and expensive building construction to their existing facility layouts in order to adhere to the regulated area requirements. For example, Gregory Timmons, from Eramet and Bear Metallurgical Company, wrote:

> Bear's facility consists of an open process building which cannot be broken down into regulated areas by constructing partitions, due to the

> necessary use of large machinery to move the products between areas. In order to establish a regulated area Bear would need to build a new facility that would accommodate such a breakdown… (Document ID 2082, p. 7).

Jeff Wherry, of the Unified Abrasives Manufacturers Association, raised a similar issue, and expressed concern that employers would need to spend money to construct barriers before the new engineering controls were required to be in place. He stated:

> Regulated [a]reas and [a]ccess [c]ontrol clearly requires demarcation of areas expected to be in excess of the PEL. Proper [d]emarcation would require the construction of a physical separation on these work stations yet this construction task appears to be exempt from the 1 year [e]ngineering controls extension granted under Start-up dates (k)(2)(ii) (Document ID 3398, p. 2).

James Toscas, from the Precast/Prestressed Concrete Institute (PCI), also submitted comments on the costs of constructing enclosures for regulated areas, but his comments were specific to abrasive blasting:

> A plant with limited yard space doing outdoor abrasive blasting would need to enclose the work area with a building or other enclosure at an estimated cost of $300,000 to $1,000,000 (Document ID 2276, p. 5).

OSHA notes, with respect to this comment, that the large majority of abrasive blasting occurs in construction where there is no regulated area requirement, and that the regulated area provision does not require physical enclosure to demarcate the space. Also, the OSHA standard covering abrasive blasting (29 CFR 1910.94) already contains provisions for controlling exposures outside the immediate blasting area. For the purposes of estimating costs, the Agency assumes full compliance with existing standards, so the incremental costs of the regulated area provision in the final silica rule for establishments where abrasive blasting is being performed will be minimal.

Other commenters noted that demarcating areas is both common and straightforward, even in relatively open work areas—even if the demarcated areas are not being referred to as "regulated areas." Kenny Jordan, the Executive Director of the Association of Energy Service Companies, in response to a question on how companies try to limit exposures by limiting the numbers of people who are in the exposure area, testified:

> [Those who may be exposed are] identified by job title, the scope, where those particular areas are. And the rest of the employees…they know during the [Job Safety Analysis]… that they are to stay out of those areas. Usually, they will rope those areas off and just say you

> have no business in here, you have no job function in here, don't go in here (Document ID 3589, Tr. 4079-4080).

Similarly, Dr. Franklin Mirer, speaking on behalf of the AFL-CIO, testified:

> You post signs. I mean, in a foundry the regulated area is probably a workstation or a series of workstations… you determine the extent of the dust cloud, assuming it's still there, and you post it [the sign]. … this is like a simple concept, not something very difficult (Document ID 3578, Tr. 1003).

While the physical separation of work areas might minimize worker silica exposures, the regulated area provision does not obligate establishments to construct barriers between work areas. As discussed in more detail in the preamble explanation of this requirement, this provision only requires employers to demarcate the areas where exposures exceed or can reasonably be expected to exceed the PEL. The Agency does not stipulate specific methods of demarcation—other than signage—so employers are not required to take on the types of costly modifications described by the commenters. As in the proposal, OSHA has left the method of demarcation to the employer in the final standard for general industry, so long as the demarcation is accomplished in a manner that minimizes the number of employees exposed to respirable crystalline silica within the regulated area. Cones, stanchions, tape, barricades, lines, or textured flooring may each be effective means of demarcating the boundaries of regulated areas.

The Agency notes, however, that the FEA does include costs for enclosures and control rooms for a number of operations for employers in general industry and maritime, but these enclosures and control rooms are engineering controls meant to reduce exposures, not to demarcate regulated areas. These controls and costs are therefore included in the engineering control cost analysis earlier in this chapter.

Comments on facility downtime

Regarding Mr. Wherry's concern about the timing of the regulated areas requirement, this has been resolved by a change in the final rule: OSHA will not begin enforcing any requirements of the final rule until two years after the effective date of the rule (and five years after the effective date of the rule for hydraulic fracturing operations in the oil and gas industry), giving employers ample time to comply.

Charles Drevna, of American Fuel & Petrochemical Manufacturers (AFPM), argued that implementing regulated areas would be of such magnitude as to involve facility downtime and lost productivity:

> AFPM's members will endure the direct costs of compliance up front; e.g., implementing regulated areas or access control plans…But they will also be forced to endure lost productivity from the cumulative compliance delays that will prevent the facility from re-entering production (Document ID 2350, p. 8).

OSHA does not believe that the establishment of a regulated area would be so complex or time-consuming as to require a facility to shut down just for that purpose. Furthermore, the Agency notes that most facilities periodically have downtime for maintenance or other purposes. Even if the process of establishing a regulated area is more complicated than estimated in this FEA, given the two years provided for employers to come into compliance with this final rule, and the fact that most facilities will have periodic downtime for other purposes, there is no reason to believe that facilities would incur additional downtime just to comply with this provision of the final rule.[43]

Final cost estimates

Other than the issues raised above, OSHA did not receive comments on the other elements of the PEA cost analysis for regulated areas in general industry or maritime. The Agency has therefore retained the same general cost structure used in the PEA, with the only changes being to adjust costs to 2012 dollars and to remove the costs for protective clothing (not required in the final rule). As before, OSHA estimates that one regulated area would be necessary for every eight workers in general industry and maritime exposed or expected to be exposed above the PEL.[44] Planning time for a regulated area is estimated to be an initial seven hours of supervisor time (initial cost of $282.67 in 2012 dollars), and one hour for changes annually (at a cost of $40.38 in 2012 dollars); material costs for signs and boundary markers (annualized at $73.52 in 2012 dollars); and costs of $526 annually for two disposable respirators per day to be used by authorized persons (other than those who regularly work in the regulated area) who might need to enter the area in the course of their job duties.[45] Note that these disposable

---

[43] See Chapter V of this FEA, Engineering Control Costs: *Accounting for Costs of Downtime*, for further discussion of the issue of downtime.

[44] This is the same methodology OSHA used to determine the number of regulated areas in the PEA. OSHA solicited comment on its estimate of one regulated area for every 8 workers exposed above the PEL but did not receive any comments on this estimate. Thus, the Agency has retained the estimate for this FEA.

[45] The estimate of two disposable respirators per regulated area per day is intended to represent an *average* for all affected regulated areas in general industry and maritime—some will inevitably need more, some fewer; and many will require none. Establishments with more than 8 workers with exposures above the PEL will be costed as having more than one regulated area and, accordingly, more than two disposable respirators per day.

respirator costs incurred by authorized persons who need to enter a regulated area (other than those workers who regularly work in a regulated area and are required to wear a respirator to comply with the PEL requirements of the final rule) are not included in the respiratory protection costs presented in the respiratory protection cost section.

Table V-25 shows OSHA's cost assumptions and unit costs in general industry and maritime for the regulated area provision of the final rule. Overall, OSHA estimates that each regulated area in general industry and maritime would, on average, cost employers $666 annually. OSHA expects that regulated areas will be established: (1) for all workers that the Agency's technological feasibility analysis has determined will require respirator use; and (2) for ten percent of the remaining workers currently exposed above 50 $\mu g/m^3$ at covered workplaces.[46] In all, OSHA estimates that there will be 3,958 regulated areas annually in general industry and maritime. Table V-26 shows total estimated costs for regulated areas in general industry and maritime of approximately $2.6 million annually and also provides a breakdown of costs by NAICS industry.

[46] This additional 10 percent is designed to cover circumstances in which engineering controls do not reduce exposure levels to the extent anticipated by the technological feasibility analysis (e.g., because controls are not selected, used, or maintained properly).

Table V-25:
Cost Assumptions for Regulated Areas - General Industry and Maritime

	Parameter	Unit cost	Comment
Regulated area setup			
Time to set up regulated area (hours) - First year only	7	$282.67	Estimated by ERG. Valued at supervisor's wage (BLS, 2012b)
Annual time for changes to regulated areas (hours)	1	$40.38	Estimated by ERG. Valued at supervisor's wage (BLS, 2012b)
Annualized regulated area set up costs		$73.52	Annualized set up costs plus annual costs
Respirators			
Respirators per authorized person per day	2		Assumes 2 disposable respirators used per day
Cost - disposable particulate respirator (N95)		$1.05	$1.00 per respirator, typical cost for N95 disposable respirator (Lab Safety Supply, 2010); inflated to 2012
Respirator cost - annual per authorized employee		$526	
Materials			
Hazard tape per job (300 ft)		$6.10	$5.80 per roll, (Lab Safety Supply, 2010); inflated to 2012
Warning signs (6)		$159.64	$25.30 per sign; (Lab Safety Supply, 2010); inflated to 2012
Warning signs - annualized cost		$60.83	Assumes 3 year life for signs
Annualized materials cost per area		$66.93	Sum of hazard tape and annualized warning sign costs
Total annualized cost per area		$666	Sum of respirator, materials and labor cost
Assumptions			
Average number of workers above the PEL per regulated area	8		
Number of working days per year	250		
Share of workers needing regulated areas (percent of at-risk workers initially exposed above the PEL)	10.0%

Written Exposure Control Plan

A written exposure control plan provision was not included in the silica proposal, and no costs for a written exposure control plan were estimated in the PEA. Paragraph (f)(2) of the final standard for general industry and maritime contains requirements for a written exposure control plan. The Summary and Explanation section of the preamble provides a thorough explanation of the reasoning behind the inclusion of the written exposure control plan provision in the final standard.

As specified in paragraph (f)(2)(i), the employer must establish and implement a written exposure control plan that contains at least the following elements: (A) a description of the tasks in the workplace that involve exposure to respirable crystalline silica; (B) a description of the engineering controls, work practices, and respiratory protection used to limit employee exposure to respirable crystalline silica for each task; and (C) a description of the housekeeping measures used to limit employee exposure to respirable crystalline silica. Under paragraph (f)(2)(ii), the employer must review and evaluate the effectiveness of the written exposure control plan at least annually and update it as necessary.

As shown in Table V-27, unit costs for a written exposure control plan were calculated based on establishment size. OSHA assumed, for costing purposes, that a supervisor would develop and update the written exposure control plan for each establishment, spending one hour for establishments with fewer than 20 employees (very small establishments), four hours for those establishments with between 20 and 499 employees, and 16 hours for those establishments with 500 or more employees. OSHA estimated that one hour would be sufficient for very small establishments because there is, on average, slightly more than one worker covered by the standard per very small establishment in general industry and maritime. In general, the Agency judges the number of employees per establishment to be a fair proxy for the amount of time required to develop a written exposure control plan. OSHA expects that both the number of work stations covered and amount of time needed to control exposures will increase with the number of employees involved. Larger establishments may encounter a greater diversity of exposure sources, as well a greater challenge of coordinating control strategies for different tasks.

OSHA further estimated that the additional supervisory time needed to review and evaluate the effectiveness of the plan, and to update it as necessary, will also vary by establishment size for the same reasons as described above for the establishment of the original plan. OSHA is estimating 0.5 hours for establishments with fewer than 20 employees, two hours for those with between 20 and 499 employees, and eight hours for those with 500 or more employees to perform the annual review and update. The Agency expects that no other labor or materials will be required to implement the plan because any such labor or materials would be accounted for in the cost of the regulated area provision, so the sole cost for this provision is the time it will take to develop, review, and update the plan.

The annualized unit costs for the written exposure control plan presented in Table V-27 have been applied to the employers in general industry and maritime covered by the standard—in all, 51,949 establishments with fewer than 20 employees, 24,271 establishments with between 20 and 499 employees, and 641 establishments with 500 or more employees. The annualized costs, broken out by NAICS industry, are shown in Table V-28. For general industry and maritime, the total annualized cost of developing, reviewing, and updating the written exposure control plan is $4.1 million.

Table V-27: Unit Costs for a Written Exposure Control Plan in General Industry or Maritime

Establishment size	Small (<20)	Medium (20-499)	Large (500+)	
Time to develop plan (hours)	1.0	4.0	16.0	
Annualized cost for plan development	$5.75	$23.00	$91.99	One-time cost to develop plan annualized over ten years. Valued at weighted average of supervisors' hourly wage rate for affected industries (covered by general industry and maritime standard) of $40.38 per hour. Wages include fringe benefits. (BLS, 2012b)
Time for annual review and updating (hours)	0.5	2.0	8.0	
Annual review cost	$20.19	$80.76	$323.05	Annual cost to review plan. Valued at weighted average of supervisors' hourly wage rate for affected industries (covered by general industry and maritime standard) of $40.38 per hour. Wages include fringe benefits. (BLS, 2012b)
Total annualized cost	$25.94	$103.76	$415.04

Combined Control, Respirator, and Program Costs

Table V-29 shows that the combined compliance costs for general industry and maritime to comply with the final silica rule are approximately $370.8 million annually. These costs include $238.1 million annually for controls and $10.5 million annually for respirators to meet the proposed PEL of 50 $\mu g/m^3$. The remaining $122.2 million annually are to meet the ancillary provisions of the proposed rule. These ancillary annual costs consist of $79.8 million for exposure monitoring; $29.7 million for medical surveillance; $6.0 million for training and familiarization; $4.1 million for written exposure control plan; and $2.6 million for regulated areas.

Table V-B-1 in Appendix B presents estimated compliance costs by NAICS industry code and program element for small business entities (as defined by the Small Business Act and the Small Business Administration's implementing regulations; see 15 U.S.C. 632 and 13 CFR 121.201) in general industry and maritime, while Table V-B-2 presents estimated compliance costs, by NAICS code and program element, for very small entities (fewer than twenty employees) in general industry and maritime.

Table V-29: Combined Annualized Compliance Costs for General Industry and Maritime

NAICS	Industry	Control Costs	Respirators	Exposure Assessment	Medical Surveillance	Control Plan	Regulated Area	Training & Familiarization	**Total**
213112	Support Activities for Oil and Gas Operations	$84,432,467	$379,743	$9,045,642	$2,869,133	$38,287	$933,458	$229,021	**$97,927,752**

*Rail transportation costs reflect the Agency's judgment that employers performing construction activities will achieve compliance by following Table 1.

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA (2016).

COSTS FOR THE CONSTRUCTION INDUSTRY

Estimation of the costs of the final rule for the construction industry is broken out in this section for three categories of costs: (1) control costs to comply with Table 1 when available, and the PEL of 50 $\mu g/m^3$ when Table 1 is not available; (2) respirator costs, in those cases where engineering controls are not sufficient to guarantee compliance with Table 1 or the PEL; and (3) "program" and familiarization costs to comply with the ancillary provisions of the rule.

As discussed in Chapter III (and summarized in Table III-12) of this FEA, OSHA judged that there was no baseline compliance in the construction sector with any of the ancillary provisions (but 100 percent baseline compliance with the existing Hazard Communication Standard's training requirements); 56 percent baseline compliance with the respirator use and respirator program requirements; and 44 percent baseline compliance with the engineering control requirements for workers currently below the final PEL.

Construction Control Costs

In both the PEA and this FEA, OSHA determined that employers, in order to minimize exposure monitoring costs, would select appropriate controls from Table 1. The final estimate for control costs, however, includes Table 1 control costs for a larger number of employees than in the PEA. For the purpose of estimating control costs in the PEA, OSHA examined all of the employers with employees engaged in Table 1 tasks but judged that only a subset of those employers (those with workers exposed above the proposed silica PEL) would require additional engineering controls. For this final rule, OSHA has judged, for costing purposes, that all of the construction employers with employees performing any task covered in Table 1 will adopt the engineering controls for that task as specified in Table 1. Thus, in this FEA, OSHA took the more conservative approach—which may result in an overestimate of costs—of identifying the cost of controls for all employers with employees engaged in Table 1 tasks, not just the subset of employers with employees exposed above the PEL. However, as discussed in Chapter III of this FEA, OSHA did adjust control costs to reflect the 44 percent of workers in construction currently exposed at or below the PEL who are estimated to be in baseline compliance with the Table 1 requirements.

OSHA is also likely overestimating the cost of controls for another reason. If the employer is able to demonstrate by objective data, or other appropriate means, that worker exposures would be below the action level under any foreseeable conditions, the employer would be excluded from the scope of the final rule. These employers would not require additional controls. OSHA did not have sufficient data to identify this group of employers and did not try to reduce the costs to reflect this group, so OSHA's estimate of costs is therefore overestimated by an amount equal to the costs for those employers engaged in covered construction tasks but excluded from the scope of the rule.

A few tasks involving potentially hazardous levels of silica exposure are not covered in Table 1. Employers would have to engage in exposure monitoring for these tasks pursuant to paragraph (d) and use whatever feasible controls are necessary to meet the PEL specified in paragraph (d)(1). For example, tunnel boring and abrasive blasting are not covered by Table 1 and are therefore addressed separately in this cost analysis. Although several commenters identified various other activities that they believed were not covered by Table 1 that could result in crystalline silica exposure over the PEL (Document ID 2319, pp. 19-21; 2296, pp. 8-9), some of these activities were simply detailed particularized descriptions of included activities. For example, overhead drilling is addressed in the FEA, Chapter IV-5.4 Hole Drillers Using Handheld or Stand-Mounted Drills, and the demolition of concrete and masonry structures is addressed in the FEA, Chapter IV-5.3 Heavy Equipment Operators. For the remainder, the available exposure data did not indicate that these activities resulted in a serious risk of exposure to respirable crystalline silica (see Chapter III of this FEA: Industry Profile, Construction, Public Comments on the Preliminary Profile of Construction and Summary and Explanation, Scope and Application); furthermore, these other activities could be addressed using the controls identified in this FEA. Because OSHA did not have sufficient data to identify a significant number of silica exposures above the PEL of 50 $\mu g/m^3$ for these activities, the Agency did not include costs for controlling silica exposures during these activities. Nevertheless, to the extent that employers find it necessary to implement controls for any activity that OSHA did not explicitly include in this analysis, this FEA shows that those controls are clearly economically feasible.

The control costs for the construction standard are therefore based almost entirely on the tasks and controls specified in Table 1. Most of the remainder of this section is devoted to developing the Agency's costs of applying appropriate engineering controls to construction activities as required by Table 1 of the final standard. These costs are generated by the application of known dust-reducing technology, such as the application of wet methods or ventilation systems, as detailed in the technological feasibility analysis in Chapter IV of this FEA. These costs are discussed first, and, following that, the control costs for tasks not specified in Table 1 are separately estimated.

Table 1 has undergone considerable change between the PEA and the FEA. The entries included in the table have been modified with some tasks being added and some being removed.[47] In addition, the methods of controlling exposures that Table 1 requires for certain tasks have changed in response to comment and additional analysis. Excluding changes to respirator requirements, which are addressed in the preamble and in this chapter, significant and substantive revisions to Table 1 that have the potential to impact control costs include:

- New entries on Table 1—
    - Handheld power saws for cutting fiber-cement board (with blade diameter of 8 inches or less)
    - Rig-mounted core saws and drills
    - Dowel drilling rigs for concrete
    - Small drivable milling machines (less than half-lane)
    - Large drivable milling machines (half-lane and larger for cuts of any depth on asphalt only and for cuts of four inches in depth or less on any substrate)
    - Heavy equipment and utility vehicles used to abrade or fracture silica-containing materials (e.g., hoe-ramming, rock ripping) or used during demolition activities involving silica-containing materials
    - Heavy equipment and utility vehicles for tasks such as grading and excavating but not including: demolishing, abrading, or fracturing silica-containing materials
- Removed entry for drywall finishing from Table 1
- Revised entries on Table 1--
    - Drivable saw entry revised to permit outdoor use only
    - Portable walk-behind or drivable masonry saws divided into two entries—walk-behind saws and drivable saws
    - Handheld drills entry revised to include stand-mounted drills and overhead drilling
    - Combined entries for vehicle-mounted drilling rigs for rock and vehicle-mounted drilling rigs for concrete
    - Milling divided into three tasks—walk-behind milling machines and floor grinders; small drivable milling machines (less than half-lane); and large drivable milling machines (half-lane and larger for cuts any depth on asphalt only and for cuts of four inches in depth or less on any substrate)

[47] OSHA acknowledges the nomenclature changed from "Operation" in the NPRM to "Equipment/Task" in the final rule.

- Heavy equipment used during earthmoving divided into two tasks—(1) heavy equipment and utility vehicles used to abrade or fracture silica-containing materials (e.g., hoe-ramming, rock ripping) or used during demolition activities involving silica-containing materials, and (2) use of heavy equipment and utility vehicles for tasks such as grading and excavating but not including: demolishing, abrading, or fracturing silica-containing materials
- Revised crushing machines entry to require equipment designed to deliver water spray or mist for dust suppression and a ventilated booth or remote control station.

In addition to the new and revised tasks in Table 1, some of the controls and specifications required by Table 1 were revised for this final rule, including removal of "Notes/Additional Specifications" from individual Table 1 entries and addition of substantive paragraphs after the table. Those revisions include:

- Revised or newly required controls/specifications for Table 1 tasks—
    - Revised requirement to operate and maintain tools/machine/equipment in accordance with manufacturer's instructions to minimize dust emissions.
    - Revised specifications for dust collectors to require they provide at least 25 cubic feet per minute (cfm) of airflow per inch of blade/wheel diameter (for some, but not all entries that include a dust collection system as a control method).
    - Revised specification for dust collectors to require they provide the air flow recommended by the tool manufacturer, or greater, and have a filter with 99 percent or greater efficiency and a filter-cleaning mechanism (for some, but not all entries that include a dust collection system as a control method). The entries for handheld grinders for mortar removal (i.e., tuckpointing) and handheld grinders for uses other than mortar removal require a cyclonic pre-separator or filter-cleaning mechanism.
    - Revised requirement for tasks indoors or in enclosed areas to provide a means of exhaust as needed to minimize the accumulation of visible airborne dust (paragraph (c)(2)(i)).
    - Added requirement for wet methods to apply water at flow rates sufficient to minimize release of visible dust (paragraph (c)(2)(ii)).
    - Revised specifications for enclosed cabs to require that cabs: (1) are maintained as free as practicable from settled dust; (2) have door seals and closing mechanisms that work properly; (3) have gaskets and seals that are in good condition and working properly; (4) are under positive pressure maintained through continuous delivery of fresh air; (4) have intake air that is filtered through a filter that is 95% efficient in the 0.3-10.0 µm

range (e.g., MERV-16 or better); and (5) have heating and cooling capabilities (paragraph (c)(2)(iii)).

  - Added requirement to operate handheld grinders outdoors only for uses other than mortar removal, unless certain additional controls are implemented.

  - Added wet methods option for use of heavy equipment and utility vehicles for tasks such as grading and excavating but not including: demolishing, abrading, or fracturing silica-containing materials.

  - Added requirement to use wet methods when employees outside of the cab are engaged in tasks with heavy equipment used to abrade or fracture silica-containing materials (e.g., hoe-ramming, rock ripping) or used during demolition activities involving silica-containing materials.

- Removed controls/specifications for Table 1 tasks—

  - Removed requirements to change water frequently to avoid silt build-up in water.

  - Removed requirements to prevent wet slurry from accumulating and drying.
  - Removed requirements to operate equipment such that no visible dust is emitted from the process.
  - Removed local exhaust dust collection system option and requirement to ensure that saw blade is not excessively worn from the entry for handheld power saws.
  - Removed requirement to eliminate blowing or dry sweeping drilling debris from working surface from the entry for handheld and stand-mounted drills (including impact and rotary hammer drills).
  - Removed additional specifications for dust collection systems for vehicle-mounted drilling rigs for concrete (e.g., use smooth ducts and maintain duct transport velocity at 4,000 feet per minute; provide duct clean-out points; install pressure gauges across dust collection filters; activate LEV before drilling begins and deactivate after drill bit stops rotating).
  - Removed requirements to operate grinder for tuckpointing flush against the working surface and to perform the work against the natural rotation of the blade.
  - Removed dust collection system option and requirement to use an enclosed cab from crushing machines.

These and other changes to Table 1 are discussed in detail in Section XV: Summary and Explanation of the preamble. While Table 1 has changed with regard to the tasks included and the control methods required, OSHA's methodology used to estimate the costs of controls for the construction industry has remained basically the same as that explained in detail in the PEA, with steps added (and explained in the following discussion) to address cost issues raised during the comment period and the updates and revisions to Table 1. OSHA summarizes the methodology in the following discussion, but the PEA includes additional details about the methodology not repeated in this FEA. OSHA adopted the control cost methodology developed by ERG (2007a) for the PEA and subsequently for this FEA. In order to provide some guidance on that cost methodology, OSHA itemizes below the three major steps, with sub-tasks, used to estimate control costs in construction, with two additional steps added for this FEA to estimate the number of affected workers by industry and equipment category[48] (numbered Step 3) and to estimate control costs for self-employed persons (numbered Step 5):

- Step 1: Baseline daily costs, relative costs of controls, and labor share of value
  - Use RSMeans (2008) estimates to estimate the baseline daily cost for every representative job associated with each silica equipment category (Table V-30) and unit labor and equipment costs (Table V-31).
  - Use vendors' equipment prices and RSMeans estimates to estimate the unit cost of silica controls (Table V-32), and estimate the productivity impact for every silica control and representative job, to be added to the cost of the control applied to a particular job (Table V-33).[49]
  - Use the costs from Tables V-32 and V-33 to calculate the incremental productivity impact, labor cost, and equipment cost for each representative job when controls are in place (Table V-34).
  - Using Tables V-30 and V-34, calculate the percentage incremental cost of implementing silica controls for each representative job (Table V-35).
  - Calculate the weighted average incremental cost (in percentage terms) and labor share of total costs for each silica job category (outdoors and indoors estimated separately) using the assumed distribution of associated representative jobs (Tables V-36a and V-36b).

- Step 2: Total value of activities performed in all Table 1 silica equipment categories
  - Match BLS Occupational Employment Statistics OES occupational classifications for key and secondary workers with the labor requirements for each equipment category (Table V-37) and estimate the full-time-equivalent (FTE) number of employees by key and secondary occupations working on

[48] The term "equipment category" as used here matches the broad headings used in the Technological Feasibility analysis. Later on in this section, OSHA identifies which Table 1 tasks are included in each equipment category.

[49] This latter sub-step was performed in the PEA, but it was inadvertently omitted in the text summary.

each silica task (Tables V-38a and V-38b).

- o Based on the distribution of occupational employment by industry from OES, distribute the full-time-equivalent employment totals for each equipment category by NAICS construction industry (Table V-39).

- Step 3: Total affected employment by industry and equipment category
  - o Disaggregate construction industries into four distinct subsectors based on commonality of construction work (Table V-40a) and then estimate the percentage of affected workers by occupation, equipment category, and construction subsector (Table V-40b).
  - o Use the percentage of affected workers by occupation, equipment category, and construction subsector (Table V-40b) to obtain total affected employment by occupation (Table V-41) and total affected employment by industry and task (Table V-42).

- Step 4: Aggregate silica control costs (not including self-employed persons)
  - o Using the FTE employment totals for each task by NAICS construction industry (Table V-39) and the mean hourly wage data from OES, adjusted for fringe benefits, calculate the annual labor value of each Table 1 silica activity by NAICS construction industry (Table V-43).
  - o Using the labor share of value calculated for each activity performed in a silica-related equipment category (Table V-43), estimate the total value of each Table 1 equipment/task category by industry (Table V-44).
  - o Estimate the distribution of silica work by equipment type, duration of activity, and location of activity (Table V-45).
  - o Multiply the total value of Table 1 construction activities requiring controls (Table V-44) by the percentage incremental cost associated with the controls required for each activity that uses equipment in each equipment category (Tables V-36a and V-36b) and weighted by the percentage of tasks performed outdoors and indoors/within an enclosed space (Table V-45), to calculate the total control costs, adjusted for baseline compliance, by Table 1 equipment category and industry (Table V-46).
  - o Calculate engineering control costs for silica-generating construction activities not covered in Table 1 (Tables V-47a and V-47b)
  - o Combine the control costs for Table 1 construction activities (Table V-46) and the control costs for construction activities not covered in Table 1 (Tables V-47a and V-47b) to calculate the total control costs by equipment category and construction industry (Table V-48).

- Step 5: Adjust aggregate silica control costs to include self-employed persons
  - o Use data from the BLS Current Population Survey (BLS, 2013) to estimate the ratio of the number of self-employed persons to the number of employees

by occupation (Table V-49) and then redo the estimation after restricting self-employed persons to just those occupations covered by OSHA that potentially involve exposure to hazardous levels of respirable crystalline silica (Table V-50).

- o Multiply the FTE rate for each occupation (from Tables V-38a and V-38b) by the number of self-employed workers and employees in that occupation (from Table V-50) to obtain the ratio of FTE self-employed persons to FTE employees and then reduce that ratio to reflect only self-employed persons working on a multi-employer worksite where the work of the self-employed person cannot be isolated in time or space (Table V-51).
- o Increase the earlier estimate of control costs by equipment category and industry (Table V-48) by the adjusted FTE ratio of self-employed workers (Table V-40) to calculate total control costs by equipment category and industry with self-employed persons included (V-52).

Baseline Costs of Representative Jobs

Baseline Job Safety Practices

OSHA's cost estimates address the extent to which current construction practices incorporate silica dust control measures. Thus, OSHA's baseline reflects such safety measures as are currently employed. To the limited extent that silica dust control measures are already being employed, OSHA has reduced the estimates of the incremental costs of silica control measures to comply with the final PEL. As discussed in Chapter III of this FEA and summarized in Table III-22, OSHA estimates that 44 percent of workers with exposures currently below the final PEL are using the controls required in Table 1.

Representative Jobs

Unlike the situation with the general industry/maritime standard, OSHA does not have extensive data identifying the number of employees engaged in Table 1 tasks or the duration of their exposure to respirable crystalline silica during those tasks. Therefore, ERG developed a model based on "representative jobs" for the purposes of identifying the control costs necessary to comply with Table 1. Using RSMeans *Heavy Construction Cost Data* (RSMeans, 2008), which is a data source frequently used in the construction industry to develop construction bids, ERG (2007a) defined representative jobs for each silica-generating activity described in the feasibility analysis. These activities and jobs are directly related to the silica-related construction activities described in the technological feasibility chapter of the FEA. ERG (2007a) specified each job in terms of the type of work being performed (e.g., concrete demolition), the makeup of the crew necessary to do the work, and the requisite equipment. For example, for the impact drilling activity, ERG defined three representative jobs for various types of demolition work. For each job, ERG derived crew composition and equipment requirement data from the RSMeans (2008) guide and then calculated the per-day baseline cost from the labor rates, equipment charges, material costs, and overhead and profit markups presented in the cost estimating guide.

Table V-30 shows the specifications for each representative job and the associated daily labor, equipment, and material costs. Table V-31 provides a summary of the labor rates and equipment charges used to estimate the daily cost of each representative construction job in Table V-30. Note that the data on hourly wages with overhead and profit in Table V-31, obtained from RSMeans (2008), are employed here to be consistent with other RSMeans cost parameters to estimate the baseline costs of representative jobs. The RSMeans estimates are published for the purpose of helping contractors formulate job bids, so ERG relied on that data as an indicator of the amount of labor and time that would be required for each of the representative jobs in the cost model developed for this analysis. These RSMeans estimates are later used only to determine two ratios: the labor share of the costs of representative construction jobs and the percentage increase in the cost of each representative job due to the addition of controls to comply with the final rule. Everywhere else in this cost chapter, when the actual wages were important to the calculations and are expressed as fixed amounts and not just ratios, OSHA used 2012 BLS wage data (BLS, 2012b), which include fringe benefits but not overhead and profit.

For example, as shown in Table V-30, Job 4 for grinding and tuckpointing floors using hand-held tools category involves a simple crew (i.e., only two cement finishers). Other crews, such as that for impact drilling (Job 12), involve several workers, including an equipment operator, a labor foreman, and laborers. The daily labor cost for Job 4 is calculated at $896.80. The total daily costs of labor, equipment, and materials for representative jobs range from $427.42 per day for hand-held milling, wall grinding (Job 7) to $7,295.85 for asphalt cold planing and cleaning (Job 20).

SBREFA Panel Comments on Cost Methodology for Construction

Prior to the publication of the PEA, one SBREFA commenter[50] criticized the methodology for estimating engineering control costs on the grounds that while RSMeans estimates were used to establish the marginal costs of new controls (as a percentage of baseline costs), average wage rates (including fringe benefits) from the BLS *Occupational Employment Statistics Survey*, 2000, were used to calculate the value of at-risk tasks without providing a justification for not using RSMeans wage data (Document ID 0968, p. 13). Since BLS wage rates are significantly lower than the RSMeans rates used by ERG in earlier parts of the analysis, the commenter argued that this would significantly lower the base to which the marginal cost factors are applied to estimate compliance costs (Id.). This SBREFA commenter further argued that the RSMeans estimates are likely to be on the high end of estimated wages because they only cover unionized labor and are therefore likely to lead to high estimates of impacts. The commenter then recommended that more appropriate indexed labor wage costs be computed and used consistently throughout the analysis (Document ID 0968, p. 14).

First, the commenter's concern is misplaced because the choice of the RSMeans source for estimates does not skew the results in the manner suggested by the commenter; nor does it even have a significant impact on the cost analysis. The RSMeans estimates was used only to develop the *ratio* of costs for the representative jobs to the total labor cost and then to determine the incremental compliance costs as a percentage of the total and the share (percentage) of project value with controls accounted for by labor. Because the RSMeans estimates are organized by project cost to assist contractors in bid planning, that data set is the logical choice for this purpose over BLS data, which provides wage data but does not provide comparable costs for projects. Dividing project labor value by the labor share of project value yields an estimate of total project value.

The absolute level of the RSMeans wage and equipment cost levels do not directly affect the resultant aggregate compliance costs. While lower wage rates would lower the baseline costs of the representative jobs, it does not follow that control costs as a percent of baseline costs would also be lower. In fact, if lower wage rates are combined with the same equipment costs, the equipment part of incremental control costs would be a *higher* percentage of total baseline costs. Only the labor share (percentage) of baseline costs, along with the incremental compliance costs as a percent of baseline costs, are taken from the analysis of representative costs and used in the subsequent estimation of aggregate costs. The absolute levels of the wage rates and equipment costs taken from RSMeans do not directly enter the aggregate cost analysis.

---

[50] This commenter was a third-party stakeholder who was not a SER.

Second, OSHA notes that the BLS wage data, on which the aggregate compliance costs are based, are obtained from a statistically valid, national survey of employment and compensation levels and are the best available data characterizing national averages of wages by detailed occupation. For some of the reasons the commenter noted, OSHA believes that the BLS wage estimate provides a more accurate reflection of average wages.

Another set of SBREFA commenters criticized OSHA's cost estimation methodology, arguing that fundamental errors resulted in serious underestimates of the costs of engineering controls. The commenters asserted without any significant explanation that the task-by-task incremental cost estimates (shown in Table V-23 of the PIRFA, Document ID 1720, p. 749) should have been multiplied by two factors: (1) "the ratio of the RSMeans labor rate to the BLS wage and benefits rate," and (2) the inverse of the "percentage in key occupations working on task" from Table V-26 (also in the PIRFA, Document ID 1720, p. 766). Under this approach, the commenters argued that

> the cost of PEL controls for brickmasons, blockmasons, cement masons and concrete finishers performing grinding and tuckpointing would be approximately seventy-two (72.0) times the ERG estimate, and . . . the cost of PEL controls for drywall finishing (at the 50 μg/m3 PEL) would be approximately 7.2 times the ERG estimate (Document ID 0004 p. 34 of memo).

The rationalization for these calculations was not provided, and OSHA found these conclusions without merit. The incremental control costs shown in Table V-34 of this FEA were based on RSMeans estimates for labor and equipment costs. As shown in Table V-34, these cost estimates, after adjustments for productivity impacts, are used to calculate the percentage increase in baseline costs associated with each control. The RSMeans-based cost estimates shown in Table V-34 are also used to estimate the share of total baseline task/project costs accounted for by labor requirements. The averages of the percentage increase due to incremental control costs and the labor share (percentage) of total baseline costs are shown in Table V-37 of this FEA. These two percentages are used to extrapolate the aggregate control costs associated with each task. This extrapolation was based on (1) the full-time-equivalent employment in key and secondary occupations associated with each task, and (2) the value of the labor time as measured by the BLS occupational wage statistics, adjusted for fringe benefits.

OSHA provided similar responses in the PEA and requested comment on its responses to the SBREFA comments, but received none (see PEA, p. V-131).

The same set of SBREFA commenters further argued that OSHA's analysis contained five more "fundamental errors" (Document ID 0004, p. 35 of memo). First, the commenters asserted that OSHA's calculations understate the actual cost because they are based on old data (1999 or 2000 data from RSMeans rather than RSMeans 2003 data). OSHA used the most recent available data at the time the initial preliminary analysis was completed and subsequently updated those data for the PEA (and this FEA) using RSMeans estimates from 2008 (Document ID 1331). However, as noted previously, the RSMeans estimates do not directly determine the absolute level of aggregate compliance costs, but rather the labor share (percentage) of project costs and incremental compliance costs as a percentage of baseline costs. This aspect of the analysis received no further comment and has been retained for the FEA.

Second, the commenters asserted that there is no information to "suggest much less substantiate the premise that the exposure monitoring data in Tables 3-1 and 3-2 [in the ERG (2007a) report] (even if they were properly collected and analyzed) are in any way representative of current workplace exposures across the country" (Document ID 0004, p. 35 of memo). In response, OSHA points out that the profiles used to estimate the numbers of workers exposed in excess of each PEL option were, in fact, based on the extensively documented technological feasibility analysis with many of the data points in the exposure profiles being taken from the findings of OSHA inspections (and based on ERG, 2007a). OSHA is tasked with using the best available evidence to develop the analyses, and the data in the exposure profile represent the best available evidence on current workplace exposures to respirable crystalline silica. More importantly, for estimating the cost of controls, Table 1 in the final rule is intended to be the default option for protecting workers performing covered tasks, regardless of actual exposure level. The FEA reflects this, while recognizing that a sizable minority of workers with exposures below the PEL have limited their exposures by using such controls currently.

Third, the commenters claimed that there is

> no information to suggest much less substantiate the premise that the exposure monitoring data in Tables 3-1 and 3-2 (even if they were representative of current workplace exposures) are in any way representative of the non-existent, theoretical jobs artificially created by the FTE [full-time equivalent] analysis so as to justify their use as the foundation for Table 4-12 (Document ID 0004, p. 35 of memo).

However, OSHA notes that the representative jobs on which the cost analysis is based were designed to correspond directly to the tasks assessed in the technological feasibility analysis. Furthermore, Table 4-12 in ERG (2007a) was derived directly from Table 3-2 and is independent of the "FTE analysis."

Fourth, the commenters argued that a more logical and appropriate methodology would assume that all FTEs were exposed above the PEL in the absence of controls, and the commenter could find

> no justification, and substantial support to the contrary, for an approach that artificially condenses actual exposures into far more highly concentrated exposures (by condensing all at-risk task hours into FTEs) and then [assumes] that, despite the impact of this change, the grab bag of exposure monitoring described in ERG Tables 3-1, 3-2 and 4-12 represents these FTEs (Document ID 0004, pp. 35-36 of memo).

The commenters asserted that the effect in ERG (2007a) of

> first multiplying total project costs by the FTE percentage (from Table 4-8) and then by the 'Percentage of Workers Requiring Controls' from Table 4-12 (and then by the average 'Total Incremental Costs as % of Baseline Costs' by job category from Table 4-7) results in an unjustified double discounting of exposed workers in the incremental cost calculation (Document ID 0004, p. 36 of memo).

OSHA disagrees. The Agency notes that ERG (2007a) used the exposure profiles from the industry profile to estimate the number of full-time equivalent workers that are exposed above the PEL. In other words, this exposure profile is applicable if all exposed workers worked full time only at the specified silica-generating tasks. The *actual* number exposed above the PEL is represented by the *adjusted* FTE numbers (see Table 4-22 in ERG, 2007a). The adjusted FTE estimate takes into account that most workers, irrespective of occupation, spend some time working on jobs where no silica contamination is present. The control costs (as opposed to some program costs) are independent of the number of workers associated with these worker-days. OSHA noted in the PEA that the thrust of the comment about "double discounting" was unclear, but the commenters did not respond with clarification. Nothing is "discounted" in the estimation of aggregate control costs.

Finally, the SBREFA commenters argued that the

> application of the FTE analysis to the additional equipment costs is based on the wholly unfounded assumption, contrary to actual experience, that

> this additional equipment could be used with perfect efficiency (i.e., never idle) so that it is only at a particular site during the time the at-risk tasks are being performed (Document ID 0004, p. 36 of memo).

In response, OSHA notes that its analysis does in fact assume some efficiency with respect to the use of additional equipment required for controls. However, many of the equipment costs are based on monthly equipment rental rates provided by RSMeans that already embody some degree of idleness over the course of a year (see ERG, 2007a, Table 4-3). In other cases, daily equipment costs were directly estimated based on equipment purchase costs, annualization factors, and assumed operating and maintenance costs.[51] OSHA did receive further comment on the issue following the publication of the PEA (Document ID 4217, pp. 84-88), and, in response, the Agency developed prorated ownership costs (equivalent to twice the rental rates) for control equipment for tradespersons performing tasks involving short-term, intermittent silica work.

Comments and Responses on Engineering Control Costs in Construction

Having already incorporated comments from small business in the SBREFA panel process, the Agency produced revised estimates for the PEA in support of the proposed silica rule. In the PEA, OSHA requested comment from rulemaking participants on the Agency's preliminary estimate of control costs in construction. Below are comments representative of the prominent issues that raised concerns.

The most broad-based critique of the construction cost analysis came from the Construction Industry Safety Coalition (CISC), and its consultant Environomics (Document IDs 2319, 2320, and 4217). Several of their arguments regarding underestimation of costs related to an undercount of the affected construction population (for example, they believed the Agency should have accounted for the cost to control silica exposures for plumbers). The Agency agrees in part that there were some occupations—plumbers, plumber helpers, electricians, electrician helpers, roofers, roofer helpers, terrazzo workers and finishers, and sheet metal workers—that likely have exposure and should be included in this analysis, as they do perform some activities covered by Table 1. These are discussed in more detail in Chapter III, Industry Profile.

Owning Versus Renting Engineering Controls in Construction

[51] These were originally translated to daily costs on the assumption of full-time usage (240 days per year). However, in response to this comment, this rate was adjusted downward, assuming instead that equipment would be used 150 days per year (30 weeks), on average; OSHA applied this downward adjustment to equipment usage in the PEA and the effect of this change in equipment usage was to increase the daily cost of control equipment.

OSHA also received comment regarding the availability of control equipment. In its post-hearing brief, CISC commented:

> In the Agency's cost analysis, it has also made the entirely impractical assumption that controls (e.g., wet methods, LEV) for the tools that construction workers use in performing tasks that generate respirable silica need to be available only during the exact duration while a dusty task is performed. The CISC estimates costs instead to provide control equipment on an "always available" basis to workers who engage in dusty tasks. Control equipment must be available whenever a worker may need to perform an at-risk task, and not for only the very limited duration when the at-risk task is actually being performed. Costs for the engineering controls required to meet the reduced PEL in the proposed rule will be far higher than OSHA estimates (Document ID 4217, p. 29).

While OSHA agrees that CISC's argument has merit, during hearing testimony CISC's representative acknowledged that its estimates did not initially take into account the economic life of a control. This is reflected in the following conversation between CISC's Stuart Sessions and OSHA's Robert Stone:

> MR. STONE: So returning to the methodology for costing, you pretty much used our numbers and you used our, presumably, like you mentioned the dust shroud that has a one-year life and, therefore, after one year, you take the cost again the second year, is that right? And the third year, and so on? Okay. I think this is perhaps a problem with the way you've done your analysis. We used basically FTEs, full-time equivalents. You're using three percent of the time let's say for plumbers, as an example, you're applying it to three crews, all right? At the end of one year, you're having them buy another dust shroud. And my view . . . they will have used nine percent of the economic life of the dust shroud. Now, you can argue I'd make an adjustment because we estimate 150-[day construction work-year] use of it, for full-time use. This would suggest, though, that after one year, you will have used one-sixth of the life of that dust shroud and an employer is not going to throw it out. It's still functional. He'll use it for the next five years. He'll use it for six years. Any views on that?
>
> * * *
>
> MR. SESSIONS: Yes. That's a good point, and I hadn't thought about that.
>
> MR. STONE: Okay, thank you. A related point is actually the same issue. It would be operating in maintenance costs. You're -- it's going

> to be one-sixth of our original estimate, but I don't think you've made that adjustment.
>
> MR. SESSIONS: Correct. (Document ID 3580, Tr. 1501-1502).

After the hearing discussion, CISC revised its methodology, noting:

> After additional thought and discussion about this issue with several construction tradespeople, we … concluded that useful life is a function of both how often the tool and controls are used, but also how long they sit in the construction worker's truck and get bounced around going from job site to job site (even when they are not used), and how often they are taken out of the truck and returned to the truck (even when they are only set up then taken down at the job site but not actually used). Thus useful life will increase if a tool sits idle for some percentage of the time when it is available, but useful life will not increase to the same proportional extent as the decrease in usage. We assumed in the example in workbook Tab # X2B that using the tool and equipment 1/4 as often will double its useful life (Document ID 4217, p 89).

OSHA agrees with this updated methodology and has adopted CISC's approach—essentially assuming one-half of the usage life over which to amortize the purchased control equipment—for jobs that typically involve intermittent short-term exposure. The jobs for which the Agency assumed a half-life of the control equipment were: (1) hole drillers using hand-held or stand-mounted drills—for electricians, plumbers, carpenters, and their helpers, and for sheet metal workers; and (2) handheld power saws for carpenters and their helpers. Note that OSHA's adoption of this updated approach resolves CISC's criticism that OSHA had not accounted for productivity decreases from controls not being available when the worker needs to use them for short-term or intermittent silica jobs.

For all other construction jobs (i.e., those not itemized above involving intermittent short-term exposure), OSHA did not adopt CISC's approach but instead (as in the PEA) used the market-derived rental rate for control equipment without either doubling the rental rate to take into account "down-time" or requiring purchase of the control equipment. There are several reasons the Agency retained its PEA approach for these jobs in the final rule:

- In most cases, an employer's own/rent decision for control equipment will be determined by the own/rent decision for the construction equipment (including construction tools) to which the control equipment will be applied. If the employer rents/owns the construction equipment, the employer will rent/own the control equipment.

The major exception would be if a particular piece of control equipment could be applied to many types of construction equipment. An example might be a dust collector. In that situation, the employer might find it economic to rent the construction equipment and own the control equipment. But, in that case, the purchased control equipment will not be sitting idle.

- Construction equipment is sufficiently expensive that employers, as a general matter, will not find it economically efficient to have it sitting idle. That is why employers so frequently rent construction equipment. Of course, employers that do only one type of construction job all year (or those that are sufficiently large that they work on that particular type of construction job all year) will find it economic to own the construction equipment—as well the control equipment—but then the control equipment will not be sitting idle.
- In light of permit requirements and other job-planning requirements, in almost all cases, the employer will have advance knowledge of the details of the construction job (as opposed to, sometimes, repair work in general industry). This knowledge would include the construction equipment—and controls—required to perform the job. In fact, employers will often schedule construction jobs precisely to avoid having construction equipment sitting idle. In other words, the typical employer—and certainly the competent employer—won't come to the job site unprepared, needing to leave the job site to obtain rental equipment or controls.
- The construction sector is a significant component of the U.S. economy. There is a large, competitive construction equipment/control rental market in place to serve it. In most places, employers should be able to obtain needed construction equipment/controls in a timely manner under terms similar to those estimated here.

For the aforementioned reasons, OSHA believes that the ownership-versus-rental cost issue, except in the case of construction jobs that involve intermittent short-term exposure, is somewhat of a red herring. The difference in amortized cost should be negligible, given that employers will choose to own or rent based on whichever is the lower-cost alternative. In fact, because rental costs are typically somewhat higher than amortized ownership costs, OSHA may have overestimated compliance costs for those employers who purchase control equipment.

Self-employed Persons

CISC, and its contractor Environomics, claimed in their comments that OSHA had omitted the costs of compliance by sole proprietors (typically self-employed persons) (Document ID 4217, p. 80). The inclusion of such costs and the circumstances under which they would arise were previously discussed in Chapter III of this FEA. In this FEA OSHA has accounted for costs associated with controlling employee exposures from sole proprietor activities. The actual self-employment data and the estimated effect on employer costs are presented at the end of this section on engineering control costs in construction.

Full cost vs. incremental cost

Prior to the PEA, a participant in the SBREFA process noted that while OSHA established the total incremental cost for each silica control method (summarized for the final rule in Table V-35 of this FEA), the cost estimates were based on the application of a single control method. The commenter argued that there may be cases where two or more control methods would have to be applied concurrently to meet the exposure limits (Document ID 0968, p. 14). In response, OSHA noted in the PEA that for each task, specified control options correspond to the control methods described in the technological feasibility analysis in Chapter IV (of the PEA). These methods reflected the choices laid out in Table 1 of the proposed rule; they were also presented in Table V-25 in the PEA along with OSHA's calculation of the weighted average proportion of project costs attributable to labor and the incremental control costs as a percentage of baseline project cost.

Throughout the comment period, CISC reiterated the pre-PEA objections to OSHA's methodology of estimating incremental costs instead of the "full" compliance costs, which CISC defined as including the costs for employers to meet their existing duty to comply with OSHA's old PEL (CISC claims employers of "nearly 60,000 workers" were not in compliance with OSHA's preceding standard and would have OSHA attribute the costs of compliance with the preceding standard to the costs of this rule) (Document ID 4217, p. 33):

> In our view, OSHA has made two errors in the approach it has taken:
>
> - First, the "full" compliance costs for reducing worker exposures from their current levels to below the proposed new PEL are the conceptually correct costs to estimate when assessing economic feasibility, not the "incremental" costs for reducing exposures to below the proposed new PEL from a starting point assuming compliance with the current PEL. In practice, employers will face the full costs, not the lesser incremental costs, and the economic feasibility assessment should consider whether employers can afford these full costs, not the hypothetical and lower incremental costs.
> - Second, OSHA has made a conceptual error in the Agency's methodology for estimating compliance costs* * * Insofar as OSHA omits all costs for [employees with exposures > 250 μg/m^3] -- failing to estimate the costs to reduce their exposures all the way down below 50 μg/m^3 instead of only to below 250 μg/m^3 -- OSHA estimates costs that fall short of the incremental costs of the

> Proposed Standard that the Agency aims to estimate (Document ID 4217, pp. 96-97).

Both arguments are now largely moot because in this FEA almost all of the construction engineering control costs are based on compliance with Table 1 and encompass all employees engaged in the Table 1 tasks, regardless of their current level of exposure. OSHA has included the full incremental—*and full total*—costs for *all* employers in construction who have workers who are performing tasks listed on Table 1, even those workers with exposures currently above 250 μg/m^3.

CISC's arguments for the construction sector are now only relevant to the very few tasks not covered by Table 1, such as tunnel boring. OSHA therefore addresses CISC's arguments in the context of those few tasks.

The first argument is that employers who are not in compliance with the preceding PEL of 250 μg/m^3 will have to incur costs to achieve that PEL in addition to the costs they will incur to reach the new PEL of 50 μg/m^3. As laid out in the PEA, OSHA rejects this position, as this is inappropriate for estimating economic feasibility among firms making a good faith effort to comply with the existing silica rule. Employers who had a legal obligation to comply with OSHA's preceding PEL but failed to do so are not excused from their previous obligation by the new rule; nor can the fulfillment of a pre-existing duty be fairly re-characterized as a new duty resulting from a new rule. But this issue is not limited to construction, and a more complete discussion is presented in the general industry engineering control cost section.

The second argument can be dismissed on similar grounds. CISC's argument appears to assume that employers will incur different costs for different controls necessary to reduce exposures from above 250 μg/m^3 down to 250 μg/m^3, and from 250 μg/m^3 down to 50 μg/m^3. In many cases, however, the same controls needed to bring exposures below 250 μg/m^3 will also bring exposures below 50 μg/m^3, so there would be no cost associated with the new rule. To the extent that separate controls are required to reduce exposures down from 250 μg/m^3 to 50 μg/m^3, OSHA does account for the costs for those controls.

General Comments on Cost Methodology

James Hardie Building Products commissioned Peter Soyka of Soyka & Company LLC to perform an evaluation of the PEA. While Mr. Soyka's comments cover many aspects of the analysis and overlap with those of other commenters, some were relatively unique. In one place, Mr. Soyka questions the entire method of analyzing jobs from the level of workers and their tasks. He expressed concern about both what he termed the failure to capture the cost to the establishment, as well as the need for workers to have controls available (Document ID 2322, Attachment G, p. 165). OSHA did not, however, ignore other costs for establishments. Elements of these costs are dealt with at the establishment level for some ancillary provisions of the standard, and are discussed later in this chapter. The second element, regarding the availability of controls for certain occupations, mirrors concerns raised by Environomics and CISC, and has been dealt with above.

Elsewhere in his comments, Mr. Soyka states that “OSHA should develop revised unit costs that consider the full array of elements that affect what a business charges its customers for a unit of time expended.” Such unit costs,” he submitted, “would include direct labor, fringe benefits, overhead, SG&A, and a reasonable allowance for profit (e.g., the typical cost of capital found in a specific industry or overall)” (Document ID 2322, Attachment G, p. 182). The approach put forward in the PEA and in the FEA incorporates fringe labor costs. With respect to overhead and SG&A, OSHA recognizes that there is debate about when and whether these elements should be included and how they can be accurately measured. OSHA continues to view labor plus fringe benefits as one reasonable approach to measuring marginal costs of labor, but has provided a sensitivity analysis of the effects of including other cost elements in the sensitivity analysis section of the FEA.

The National Association of Home Builders (NAHB) faulted the costing of engineering controls in the PEA on several grounds, including several very similar to those raised by Mr. Soyka and addressed earlier. NAHB also stated that OSHA has not considered the “unique nature of construction, in that sites are not fixed in nature, and that equipment may need to be moved between several sites in a single day” or the “compliance costs for cleanup of the jobsites” (Document ID 2296, p. 38). Both are addressed in the FEA as opportunity costs or housekeeping costs.

Other Aspects of Unit Costs

Following publication of the NPRM, a representative of petrochemical employers, the American Fuel and Petrochemical Manufacturers, raised concerns about retrofitting and clean-up costs that it claimed were improperly omitted from OSHA’s analysis of engineering controls in construction:

> OSHA claims “[t]he estimated costs for the proposed silica standard rule include the additional costs necessary for employers to achieve full compliance.”[] Yet it fails to consider the additional costs of retrofitting existing equipment to comply with Table 1 in Section 1926.1053 (Table 1). In addition to acquiring new engineering controls not previously implemented, many employers will have to modify pre-existing equipment to come into compliance (*e.g.*, outfitting the cab of a heavy equipment

> bulldozer with air conditioning and positive pressure). Table V-3, found in OSHA's complete PEA, begins to address these costs by enumerating the capital and operating costs for the engineering controls required by Table 1. But it does not account for the ancillary costs of retrofitting those controls, including the cost of retrofitting the equipment itself as well as the lost time the facility may absorb in doing so.
> OSHA also fails to account for the clean-up costs associated with the natural by-products from Table 1's required engineering controls. For example, many of the engineering controls require the use of wet methods or water delivery systems. [] Employers will incur costs from removing (from the clean-up process itself and lost time) excess water to prevent ice or mold from developing. Yet these costs go unaccounted for in the PEA (Document ID 2350, pp. 6 – 7).

In the FEA, the Agency does not include any specific cost for retrofitting equipment. The record indicates that almost universally employers either already have equipment with the required controls available for use (e.g., wet method for saw), or the equipment allows for the easy addition of a control (e.g., shroud for HVAC). Furthermore, most equipment is portable and/or handheld and is relatively inexpensive with a useful life of two years or less. As a result, it would simply not make economic sense to retrofit the equipment when it would be less expensive to replace it. In addition, most other types of relevant construction equipment—heavier and drivable—generally have a useful life of ten years or less; control-ready equipment of this type has been on the market for years and is typically already in use. Thus, OSHA did not estimate any retrofitting costs. While some employers might still retain pieces of earth-moving equipment that do not have a cab that complies with Table 1, equipment with a cab is the industry standard for both purchase and rental. As discussed in this chapter in the context of productivity, the implication is that the market has shifted to heavy equipment with cabs even in the absence of a silica standard. In addition, in final Table 1 OSHA has reduced the number of tasks that require equipment with enclosed cabs to just a single task: heavy equipment and utility vehicles used to abrade or fracture silica-containing materials or used during demolition activities involving silica-containing materials. For the odd piece of old, cab-less heavy equipment which does not conform to the requirements of Table 1, individual employers have the choice of renting the required equipment to perform that single task, or simply using the cab-less equipment only on non-silica tasks (thereby ceding the one silica-abrading construction task to employers that have more up-to-date equipment). In short, the requirement to use a cab when performing Table 1 tasks is not a requirement to retrofit all existing equipment that might conceivably be used for a Table 1 task.

Regarding the question of clean-up costs, the commenter treats the issue as if there were no clean-up costs associated with generating silica currently. As discussed in the Environmental Impact Analysis (Chapter X) and in the discussion of productivity impacts later in this section, there was substantial comment to the record indicating that in many, if not most, situations, the controls associated with reducing silica exposure will lead to a net decrease in the amount of time required for cleanup after a job. While OSHA is not attempting to quantify any potential cost savings, the record likewise does not support attributing additional costs to cleanup.

Specific Industry/Equipment Category Cost Comments

Crushing Machines

William Turley, executive director of the Construction & Demolition Recycling Association (CDRA), broadly described the impacts he anticipated for his industry.

> Recyclers who crush materials for reentry into the economic mainstream as aggregate products would appear to have to do all of the following:
>
> - Purchase and install climate-controlled enclosures or cabs for all crusher operators;
> - Install crusher baghouses for particulate emission reduction;
> - Enclose conveyor belts – a measure unprecedented in our industry;
> - Install effectively designed and maintained water spraying equipment;
> - Impose full-shift use of respirators for all quality control hand pickers working on processing lines;
> - Establish and implement emission testing protocols and procedures to ensure compliance with the PEL;
> - Implement medical surveillance programs for all employees engaged in material crushing activities; and
> - Achieve a “no visible emissions” standard, which frankly is both unattainable and utterly unreasonable.
>
> To the best of our knowledge, no recycler in the United States has a system even resembling the above. The cost of such systems will unquestionably threaten the economic viability of construction & demolition debris recyclers across the Country. It must also be pointed out that the industry has an exceptionally diverse composition of larger operators with higher economic margins and small operations with limited capabilities to capitalize the type of equipment called for in this rulemaking (Document ID 2220, pp. 2-3).

The final silica rule does *not* require all the above steps. OSHA expects that crushing machines will be used for construction/demolition activities, as discussed in detail in the

Summary and Explanation of the standard. As such, OSHA anticipates that employers engaged in the recycling operation would follow Table 1 and would not need to conduct exposure monitoring.

For crushing machines, OSHA removed the “no visible emissions” requirement and the requirement for enclosed cabs, both of which had been in proposed Table 1. Employers are now required to use a spray system and comply with manufacturer instructions. Also, there is no requirement to enclose conveyor belts or install crusher baghouses. Instead, employees must use a remote control station or ventilated booth that provides fresh, climate-controlled air to the operator. For this FEA, OSHA added the cost of a ventilated booth for the use of crushing machines in construction/demolition activities. Most crushing machines are already equipped with movable controls that will allow operation of the machine from inside the booth, so no additional equipment modifications will be required for most machines. Crushers available for purchase or rental are also typically equipped with a water spray system, so OSHA has not assessed any incremental cost for sprayers.

Homebuilding – Roofing

The National Roofing Contractors Association (NRCA) objected to OSHA’s preliminary cost estimates for controls used to limit silica exposure in roofing operations, claiming that OSHA’s preliminary estimate of an average of $550 per year for firms that employ 20 workers or fewer (covering the majority of roofing contractors) had significantly underestimated the cost of specialized saws that would be required for roofing equipment. In support of the argument that OSHA had underestimated costs, NRCA identified costs for retrofitting portable saws with integrated dust collection systems along with specialized vacuums equipped with HEPA filters (Document ID 2214 p. 4).

The task of cutting most roofing materials would fall under “Handheld power saws (any blade diameter)” in Table 1, and the final version of Table 1 does not allow for the dust collection methods described, so the majority of costs quoted by NAHB are not relevant. Instead, the final version of Table 1 requires that the employer use wet methods. Second, the estimate of $550 a year in costs to very small employers was an estimated average across *all* affected establishments with fewer than 20 employees, not just roofing operations in homebuilding. Questions of small business impact or economic feasibility for the roofing industry are dealt with Chapter VI of this FEA.

The comments submitted by consultant Peter Soyka on behalf of James Hardie Building Products (“Hardie”) presented a table of typical devices with engineering controls involved in fiber cement cutting and an un-sourced range of costs for the retail prices of those types of devices and their controls (Document ID 2322, p. 13).

Hardie's inclusion of a table of retail prices for the purchase of equipment with controls suggests there may have been a misunderstanding of the nature of OSHA's cost methodology—it is not based on purchasing entirely new pieces of equipment, but making sure the equipment has the controls necessary to comply with Table 1. To the extent commenters submitted estimates addressing the latter question, the Agency has taken them into consideration in its final estimates.

Asphalt Milling

Fann Contracting, Inc. acknowledged that the availability of equipment with built-in controls is rising. However, the commenter suggested that OSHA's preliminary assessment of the design specifications and costs for the engineering controls identified in Table 1 of the proposed rule had under-counted the amount of milling machines and other paving-related equipment that the commenter believed would still require additional retrofits to enclosed cabs (sealing cracks, adding air conditioning, upgrading to HEPA filters, etc.) to satisfy the requirements in Table 1 (Document ID 2116, pp. 6-7).

Table 1 in the final rule does not require a cab for milling machines or any of the equipment identified by the commenter for paving purposes, so the commenter's concerns are not relevant. Table 1 only requires cabs for "(xvii) Heavy equipment and utility vehicles used to abrade or fracture silica-containing materials (e.g., hoe-ramming, rock ripping) or used during demolition activities involving silica-containing materials," and specifies it as an option for "(ix) Vehicle-mounted drilling rigs for rock and concrete." Table 1 requires employers to use wet methods to control dust emissions from milling machines. These costs have been accounted for in the cost analysis.

Drywall Finishing

A SBREFA commenter raised questions about the availability of silica-free joint compound for drywall finishing (Document ID 0004, p 38 of memo). In the PEA, OSHA relied on NIOSH studies showing that silica-free joint compounds had become readily available in recent years (see ERG, 2007a, Section 3.2). The cost model for the PEA assumed that 20 percent of drywall finishing jobs would continue to use conventional joint compound. Based on additional information, OSHA has determined that all commercially available joint compounds have no, or very low amounts of, silica and do not pose a risk to workers from respirable crystalline silica (Document ID 2296, pp. 32, 36; 1335, p. iii) and has therefore not included drywall finishing in Table 1 or taken any costs for this task (See Summary and Explanation, Specified Exposure Controls for more information).

Number of Days Controls Are Used Annually

Whether equipment, and the relevant controls, are rented or purchased, the effective annual cost of the equipment is based on the assumed number of days per year that it would be used. In the PEA, OSHA had estimated rental of the equipment for 150 days during each 365-day period. Based on comments received from industry representatives during the 2003 SBAR Panel process (Docket ID 0968), this estimate had been reduced from an average of 250 days in the Preliminary Initial Regulatory Flexibility Analysis (PIRFA). This reduced workday estimate presumably reflected winter weather slowdown in many parts of the country, as well as general weather conditions (such as rain) that can interfere with many construction processes, and resulted in 2/3 higher daily rental rates for control equipment.[52]

However, Environomics, in developing its own cost estimates, assumed that control equipment would be used for 250 days a year, without an articulated rationale for departing from the estimate provided during the SBAR Panel process (Document ID 4023, Attachment 2, X2B- Hole Drilling Unit Costs, Cell P:Q44). More importantly, Environomics selectively and inconsistently applied 250 days only to the frequency of usage but not to the daily rate (which OSHA had based on 150 days of usage). To see why it is a problem to apply a different number of days to the same daily rate, consider a piece of control equipment, with a one-year life, known to cost $1,500. Using a 150-day construction work-year, OSHA would estimate a daily rate for the control equipment of $10 ($1,500 / 150 days in the construction work-year). The annual cost for that control would be $1,500 ($10 multiplied by 150 days). Using the same example, Environomics would keep OSHA's daily rate of $10 (amortized over 150 days) but apply it to a 250-day calendar to arrive at an annual cost of $2,500—where the one-year cost of the equipment was known to be $1,500. In short, the selective 250-day methodology Environomics used results in an overestimation of costs by 67 percent.

Accordingly, OSHA has decided to retain the 150-day construction work year based on the best available evidence, and the Agency has consistently applied that work-year throughout the cost analysis developed in this FEA for construction. (General industry and maritime work is typically less affected by weather, so a separate work-year number of days is used for those calculations).

[52] To see the effect of this change, let X equal the yearly cost for a piece of control equipment. The daily rate over 250 days is X/250; the daily rate over 150 days is X/150. So the effect of reducing the number of workdays in a year from 250 to 150 on the daily rate is X/150 divided by X/250, or 250/150 = 1 2/3. That is, the daily rate is increased by 2/3.

Unit Control Costs

In developing the cost estimates in this FEA, OSHA defined silica dust control measures for each representative job (see ERG (2007a)). Generally, these controls involve either a water-spray approach (wet method) or a dust collection system to capture and suppress the release of respirable silica dust. Wet-method controls require a water source (e.g., tank) and hoses. The size of the tank varies with the nature of the job and ranges from a portable water tank (unspecified capacity) costing $15.50 a day to a 10,000 gallon water tank with an engine-driven discharge, costing $168.38 a day.[53] Depending on the type of tool being used, dust collection methods entail vacuum equipment, including a vacuum unit and hoses, and either a dust shroud or an extractor. The capacity of the vacuum depends on the type and size of tool being used. Some equipment, such as concrete floor grinders, comes equipped with a dust collection system and a port for a vacuum hose. The estimates of control costs for those jobs using dust collection methods also include the cost for HEPA filters.

The unit costs for most control equipment are based on price information collected from manufacturers and vendors. In some cases, control equipment costs were based on data from RSMeans (2008) on equipment rental charges. Table V-32 shows the general unit control equipment costs and the assumptions that OSHA used to estimate the costs for specific types of jobs.

For each job identified as needing engineering controls, OSHA estimated the annual cost of the appropriate controls and translated this cost to a daily charge, based on an assumed use of 150 days per year (30 weeks), as explained earlier. The only exceptions were engineering controls expected to be used for short-term, intermittent work. For these controls, consistent with the CISC methodology that OSHA adopted, carpenters and other occupational groups were estimated to purchase this control equipment, and for costing purposes, OSHA amortized the equipment over its "half-life"—that is, over 75 days rather than 150 days (effectively doubling the daily capital costs of the equipment). Accordingly, Table V-32 shows separate daily cost estimates, for regular and for infrequent use, for a dust extraction kit and for a10-15 gallon vacuum with a HEPA filter.

[53] See Chapter X in this FEA for a discussion on the environmental impacts resulting from the use of wet methods for controlling exposure to silica.

Table V-32

Unit Control Costs for Construction

Control Equipment Category	Equipment Cost	Average Lifetime (yrs)	Average Annualized Cost	Average Ann. Cost/ Day of Use [a]	Maintenance and Operating Cost/Day [b]	Total Ann. Cost/ Day of Use	Source; Comments
Wet kit, with water tank	$227	2	$118.49	$0.79	$0.17	$0.96	Contractors Direct, 2009; Berland Tools Outlet, 2009; Mytoolstore, 2009

use.

[c] Daily equipment costs derived from RS Means monthly rental rates which include maintenance and operating costs.

[d] Derived by ERG based on vendor-derived capital cost of $27.00, 2 year equipment life, accessory cost of $295.52. Also includes annualized training cost of $50.34, fit test cost of $26.45, and respirator cleaning cost of $81.49 to derive total annual costs of $468.74.

Source: ERG estimates based on vendors' equipment prices and R.S. Means, Heavy Construction Cost Data, 2009.

Incremental Labor Costs and Productivity Impacts in Construction

In addition to incremental equipment costs, OSHA estimated in the PEA the incremental labor costs generated by implementing silica dust controls. These labor costs were generated by: (1) the extra time needed for workers to set up the control equipment; (2) potential reductions in productivity stemming from use of the controls; (3) additional time to service vacuum dust control equipment; and (4) additional housekeeping time associated with or generated by the need to reduce exposures. All additional labor costs related to the use of controls were subsumed into a single additional labor productivity impact estimate for each of the representative job categories. Except where otherwise noted, the productivity impact described is negative, meaning that the addition of the control is expected to reduce productivity. To develop estimates of the labor productivity impacts of the dust control equipment that would be required as a result of the proposed standard, ERG interviewed equipment dealers, construction contractors, industry safety personnel, and researchers working on construction health topics.

In part, because most silica dust controls are not yet the norm in construction, knowledge about the impact of dust controls on productivity was uneven and quite limited. More precisely, few individuals that ERG interviewed were in any position to compare productivity with and without controls and the literature on this topic appears deficient in this regard. Overall, telephone contacts produced a variety of opinions on labor productivity effects, but very few quantitative estimates. Of all the sources contacted, equipment rental agencies and construction firms estimated the largest (negative) productivity impacts. Some equipment vendors suggested that there are positive productivity effects from control equipment due to improved worker comfort (from the reduction in dust levels). Others suggested that the use of dust collection equipment reduces or eliminates the need to clean up dust after job completion. Comments to the record, discussed below, closely mirrored this preliminary information.

The estimation of labor productivity effects is also complicated by the job- and site-specific factors that influence silica dust exposures and requirements for silica dust control. Potential exposures vary widely with hard-to-predict characteristics of some specific work tasks (e.g., characteristics of materials being drilled), environmental factors (e.g., wet or dry conditions, soil conditions, wind conditions), work locations (e.g., varying dust control and dust cleanup requirements for inside or outside jobs), and other factors. Generalizations about productivity impacts, therefore, are hampered by the range of silica dust control requirements and work circumstances.

After considering the existing evidence OSHA concluded that labor productivity impacts are often likely to occur and accounted for them in the PEA analysis. In the PEA, depending on the general likelihood of productivity impacts for each activity, OSHA used a productivity impact ranging from zero to negative five percent of output. After considering the many comments advocating for both increasing and decreasing the productivity impact estimates, OSHA has concluded that the estimates in the PEA were approximately correct and has retained the PEA estimates for this FEA. The comments and factors influencing each selection are described in the following discussion.

SBAR Panel Comments on Productivity Impacts

In response to the SBAR Panel, the Reform OSHA Coalition commented on the estimates of the impact of exposure control equipment on productivity during construction operations. This SBREFA commenter noted that the estimates of the productivity impact of using additional control measures were based on interviews with dealers, contractors, and researchers working on construction health topics and expressed its opinion that it was not clear how this "purely qualitative analysis [was translated] into productivity [impact] rates . . . ." (Document ID 0968, p. 14). The commenter indicated that engineering control compliance costs would be sensitive to the ultimate choice of productivity impact measures (Id.).

OSHA responded to these comments in the PEA as part of the discussion of the basis for OSHA's productivity estimates. OSHA summarizes the responses to SBREFA comments here for the convenience of the reader. As described in the PEA, ERG's research revealed little substantive, quantitative evidence about the magnitude of the productivity impacts of the controls, and in some cases, the direction of the impacts (positive or negative) appeared to depend on the specific nature of the job. OSHA's estimates in the preliminary analysis reflected ERG's best professional judgment about the likely magnitude of these impacts. Some of the estimates may be conservative because under some scenarios for certain tasks the productivity impacts could be significantly smaller than those shown in Table V-23 of the PEA. In some scenarios the productivity impact may even be positive.

The same commenter also expressed a concern that even though "silica is not now considered a hazardous waste," OSHA had not analyzed the impact of the proposed rule on disposal of "[silica-]contaminated" wastes such as "filters of dust control vacuums and contaminated water discharge" (Document ID 0968, p. 28). The commenter asserted that disposal issues are "acute on the construction site where a means to readily dispose of such material or water is not available" (Id.). The comment was somewhat puzzling because the comment was premised on the fact that there is not currently any "hazardous" classification for such waste that would trigger special disposal duties, and the commenter did not explain why any additional costs would be incurred beyond normal disposal practices. OSHA did not identify any new areas of cost in its Environmental Impacts analysis presented later in this FEA, and finds no evidence that employers will be required to incur additional environmental costs as a result of this rule, other than some potential permit-modification notification costs addressed in the discussion of engineering control costs for general industry. The incremental disposal costs resulting from dust collected in vacuums, discarded filters, and other sources in construction are therefore likely to be de minimis. An analysis of wet methods for dust controls suggests that in most cases the amount of slurry discharge is not sufficient to cause a runoff to storm drains or surface water.[54]

Comment and Responses on Productivity Impacts in Construction

OSHA invited comment on the productivity impacts—positive and negative—resulting from the introduction of controls to limit exposure to silica. In the discussion below, OSHA reviews comments supporting both negative productivity impacts and positive productivity impacts. The comments supporting negative productivity impacts include assertions that OSHA underestimated the negative productivity impact of complying with the silica rule, failed to include a productivity impact on equipment, and failed to include a fixed productivity impact. OSHA considered those comments before concluding that it will generally retain the approach it used in the PEA, with the exception of selectively adding additional costs for productivity impacts on equipment in response to a point raised by CISC. OSHA will also explain separately why it is not calculating any productivity impact for two specific activities: (1) use of cabs for earthmoving equipment, and (2) drywall installation.

Public comments suggesting that OSHA underestimated the productivity impacts associated with engineering controls

The Interlocking Concrete Pavement Institute reported that “converting from in-place paver cutting to wet cutting and/or vacuum systems could induce a 50% productivity penalty,” but did not otherwise substantiate that claim beyond noting that it was a survey response from one of its members (Document ID 2246, Attachment 1, p. 3).

Mr. Soyka, in the comments prepared for Hardie, critiqued OSHA’s estimates of the productivity impact on construction operations as “far too small” and urged OSHA to adjust productivity-loss estimates based on empirical data “if available” (Document ID 2322, Appendix G, pp. 14-15 and 21-22). However, the

[54] For a more detailed discussion of this issue, see Chapter X of this FEA.

commenter did not clearly identify any such empirical data in the comments. The only labor-based engineering control cost alternative offered by the commenter that resembled "empirical data" is the addition of a seven-hour penalty per job that was "based on a JHI time-motion study" apparently conducted exclusively in a single industry (new home construction) and comprised of data from just the JHI study (Document ID 2322, Appendix G, Attachment A, p. A-8). OSHA could not determine whether it would actually supply new "empirical evidence" that would warrant a change from the preliminary estimate because the study was not submitted into the record. The commenter cites "James Hardie Building Products, Inc., undated, pg. 15," which appears to align with an entry in the list of references to an undated "James Hardie Labor Efficiency Manual," but that manual was not submitted into the record.

Mr. Soyka recommended that OSHA use time-motion studies to derive the estimated productivity impacts.

> […F]ew [of the productivity penalties estimated by OSHA] are supported by actual data (e.g., time-motion studies). OSHA should apply a more conservative approach that considers how work flow and task completion are likely to be affected by newly required changes to existing practices as well as entirely new activities (Document ID 2322, Appendix G).

In addition, Mr. Soyka developed an alternative cost model that included additional productivity impacts that OSHA did not include. In this model Mr. Soyka "assumed that wherever possible, company owners in the residential construction industry will outsource their compliance obligations to specific subcontractors . . .providing the products and services that might generate significant amounts of silica dust" (Document ID 2322, Appendix G, p. 26). In this scenario, Mr. Soyka determined that the employer would require "the subcontractor to relocate its work location outside the house(s) being constructed to a distance sufficient to ensure that silica dust concentrations remained minimal inside and around the house(s)" and that "relocating the materials and work giving rise to silica dust generation […] would add substantially to the time required to complete the associated tasks" (Document ID 2322, Appendix G, p. 30). He accounted for this additional time by increasing the productivity impact on the specialty subcontractors to seven hours per job, "based upon time-motion studies conducted by James Hardie (James Hardie Building Products, Inc., undated, pg. 15)" (Document ID 2322, Appendix G, p. 31).

Mr. Soyka's model also included a productivity impact for "wearing respirators to account for fatigue and adverse impacts on employee-to-employee communication" (Document ID 2322, Appendix G, p. 32).

OSHA fundamentally disagrees with the Mr. Soyka's assumptions. Mr. Soyka's assumption that all silica-generating tasks need to be removed from the homebuilding site results from a misunderstanding of OSHA's statement that "[i]n response to the proposed rule, many employers are likely to assign work so that fewer construction workers perform tasks involving silica exposure; correspondingly, construction work involving silica exposure will tend to become a full-time job for some construction workers" (FR, 2013, at 56357) (Document ID 2322, Appendix G, p. 25). OSHA did not mean that silica-generating tasks will be subcontracted out and that subcontractors will be forced to perform these tasks off-site. Rather, the Agency was acknowledging that construction employers would likely consolidate the responsibilities for performing silica-generating tasks to as few workers as possible in order to limit exposures to peripheral workers.

As mentioned previously, the "time-motion studies" performed by James Hardie, compiled in an unpublished reference, were not provided for public inspection. Moreover, the description of how those data were used in developing the model suggests that Mr. Soyka's relevant assumptions are not based on time-motion studies of how long it actually takes to perform specific tasks with controls added. Rather, it appears that Mr. Soyka assumed inflated times to perform the tasks, based on a misunderstanding of what the proposed rule required; in any case, it is not descriptive of the requirements for the final rule. Mr. Soyka's suggested approach contrasts with the estimates provided by CISC/Environomics, which accepted the limitations of the analytical exercise and agreed with most of the estimates in the PEA regarding the "variable" productivity effect.

Moreover, it should be noted that aside from weighing the possible competing forces on productivity in the course of a shift (e.g., more time for set up vs. less time required for clean-up), there is also a short-run/long-run phenomenon over a longer period as the standard comes into use. There may be a short learning curve until workers determine the most efficient way to perform a job when controls are introduced (Document ID 3581, p. 1700); in some cases, the effect may be relatively larger until the method of performing a job is re-conceptualized. Mr. Soyka criticizes OSHA for not recognizing "the dynamic nature of construction" (Document ID 2322, Appendix G, p. 19), but one obvious aspect of the dynamic nature of construction is that employers will be constantly adapting to changing circumstances and trying to find ways to perform the job in the most cost-effective manner. In short, the Agency believes that a time-motion study of a particular task is neither necessary to determine approximately what the effect will be in the short-run, nor would it allow OSHA to determine what the long-run cost of integrating the controls will be.

CISC and its consultant Environomics, as well as some other commenters, questioned the Agency's productivity-loss estimates associated with the required controls. CISC/Environomics claimed that overall OSHA "underestimated productivity losses associated with performing tasks using the prescribed controls by an amount roughly equal to the average equipment intensity of about 42 percent" (Document ID 2320, p. 29). CISC/Environomics reported that this underestimation came largely from OSHA failing to account for what they termed "fixed productivity impacts" and for productivity impacts to equipment. Both of these concerns are discussed below.

In its post-hearing brief, CISC/Environomics presented the results from a questionnaire and interviews conducted with employers and knowledgeable tradespeople; the results included a finding that "the variable penalty percentages […] were the same as or slightly larger than those that OSHA had estimated" (Document ID 4217, p. 92). CISC/Environomics did not submit the questionnaire or the answers received, nor the details of the interviews, to the record so OSHA could not fully evaluate the findings or compare them to its own findings. Based on the available summary information it appears that, while CISC and OSHA's estimates for variable productivity costs were nearly identical, it is not clear that CISC's estimates took current compliance into account. CISC stated that its members felt that "something greater than zero variable productivity penalty should be estimated for masons using portable saws controlled with wet methods […] and for heavy equipment operations using enclosed cabs and HEPA filters" (Document ID 4217, pp. 92-93). OSHA acknowledges that there would be a productivity impact to comply with the requirements of the silica rule relative to using no controls for those activities. However, as shown in Chapter III of this FEA, Industry Profile, OSHA has found high levels of baseline compliance with the provisions of the rule for those activities. As is standard in OSHA's costing methodology, only costs above and beyond those incurred under current standards are attributable to the final rule.

In addition, CISC argued that OSHA should take higher productivity impacts because "in some fraction of these instances [(where controls would be required)], the controls are hellaciously difficult to use" (Document ID 3580, Tr. 1321). The testimony goes on to give examples of such difficulties such as when "building houses where the utilities are not yet in and the water is not yet in," when working in places where power is not readily available such as in parking garages or on scaffolding, and when doing work that requires wet methods outdoors in extremely cold temperatures (Document ID 3580, Tr. 1321-1322). A different commenter, the National Utility Contractors Association, similarly criticized OSHA's estimates for excluding additional water-transportation costs: "there is not always a water supply available which would require trucking large volumes of water to the job site which adds additional costs" (Document ID 3729, p. 3).

Given the fact that the majority of the silica-generating equipment requiring controls under this standard—such as tuckpointing grinders and concrete drilling equipment—require electricity, OSHA does not find merit in applying any productivity impact simply because the controls for those tools may also need electricity. If the employer can find a way to power the equipment, it can also power the controls when necessary. Similarly, employers must commonly transport water to worksites without it for cleanup and sanitation purposes, and OSHA's technological feasibility analysis explains why the amount of water required to generate the spray mist is not typically very significant. Although it seems plausible that wet methods would occasionally be used outdoors by some employers in weather cold enough to freeze the water mist used to control the silica dust, this is far from a common construction occurrence. Moreover, it is not entirely clear from the record that freezing mist would decrease productivity. OSHA's estimates of productivity impacts are intended to represent an average across all situations, and the tiny fraction of time wet methods will need to be used outdoors in extremely cold weather should not skew the average productivity impact.

CISC/Environomics stated that there should also be a productivity impact on equipment rental or use as well as for the additional labor to operate that equipment longer. Environomics reported that a complete cost estimate of productivity loss would include not only the additional labor time required, but also the cost of having to rent equipment for a longer period of time.

> . . . Simply put, a productivity penalty for labor will translate to a productivity penalty for equipment. For example, if due to a labor productivity loss, the labor time required to complete a job increases from eight hours to eight hours and 15 minutes, the equipment time required for job completion will also increase to eight hours and 15 minutes. Additional equipment rental costs will be incurred for the additional 15 minutes, or equipment owned by the employer will be delayed for use on another job by 15 minutes (Document ID 2320, p. 29).

This concern was reiterated both in its hearing testimony (Document ID 3580, Tr.1323) and in its post-hearing brief where Environomics stated that "OSHA's analysis should add an equipment component to the costs associated with whatever productivity penalty is incurred in performing a construction task using the Table 1 controls" (Document ID 4217, p. 91). OSHA agrees, in part, and recognizes that there can be a productivity impact for equipment (as well as for labor) for many tasks when there is a cost created by having to extend the rental time of the equipment.

In the PEA, OSHA had estimated the labor productivity impacts associated with engineering controls to reduce silica exposure. For this FEA, the Agency has added a parallel cost for the equipment portion of the cost for a number of equipment categories. These are itemized in Table V-34. For example, for Task 15 (Demolition of concrete slabs, mesh-reinforcing, up to 3" deep), there is estimated to be a 2 percent labor increase related to maintaining wet methods for dust suppression. In the original RS Means estimates, it was estimated that approximately 70 percent of the costs of the task were labor-related, divided between an operator and a laborer. This 2 percent additional cost is estimated to amount to $9.39 in added labor cost for an equipment operator and $7.84 for a laborer, or a total labor productivity cost per job of $17.23. For the FEA, OSHA is adding an additional cost item of $7.58 to reflect an opportunity cost, in the form of a prospective extended equipment rental cost, raising the total incremental estimated cost to $24.81 per task. As with the other construction engineering control costs, this additional cost item is task-specific.

While OSHA judged that equipment productivity can be impacted negatively by the new rule for many tasks, there are two general categories for which the Agency determined that there would be no impact on equipment productivity. The first broad category is short-term, intermittent work in which the equipment and control are often idle. An example would be a plumber drilling holes in concrete. The equipment and control are sufficiently inexpensive (relatively speaking) that the construction employer or trade contractor (or possibly even the tradesperson) would typically own rather than rent the equipment and control. As discussed elsewhere in this FEA, OSHA determined that certain tradespersons, such as plumbers, electricians, and their helpers, are more likely to purchase their equipment, rather than renting it. OSHA estimated the cost of purchasing control equipment at twice the rental cost.

The second category of tasks for which the Agency did not assess any equipment productivity impact is the group of tasks in which there is not a fixed ratio of labor to capital (capital in this case including rental costs). For example, as explained in the following unit cost discussion, Task 10 (as detailed in Table V-34) involves performing earthmoving as a heavy equipment operation task. In this case, while extra time by a laborer would be required to tend to the application of wet methods, such application would be done simultaneously with actually performing the earth-moving task. Thus, while wet methods for Task 10 would require an added labor cost (itemized as a “productivity” cost), it would not actually slow down the operation so as to require the longer period of use of the equipment that would impose an equipment impact.

CISC/Environomics also argued that part of the productivity effect was fixed and would therefore need to be accounted for separately. This fixed component, CISC/Environomics reported, would be “typically involving activities such as initial set-up and final take-down and clean-up of the control equipment, [which] often occur at the beginning and end of a job or work shift" (Document ID 4217, p. 90, see also 2320, p. 28; 3580, Tr. 1320). This would mean that shorter jobs would have a relatively larger percentage loss in productivity.

Other commenters did not agree that there would be costs related to set up. During the hearings, Deven Johnson, of the Operative Plasterers' and Cement Masons' International Association, testified that the concrete grinding "tools that are on the market today come integral with the capture device[…] The hose is attached to the grinder already. The electrical cord is attached to the motor already. […] You simply plug it in and start using it […] there's no setup time" and that for "a walk-behind concrete diamond-bladed saw for cutting slabs, the setup time is, make sure there's gas in it and . . .hook a water hose up to it and turn the water on" (Document ID 3581, Tr. 1699). During the hearing, Manafort Brothers described a wheel-based machine used to suppress dust during demolition operations, which was simply wheeled onto the worksite and hooked up to a water supply and electrical source (Document ID 3583, Tr. 2430), and the Building Trades Construction Department (BCTD) of the AFL-CIO submitted an extensive list of available tools that included the controls required by the rule that would require little or no set up (Document ID 4073, Attachment 4a).

Based on the evidence in the record, OSHA determined that any time needed to set up the engineering controls required by this rule is adequately accounted for in the productivity impacts the Agency has included, particularly in light of the fact that OSHA is not making any adjustment to account for productivity improvements that are likely to result from this rule (see the discussion of comments identifying productivity improvements later in this section). Environomics' inclusion of both a "fixed" productivity impact as well as a "variable" productivity impact, without recognizing offsetting productivity benefits identified by other commenters', results in a significant overestimate of the productivity impact.

Public comments suggesting that OSHA had overestimated the productivity impacts associated with engineering controls

BCTD strongly disagreed with CISC's estimates about productivity decreases resulting from the rule, stating in their post-hearing brief:

> [a]ll that [CISC] offered to support these significant increases [in the productivity impact] is an explanation of how its approach to calculating productivity differs from OSHA's and a few examples, such as:
>
> > So in the case of the carpenters with the dust extraction equipment on the drill and the HEPA vacuum, the carpenter takes a little bit longer to do his hole-drilling task because he's got to attach the equipment to the drill. He's got to

> attach the hose to the HEPA vacuum. He's got to walk over before he drills and he's got to turn on the HEPA vacuum. Then after he drills, he's got to turn off the HEPA vacuum. He's got to periodically empty the HEPA vacuum. He's got to worry about the vacuum hose from the drill to the vacuum getting kinked and all that sort of thing. So the job takes a little bit longer. Tr:1317-18.

CISC offered no evidence that its analytical approach is more accurate than OSHA's. Moreover, this description of how its hypothetical carpenter would deploy control technology assumes the employer would select the most cumbersome and inefficient technique available, rather than taking advantage of the range of more suitable and less costly tools that are readily available on the market. See, e.g., Ex. 4073, Att.7a (ROI: hand-held drill with integrated dust collection) (Document ID 4223, pp. 55-56).

BCTD also took exception to the fact that "CISC acknowledged that 'there may be a productivity net gain in terms of cleanup from using a control,' Tr:1319 (Sessions), [but did] not appear to have taken potential gains into consideration when estimating its lost productivity cost" (Document ID 4223 pp. 55).

Dr. Ruth Ruttenberg highlighted the various areas where the PEA may have overestimated the negative productivity effect of engineering controls in construction. She stated that the assumption of a negative impact on productivity

> is yet another example of OSHA erring on the side of being conservative in cost estimates. Despite the fact that some who were interviewed suggested there could be a positive impact on productivity, OSHA's PEA assessed anywhere from 0 percent to a 5 percent penalty in productivity loss as a result of OSHA compliance with the proposed silica rule. (PEA, p. V-123-124) The impact of an assumption of lost productivity can be profound, and OSHA acknowledges this: "…the magnitude of the productivity impacts can substantially change the estimate of the overall cost increase associated with controls" (PEA, p. V-131).
>
> Despite the fact that OSHA leaves likely productivity increases out of its calculations, it does point to opportunities to increase productivity with dust control. […]
>
> Limiting dust increases visibility for workers. (PEA, p. V-126) Vacuum systems speed up drilling because continuous removal of drill cuttings from the hole, reduce the need for workers to periodically stop and clean. (PEA, p. V-128) And the list goes on. OSHA's cost estimates are conservative, and high, when it comes to productivity impact (Document ID 2256, Attachment 4, p. 7).

Productivity improvements

In addition to comment that the productivity loss due to this rule would be minimal, the Agency also received considerable comment to the record that the controls would *improve* productivity in a number of ways the Agency had not factored in—for example by reducing clean-up time by capturing dust at the source, improving worker comfort and morale, and encouraging innovation.

Productivity improvements – reduced clean-up time

Testimony at the public hearings by the International Union of Bricklayers and Allied Craftworkers on the experience by union members with engineering controls suggested that use of controls may boost productivity by reducing the amount of dust that needs to be cleaned up during a given shift. The following is a hearing dialogue between Chris Trahan of BCTD, and Sean Barrett of the International Union of Bricklayers and Allied Craftworkers:

> MS. TRAHAN: […] In your experience is there any productivity gains or benefits that you can describe?
> MR. BARRETT: I can. These machines, when running correctly, when […] the vacs are regulated, the filters are running good. You can run that machine until 3 o'clock in the afternoon, shut it off, and go home. […] If [the machine is] not [running correctly], you constantly got to keep going back and cleaning up what you already did. You're losing productivity. And over the course of […] a month you're talking 40 man-hours. You're talking a -- paying a guy for a week. It's -- that's not the case at all [if dust controls are functioning]. You would actually increase productivity by having the right equipment there and not have people have to keep coming back or jimmy-rig little things to try to get by. Just do it the way it was designed, and you'll get a lot farther. . . . (Document ID 3585, Tr. 3055-3057).

Deven Johnson of the Operative Plasterers' and Cement Masons' International Association elaborated on the potential time savings of some of the new engineering controls:

> One of the other things that collecting the dust from these operations on the front end does, it saves time on cleanup. Some of the industry people have said that it's prohibitive to do that because it takes more time to collect the dust. That's also not true. If you're collecting the dust as it's generated and it's going into a HEPA-filtered container, it's not being blown all over the job site, you don't need anybody else to clean it up (Document ID 3581, Tr. 1594).

Walter Jones of the Laborer’s Health and Safety Fund testified that, for some tasks, reducing or eliminating the need to clean up after a job can dramatically increase productivity, in this case by one-third:

> We had the Bricklayers here a few days ago and they were talking about their ability to work till 3:00, because they did not have to clean up. Instead, when they use non-dust controlling or capturing devices, they would have to stop right after lunch in order to begin cleaning up. So we're looking at adding a few more hours to the workday. So to me, in my mind, they're way more productive (Document ID 3589, Tr. 4246).

Joel Guth, President of iQ Power Tools and a mason contractor, testified that he had been able to document the savings in clean-up time.

> In certain industries we've been able to measure the time savings from cleaning up the silica dust . . . . It saves them one to two to three hours a day in cleanup time because they don't have to wash down the house or wash the windows or wash the bushes where they're inherently dry cutting (Document ID 3585, Tr. 2981).

Scott Schneider, CIH, Director of Occupational Safety and Health. Laborer’s Health and Safety Fund of North America, discussed how engineering controls contribute to a more productive workplace:

> When you control the dust and you don't have -- you're not breathing it into your lungs, but you're also not spraying it all over the construction site, all over the sidewalk, and you have to clean it up, there's a lot of other costs involved in not controlling. So I think we're going to realize those benefits by implementing the standard (Document ID 3589, Tr. 4277).

<u>Productivity improvements – improved worker comfort</u>

OSHA also heard a good deal of testimony suggesting that productivity will be improved through the use of engineering controls due to improving the working conditions for workers.

Mr. James Schultz of Wisconsin Coalition of Occupational Safety and Health described the physiological and practical benefits of introducing or enhancing engineering controls:

> I think if you would work in the work environment that was less dust or hopefully dust free, it would definitely increase the amount of productivity just because so much of the time you're spending wiping the dust off your

> brow because it's falling into your eyes or something like that. Even if you have the respirator, it still interferes with your vision and things like that. So a cleaner environment would definitely be more productive just because […], you spend less time trying to think about how you can protect yourself from this hazard, and I know myself, after working in the place for many years, I've started to have breathing problems and so if you can eliminate those breathing problems, if you can breathe freely, you're also going to be much more productive because you're not going to stop because you have [to] wheeze or go stand outside to get some fresh air for awhile or those types of things (Document ID 3586, Tr. 3253-3254).

Deven Johnson, mentioned previously, testified about the human effect of controlling silica as well:

> Another thing is, an individual who is working in an environment where […] he or she is constantly bombarded with concrete dust all day long, your productivity drops as you get more and more miserable as the day goes on. Commonsense would dictate, if you're not blasting me in the face with dust and sand and silica for eight hours a day, that I'm going to feel physically better and I'm not going to be as tired and exhausted and pissed off as I normally would be at the end of the day. Your productivity goes up […] (Document ID 3581, Tr. 1594-1595).

Mr. Javier Garcia Hernandez, from National Council for Occupational Safety and Health/ Equality State Policy Center/Laborsafe, testified on the cognitive factors that affect productivity, and why engineering controls should aid productivity:

> . . . as a construction worker, I highly believe that we're more productive when we are protected [. . .]. We spend less energy focusing on how to protect ourselves. Just imagine you're working in a roomful of dust and you're just trying to either close your eyes or cover your mouth so the less you breathe. So you're constantly thinking about how to breathe less dust but if you have the respirator or the wet, the controlled area, whether it is water or respiratory protection, you're much more productive because our mind is less occupied in how to protect ourselves and we spend that time that we would have spent protecting ourselves working (Document ID 3586, Tr. 3248-49).

Todd Ward, a bricklayer, testified that workers have some awareness of the hazards of dry cutting blocks and that

> when [workers] on the job [are] dry cutting they know -- it affects morale as well when they know […] they have some safeguards and they're protecting their lungs. So there is an increased productivity when you have a good morale then on the job (Document ID 3585, Tr. 3057).

Productivity improvements - innovation

OSHA received comments on the fact that OSHA standards often lead to innovation. The Laborers' Health and Safety Fund of North America pointed out that "[j]ust about every OSHA standard has had a look-back that has shown […that] industry has innovated to meet the new standard" and continued, saying that "[w]e believe a new OSHA standard with a lower PEL will spur innovation in the construction industry to meet the challenge" (Document ID 3589, pp. 4183-4184).

Charles Gordon observed that "reality is that the new technology will increase productivity faster, so that the actual costs will be much less than predicted" (Document ID 3855, Tr. 3815).

Conclusions regarding productivity impacts

In summary, while some commenters have asserted that OSHA has underestimated the productivity penalties of using engineering controls in construction, other evidence in the record suggests that the aggregate net productivity effect of implementing engineering controls could either be neutral, or possibly positive. In the absence of detailed quantitative data on these various potentially offsetting effects, OSHA has conservatively chosen to retain its percentage estimates from the PEA, while adding some additional productivity impacts that will cause an increase not only to labor costs but also to equipment costs.

There is one exception: OSHA has removed the productivity impact that it had included in the PEA for drywall installers. As explained in the unit cost discussion, the Agency has determined from the record that there is no economic reason why drywall installers would now use silica-based drywall installation—the U.S. market has shifted entirely to a silica-free compound (Document ID 2287, p. 38; 2296, Attachment 1, p. 30; 1335, pp. 3-4, 7, 10). Therefore, there is no longer a logical basis for a assigning a productivity loss to workers performing this task.

Table V-33 summarizes the labor productivity estimates. As discussed previously, while empirical quantitative data are quite limited on productivity, it is possible to gauge the relative productivity impacts across the principal control options. For example, OSHA judged that there are no productivity impacts for certain controls, such as mobile crushing machines. On the other hand, OSHA found that the controls required for tuckpointers and grinders may result in additional time being spent setting up and maintaining controls over the course of a workday. In Table V-34, productivity impacts, or "lost production time," are shown by task and are factors in OSHA's estimate of incremental cost per day.

As discussed, OSHA has retained most of its original estimates of the productivity effects from the PEA. In some cases, however, Table 1, which forms the basis for the equipment categories listed in Table V-33, was changed from the PEA in response to comment. (See Methods of Compliance in the preamble for further discussion on the changes to Table 1). In other cases, OSHA received clarification on the manner of exposure and added elements to Table V-33, but did not adjust the productivity impact. For example, OSHA received very specific comment on tasks involving portable masonry saws used to cut fiber cement materials (e.g. "Hardie board"), and this is reflected in specific descriptions in Table 1 and in Table V-33, but the estimated productivity impact for "masonry cutting using portable saws" remains the same. Similarly, the Table 1 task that included "heavy equipment operations" in the proposed rule has been broken out into two groups: (1) heavy equipment operators and ground crew laborers used for activities such as grading and excavating that will not involve demolition or other uses that will abrade or fracture silica-containing materials; and (2) heavy equipment operators and ground crew laborers involved in demolition or the abrading or fracturing of silica-containing materials. These two categories are now estimated to have productivity impacts of two and three percent, respectively.

Table V-33: Productivity Impact Estimates for Construction Equipment Categories

Affected by OSHA's Final Silica Standard

Productivity Impact	Source/Rationale for Productivity Impacts	Equipment Categories Affected
None	Dust control is well-integrated into equipment; control set-up can be accomplished with little or no additional effort or as part of substantial set-up effort (In some cases, dust control can improve worker comfort and might enhance productivity)	Rock and Concrete Drillers; Mobile Crushing Machine Operators and Tenders
2% (approx. 10 minutes/day)	(1) Dust control requires incremental set-up time, or (2) Incremental maintenance, or (3) Additional clean-up (Controls have little impact on job performance)	Millers Using Portable or Mobile Machines; Hole Drilling Using Handheld or Stand-mounted Drills; Masonry Cutters Using Stationary Saws; Masonry and Concrete Cutters Using Portable Saws; Heavy Equipment Operators and Ground Crew Laborers (grading and excavating)
3% (approx. 15 minutes/day)	Dust control requires incremental set-up time and some increase in maintenance or clean-up requirements	Jackhammers and Other Powered Handheld Chipping Tools (wet methods); Heavy Equipment Operators and Ground Crew Laborers (abrade or fracture silica-containing materials or demolition)

Productivity Impact Estimates, by Equipment Category

Rock and Concrete Drilling

This equipment category includes the following Table 1 tasks:

- Dowel drilling rigs for concrete; and
- Vehicle-mounted drilling rigs for rock and concrete

This equipment category covers a range of drilling activities using truck-mounted and similar drilling equipment, such as quarry drills and crawler-type drills. Dust control requires the use of either a dust collection system or wet drilling methods. Studies of the effectiveness of available dust collection systems have not addressed performance issues, but ERG judged that their use does not affect drilling productivity. While workers must service the dust control equipment during the workday, this activity generally does not affect the rate of drilling, except perhaps for short-duration jobs. The wet drilling methods are integrated into drilling equipment and also should not adversely affect the drilling rate. Thus, OSHA estimates that there will be no lost production time for these tasks.

Tuckpointers and Grinders

This equipment category includes the following Table 1 tasks:

- Handheld grinders for mortar removal (i.e., tuckpointing); and
- Handheld grinders for uses other than mortar removal

According to ERG's search of the literature, grinding tools can be retrofitted with dust control shrouds that connect to a vacuum system (Buser, 2001 & 2002, Document ID 0577). Studies on the use of these controls indicate that extra time is required to install the shroud and periodically clean, empty, or replace the vacuum drums, filters, or bags. The estimated time to install the shroud may be as short as five minutes, although some types of shrouds take longer to install. Once installed, however, the shroud can be left in place for the work at that location, so this activity need not take place at the initiation of each grinding job.

For interior jobs and for exterior work that requires site cleanup of grinding debris, the additional work time required to use a vacuum system might be partially offset by savings in the time required to seal work areas (to prevent dust migration) and to clean the work area after task completion. Overall, clean-up times will vary depending on the size of the job site, the quantity of grinding debris, and the strength and capacity of the vacuum.

Grinding without a dust-control shroud can generate clouds of dust that might impair a worker's views of the grinding area. Whereas metal shrouds also block the view of the grinding area, plastic shrouds allow workers a view of the work area. Some contractors have noted, however, that use of shrouds does not allow for the precision required for certain tasks, such as grinding an inside corner (Lattery, 2001, Document ID 0777).

For exterior jobs where cleanup is not required and where the work area is not sealed, the use of vacuum equipment is likely to decrease productivity for the amount of time required for servicing the vacuum collectors. If, for example, five minutes were required to empty the vacuums every two hours, production time would decline about 4 percent, due simply to dumping the accumulated dust.

At some construction sites, vacuums have been used during the grinding process, but without shrouds. In these cases, one worker typically holds the vacuum nozzle near the grinding tool, which another worker operates. Switching to shrouds with a direct vacuum attachment would eliminate the need for this assistant and is a more productive operation. Manufacturers and vendors cited other benefits from using the shroud-vacuum systems. Because dust does not build up on and clog the surface of the grinding wheel, the wheels last longer, resulting in an approximate 40 percent savings on the grinding discs (Eurovac, 2001, Document ID 0688). Another source contacted by ERG estimated that shrouds can increase the abrasive life of a grinding wheel by more than 500 percent (Buser, 2001 & 2002, Document ID 0577). In this regard, workers would spend slightly less time replacing wheels over the life of the equipment.

OSHA concluded that while the productivity impacts of vacuum systems can sometimes be partly offset by other factors, net productivity impacts are likely to remain negative. For exterior work, productivity is clearly lower when workers use a vacuum system. Overall, based on ERG's research, OSHA's final cost estimates include a 5 percent impact for lost production time associated with grinding operations in construction. This productivity impact is identical to the impact estimated for this activity in the PEA.

For a tuckpointing project, NIOSH researchers examined the use of vacuum system controls at a large college building complex (Gressel et al., 1999, Document ID 0718). Workers used a shroud-vacuum system with an integral impeller and a fabric dust collection bag. This system required emptying the collection bags about once an hour. The authors reported some problems caused by blocking and kinking of the hose and occasional separations of the hose from the tool. Some of these problems can be attributed to the design of the dust control system and might be rectified by future design innovations. Overall, the vacuum control systems appeared to reduce worker output. Manufacturers and vendors contacted by ERG estimated that polyurethane shroud-vacuum systems with tuckpointing equipment, similar to those used with hand-held grinders, actually enhance productivity. Among the reasons provided for productivity improvements were: (1) fewer workers were required; (2) cleanup times were reduced; (3) workers had improved visibility of the work surface; and (4) blades last longer (Buser, 2001 & 2002, Document ID 0577; Caperton, 2002, Document ID 0580; Eurovac, 2001, Document ID 0688; Nash and Williams, 2000). These observations on productivity applied to tuckpointers with 2- to 8-inch diameter wheels. In addition, positive effects on worker productivity have also been reported for shrouds that fit on 5-inch and 7- to 8-inch (18-lb) tuckpointers with integrated dust-collection systems since equipment without integrated dust-collection systems require that an additional worker be present to continually vacuum dust away from the work area (Document ID 0577). On the equipment that can be used with the tuckpointers with 5- to 8-inch wheels, an impeller inside the tool housing pushes dust down a hose into a reusable dust-collection bag (Document ID 0577). One vendor estimated that the operational productivity of these tools is no different from that of the same tool without dust control capability. Workers would still be required to periodically empty dust bags, although other clean-up time might be somewhat reduced (Document ID 0580). Because tuckpointing work is almost exclusively exterior work, however, clean-up is often not required.

Based on the considerations for hand-held grinding tools discussed above and the findings from the NIOSH tuckpointing study, OSHA judged in the PEA that use of a vacuum system during tuckpointing operations would impose, on average, a 5 percent negative productivity impact. Based on these findings and because manufacturer optimism about any positive productivity impacts has not been documented in controlled studies, OSHA included the same 5 percent negative productivity impact for tuckpointing tasks in this FEA.

Heavy Equipment Operators and Ground Crew Laborers

This activity includes the following Table 1 tasks:

- Heavy equipment and utility vehicles used to abrade or fracture silica-containing materials (e.g., hoe-ramming, rock ripping) or used during demolition; and

- Heavy equipment and utility vehicles for tasks such as grading and excavating but not including: demolishing or abrading or fracturing silica-containing materials[55]

The control method proscribed in the proposed silica standard was to enclose and ventilate the operator's cab. The requirement for an enclosed cab is only retained in the final standard with respect to the use of heavy equipment used to abrade or fracture silica-containing materials or used during demolition. Final Table 1 allows employers to control dust from heavy equipment used for other purposes (e.g., grading or excavating) by using wet methods.

Using an enclosed cab on heavy construction equipment will not require maintenance beyond the general maintenance necessary to maintain the integrity of the cab enclosure. Therefore, OSHA estimated in the PEA that no productivity loss will be incurred for this control.

In the case of heavy equipment operations, CISC/Environomics estimated that there would be a one percent productivity penalty for enclosed cabs, due to communication issues and the need to unclog HEPA filters (Document ID 4217, p. 93). For several reasons the Agency is not persuaded that the factors CISC cites would result in a net productivity loss for enclosed cabs on heavy equipment.

First, it is not clear that communication issues are being created by setting some minimal standards for enclosed cabs. Information supplied in the record indicates that there are alternate means of communication beyond shouting from the cab to the front-line workers outside the cab, including hand signals (Document ID 3583, Tr. 2441) and existing wireless communication systems (Document ID 0805, p. 4; 2262, p. 28). Many of these work environments are noisy, which seems to make alternate means of communication desirable, if not required.

Second, it appears that it may be more economical and desirable for workers to operate in a climate-controlled cab and that equipment with enclosed cabs has become standard in the construction industry. In fact, OSHA has determined that relevant heavy equipment currently comes with an enclosed cab as standard equipment (Document ID 3813, 3814, 3815, 3816), and in pricing construction jobs, RS Means included a cab as a standard equipment (meaning that it was already included in the equipment cost, not an added engineering control). In any case, the fact that cabs are standard suggests that potential buyers do not view the presence of a cab to be undesirable. While Environomics

---

[55] Heavy equipment operations (grading and excavating) was referred to as earth moving in the PEA and in comments. The term has been updated for this analysis and used throughout for the sake of consistency and to avoid confusion.

acknowledged this possibility at the hearings, their judgment remained that there would be a net productivity loss (without providing information on how these offsetting considerations were being incorporated) (Document ID 3580, Tr. 1434-1435). While OSHA is not persuaded that the evidence in the record supports Environomics conclusions, their argument is largely moot. Any productivity impact would result only from the addition of new controls, but enclosed cabs appear to have become standard on the relevant equipment, meaning that in most cases employers would not have the option of using open cabs even if OSHA's new rule was not in effect. Thus, there can be no productivity impact attributed to the requirement for a cab.

Although OSHA is not including any productivity impact to account for enclosed cabs, final Table 1 requires water, or other dust suppressants, during specified heavy equipment operations in order to protect workers outside the cab and as an alternative method of protecting operators for activities that do not involve silica abrading or fracturing. OSHA has therefore, as indicated in Table V-33, added a 2 percent productivity impact for heavy equipment tasks involving grading and excavating, and 3 percent during demolishing, abrading or fracturing silica-containing materials. OSHA judged that the abrading, fracturing, and demolition-related tasks tend to be relatively dustier, and would therefore require relatively more labor to administer.

Hole Drilling Using Handheld or Stand-mounted Drills

This equipment category includes the Table 1 task "handheld and stand-mounted drills (including impact and rotary hammer drills)."

This category includes workers in the construction industry who use handheld drills to create clearly defined holes for attachments (e.g., anchors, bolts, hangers) or for small openings for utility pass-throughs in concrete and other silica-containing construction materials. Workers use common electric drills, pneumatic drills, handheld core drills, stand-mounted drills, rotary drills, rotary hammers, percussion hammer drills, or other impact drills to drill holes. With regard to core drills, only small, handheld core drills with bits up to a few inches in diameter are included in this category. This discussion does not address the use of portable and mobile hole saws used to produce large holes or openings. That equipment is covered in the discussion of Masonry and Concrete Cutters Using Portable Saws.

Handheld and rig-mounted drills can be equipped with local exhaust ventilation to effectively capture dust generated when drilling small diameter holes. Larger core drills, also referred to as core saws, are more frequently used with water as a coolant to extend the service life of the drill bit, as well to suppress dust.

One rock-drill manufacturer asserts that use of vacuum systems speeds drilling by continuously removing the drill cuttings from the hole, making it unnecessary for workers to periodically stop drilling to accomplish this task (Atlas-Copco, 2001, Document ID 0542). On the other hand, the connection and servicing of the vacuum equipment requires incremental work that could reduce productivity. If the construction project at hand involves interior work, this impact might be offset by reductions in the time necessary for cleanup (i.e., interior work would require cleanup, while exterior drilling probably would not). In the PEA, OSHA applied a 2 percent productivity impact where this task is performed and did not receive comment suggesting that this estimate was too low, so OSHA retains the same 2 percent productivity impact in estimating compliance costs in this FEA.

Jackhammers and Other Powered Handheld Chipping Tools

This equipment category includes the Table 1 task "Jackhammers and handheld powered chipping tools."

Silica exposures generated during pavement breaking, concrete demolition, and other concrete work using jack hammers and other handheld powered chipping tools (including pavement breakers and other similar tools) are controlled through the use of wet or dry methods.

Regarding wet methods, because the work area generally cannot be presoaked effectively (i.e., dust is generated once impact drillers break through the surface), OSHA judged that adequate dust control requires a constant spray of water to the work area. Thus, dust control requires that a water sprayer be mounted onto the jackhammer (or that a mobile sprayer be set up that can move along with the work). Alternatively, a crew member can use a water hose to spray and wet the concrete and asphalt surfaces being broken, although the associated productivity loss could be substantial, and, for that reason, OSHA believes that construction firms would likely try to avoid that approach.

However, OSHA judged that the incremental productivity impact from the spraying activity is modest because various crew members could occasionally be enlisted to keep the water spray directed in the correct location. Further, because of the interactive nature of the various crew member activities, the time to move the water sprayer is unlikely to affect the overall crew output. In addition, incremental cleanup costs generally would not be significant since most drilling projects are performed outside. Nevertheless, to allow for some incremental work related to supplying water and positioning the spray when wet methods are used, as was the case in the PEA, for this FEA OSHA estimated a 3 percent productivity impact for this equipment category when wet methods are used.

A separate, higher, productivity impact was defined for use of dry methods for activities where jackhammers and other handheld powered chipping tools are used. Dry methods are somewhat less flexible and require a shroud for the close capture of dust as it is generated during operations. Workers also periodically have to empty the vacuum bags in which the dust accumulates. Thus, as discussed above with respect to the use of a shroud for grinding and tuckpointing, these controls are judged to generally have a greater productivity impact during operations and, consistent with the PEA, OSHA assigned a 5 percent productivity impact for use of this control method for this equipment category.

Masonry and Concrete Cutters Using Portable Saws

This equipment category includes the following Table 1 tasks:

- Handheld power saws (any blade diameter);
- Handheld power saws for cutting fiber-cement board (with blade diameter of 8 inches or less);
- Rig-mounted core saws or drills;
- Walk-behind saws; and
- Drivable saws

Drivable saws and walk-behind saws have an integrated water tank, and the sawing is almost always done wet (see Chapter IV, Technological Feasibility). Wet sawing keeps the blade from overheating, with the water acting as coolant. Both the PEA and this FEA included no incremental costs or productivity impacts for use of this equipment. Rig-mounted core saws used to drill larger diameter holes in concrete are typically used with water as a coolant to extend the service life of the bit, as well as to suppress dust.

As has been noted, most portable hand-held concrete saws are designed with wet-sawing capability (see Chapter IV of this FEA, Technological Feasibility). These saws have a water hookup for a hose attachment, but might also be used for dry cutting. (Dry-cut diamond blades for dry cutting are available; these are made especially so that the tips do not separate during dry cutting.)

A construction equipment distributor judged that there are no operational productivity advantages for dry cutting, as opposed to wet cutting (Healy, 2002, Document ID 0726). Wet cutting, however, requires access to water (water line or pressurized tank), and some time is needed to connect the equipment (although OSHA received a number of comments saying that this hook up is very simple and not time consuming—see “Public comments suggesting that OSHA had underestimated the productivity penalties associated with engineering controls" earlier in this section for more detail). In addition, the water hose hookup may be cumbersome and interfere with the work (Healy, 2002, Document ID 0726). For these reasons, as was estimated in the PEA, for this FEA OSHA assigned a cost of 2 percent in lost production time for equipment in this category.

For the final rule, the Agency has clarified in Table 1 that hand-held circular saws with a blade diameter of eight inches or less specially designed for cutting fiber cement board can be used outdoors without respiratory protection, when equipped with a local exhaust ventilation. The productivity impact for this group is also estimated at 2 percent because, although it does not have an impact on job performance, it involves some set-up time and incremental maintenance.

Masonry Cutters Using Stationary Saws

This equipment category includes the Table 1 task "Stationary masonry saws." Stationary saws for masonry, brick, and tile cutting come equipped with water systems for wet cutting, which is the conventional, baseline control method for this type of work. Some modest incremental time is needed to provide for and connect the water supply and to maintain the water nozzles and spray system. This incremental time was the basis for OSHA to estimate a 2 percent cost in lost production, both in the PEA and in this FEA.

Millers Using Portable or Mobile Machines

This equipment category includes the following Table 1 tasks:

- Walk-behind milling machines and floor grinders;
- Small driveable milling machine (less than half-lane);
- Large driveable milling machines (half-lane and larger with cuts of four inches in depth or less)

The activities performed using equipment in this category range from cold planing and cleaning of asphalt to surface planing or grinding of concrete. In large-scale projects, such as street resurfacing, baseline practices are judged to control silica dust exposures. No additional controls would be needed, and therefore no negative productivity impacts are expected.

While some grinding machines designed for milling concrete surfaces have built-in dust collection or wet-method systems, others must be attached to external vacuum equipment. ERG reviewed the available literature and found no evidence that the grinding operation is slowed when such vacuum equipment is attached. Nevertheless, workers must devote some time to setting up equipment, changing vacuum bags or barrels, and cleaning filters. On the other hand, using an LEV system to capture dust as it is generated reduces the time required for cleaning up the settled dust from the surfaces following completion of the grinding task. OSHA estimated in the PEA that there would be a 2 percent productivity impact for milling using wet methods and a 5 percent productivity impact when using LEV systems.[56] These estimates have been retained for this FEA.

Mobile Crushing Machine Operators and Tenders

This equipment category comprises the Table 1 task "Crushing machines."

OSHA projected in the PEA that there would be no productivity impact for this equipment category. The Table 1 requirements for this machinery have changed in the final rule, but OSHA's conclusion that there will be no productivity impact remains the same. Final Table 1 requires employers to protect employees through a combination of sprayers and requiring the operator to operate the machinery from within a ventilated booth or at a remote control station. Once installed, the sprayer systems will be part of the crushing machine operation and will not impact production rates. For the purpose of the economic analysis of this rule, OSHA has accounted for additional costs for use of the ventilated booth. Because the booth can be located close to the machinery, there would not be productivity loss from the operator having to travel to a different location for operation. In most cases the booth can be set up quickly once at each location, so in most cases there will not be any significant productivity loss associated with the use of the booth.

Baseline and Incremental Unit Control Costs

Table V-34, developed using the cost data presented in Tables V-30, V-32, and V-33, summarizes the control method and costs per day for each representative construction job. These costs include incremental equipment costs and indirect labor costs due to productivity impacts (decreases in productivity associated with the use of the control equipment).

As an example, consider Task 11: Hole drilling using hand-held or stand-mounted drills in Table V-34. The 2 percent labor productivity impact for this task (from Table V-33) was applied to the daily labor cost of this task of $495.60 (from Table V-30)—yielding a

[56] For the FEA, milling operations using LEV are accounted for under grinding operations, as indicated in Table V-24.

daily labor productivity impact of $9.91. Consistent with the CISC methodology that OSHA adopted, this task was considered short-term, intermittent work using control equipment that carpenters and other occupational groups would own. Therefore, no equipment productivity adjustment was applied to this task, and the combined daily labor and equipment productivity impact was $9.91. The daily costs for the dust extraction kit and 10-15 gallon vacuum with HEPA ($3.16 and $5.58, respectively, from Table V-32), were based on a "half-life" of the equipment because of the intermittent and short-term nature of the work (here, 75 days rather than 150 days), again consistent with the CISC methodology that OSHA adopted. Therefore, the incremental daily equipment cost of the controls for Task 11 is $8.75 ($3.16 plus $5.58, with adjustment due to earlier rounding), and the total incremental daily cost of the controls for Task 11 is $18.66 ($8.75 plus the productivity impact of $9.91).

Note that the only other silica task in Table V-34 considered to have short-term infrequent work where the employee (carpenter) would own the equipment are Task 11: Hole drilling using hand-held or stand-mounted drills and Task 18: Masonry cutting using portable saws – II. Note also that all the indoor tasks in Table V-34 have an additional daily control equipment cost of $1.67 for a fan.

Table V-35 summarizes the baseline costs and incremental control costs from Tables V-30 and V-34, respectively, for each representative silica-related job in OSHA's silica construction cost analysis, where the control costs (defined as incremental control costs per day) are shown in Table V-35 as a percentage of the baseline daily job costs. As the incremental control costs were obtained from Table V-34, they are just the sum of additional labor and equipment costs associated with the use of silica controls, including the labor and equipment productivity impacts of the use of the silica controls.

As an example, consider again Task 11: Hole drilling using hand-held or stand-mounted drills in Table V-35. The total daily baseline cost of $502 for this task was obtained from Table V-30. The total daily incremental control cost for this task of $18.66 (as well as the preceding numbers in the row) was obtained from Table V-34. The incremental control cost as a percentage of the baseline daily job costs for Task 11 is simply $18.66/$502, or 3.7 percent of the daily costs.

As shown in Table V-35, these incremental control costs range from 0.3 percent of the baseline job cost for Task 22: Rock crushing, excavation projects, to 1.5 percent of the baseline job cost for Tasks 1 and 2 under Rock and Concrete Drillers, to 7.8 percent for Task 10: Heavy construction equipment operating - II (earthmoving). As is evident from Table V-35, the magnitude of the productivity impacts can substantially change the estimate of the overall cost increase associated with the silica dust controls.

Table V-36a presents the weighted average of control costs by task category for outdoor tasks. OSHA defined “weights” for each job category (column “Relative Frequency Within Categories”) based on the projected relative applicability of the controls and/or tasks within each category (as determined in the technological feasibility analysis in Chapter IV of this FEA). For example, based on the technological feasibility analysis for jack hammers and other powered chipping tools, OSHA estimated that wet methods can be used for 80 percent of jobs but that a focused dust collection system would be required for 20 percent of the jobs. These percentages did not change from the PEA except for the two tasks that have each been further partitioned into multiple tasks in the final rule: heavy construction operators and masonry cutters using portable saws. Heavy equipment operators are subdivided into tasks that involve fracturing, abrading, or demolishing silica-containing materials such as masonry or concrete, that require use of wet methods whenever workers other than the equipment operator are present, and tasks that involve use of heavy equipment for earthmoving and excavation of soil, that require wet methods only as necessary to minimize fugitive dust. Masonry cutters using portable saws are subdivided into five categories, 1) handheld power saws such as cutoff saws, 2) handheld power saws for cutting fiber-cement board with blade diameters of less than eight inches, 3) walk-behind saws, 4) drivable saws, and 5) rig-mounted core saws. Wet methods are specified as a control method for all use of portable saws except for handheld power saws for cutting fiber-cement board, for which LEV rather than use of water to suppress dust is required. The labor cost as a percentage of project costs—which, as subsequently shown, is a critical factor in calculating the total value of all silica-generating construction activities—is derived from Table V-30. For example, for Task 11: Hole drilling using hand-held or stand-mounted drills, labor costs were $495.60 out of total project costs of $501.90, or 98.7 percent of total project costs. The incremental costs as a percentage of baseline costs were obtained directly from Table V-35.

Table V-36b presents the weighted average of control costs by task category for tasks indoors or in enclosed areas (“indoor tasks”). The procedures are identical to those used in Table V-36a, and the only difference is that the total incremental costs as a percentage of baseline costs are higher due to the addition of the cost of a fan for indoor tasks.

Once the total value of all silica-generating construction activity is calculated for each task, as shown in Table V-44, the incremental costs associated with each task category as a percentage of baseline costs (from Tables V-36a and V-36b) will determine the costs that the engineering control requirements in the final construction standard add to the costs of construction activity—that is, the incremental costs of the resulting reduction in silica exposure.

Table V-34

Silica Control Methods, Specified by Construction Activity

	Task Area/ Job Description	Control Method	Control Method Cost Summary	Indirect Labor Cost/Day (Due to productivity impact): Title	Percentage Productivity Impact	Cost per Worker Affected	Equipment Productivity Cost	Total Productivity Impact Cost	Incremental Equipment Cost/Day: Description	Daily Cost [a]	Total	Total Incremental Cost

Aggregate "Key" and "Secondary" Labor Costs for Representative Projects

To estimate aggregate labor costs or value for each equipment category, OSHA first matched OES occupational classifications with the labor requirements for each equipment category (e.g., hole drillers using hand-held or stand-mounted drills). These matching occupations are shown in Table V-37. In order to estimate the percentage of time during each work day that workers spend on activities using equipment in the relevant categories, OSHA designated some occupations as "key" and others as "secondary." The key field in Table V-37 is set to "1", if a key occupation and to "0" if a secondary one. Even those employees who are engaged in tasks on Table 1 typically spend only a portion of their workday engaged in silica-generating tasks, so the distinction between "key" and "secondary" is needed in order to estimate the amount of time workers participate in silica-generating tasks. In the preliminary and final cost analyses, OSHA applied ERG's occupation designation, as explained in greater detail below. OSHA requested comment on the designations of "key" and "secondary" designations in the PEA, but did not receive any comments challenging those designations.

"Key" occupations refer to the worker or workers on each crew who perform the principal silica-generating activity using the equipment in each equipment category. For each equipment category, ERG estimated the overall percentage of time that workers in key occupations devote to the activity. Relying mainly on the RSMeans job specifications, ERG judged, for example, that drillers represent a key occupation for the rock and concrete drillers equipment category outlined in the analysis. For each equipment category, ERG then estimated the overall percentage of time that workers in key occupations devote to the activity. As shown in Table V-37, rock and concrete drillers spend an estimated 75 percent of their time performing relevant drilling activities, such as those that generate silica exposures. In other cases, the activities of those in key occupations are less closely correlated with the equipment in the relevant category. For example, a key occupation using jackhammers and other powered handheld chipping tools was judged to be construction laborers. This group as a whole performs many diverse construction activities, and ERG estimated in Table V-37 that the time spent using jackhammers and other powered handheld chipping tools was, on average, approximately 3 percent of the group's total construction activities.

Other "secondary" crew members (e.g., first-line supervisors/managers and construction laborers) were estimated in terms of their ratio to the number of key workers required for given task areas. The secondary crew ratios range from 0 percent (no one in a secondary occupation engaged in silica-generating tasks) to 300 percent (three times the number of secondary occupation workers, in relation to the number of key workers, exposed to silica-generating tasks). As noted above, OSHA used these percentages and ratios to estimate (on an annual basis) the amount of time these employees are using relevant equipment to engage in work that causes silica exposures. The estimate of the percentage of time performing the silica-generating activity can be viewed in terms of the full-time-equivalent (FTE) employees engaged in work that utilizes equipment in each equipment category. These estimates and the corresponding ratios for secondary workers are shown in Table V-37.

Table V-37

Key and Secondary Occupations by Construction Task Area

Task No.	Task	Occ. code	Occupation	Key (1=Yes)	FTE share	Secondary ratio
1	Rock and concrete drillers					
		47-1011	First-Line Supervisors/Managers of Construction Trades and Extraction Workers	0	0.0%	50.0%

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on ERG (2007a) and OSHA (2016).

For the key occupations, OSHA was able to obtain some data with which to estimate the proportion of time workers perform activities using silica-generating equipment. For the secondary occupations, such estimates were generally not possible. Thus, the participation of secondary occupations in silica-generating activities was defined based on their relationship to the key occupations. This participation is defined by their presence in the job crews, as shown in Table V-30. To illustrate the need for this approach, consider the difficulty in predicting how often construction foremen of all types are present during activities where silica-generating equipment is used. BLS data, for example, provide only a total number of foremen, but no information about how they might spend their time. It is reasonable to forecast, however, using the job-crew definitions, that foremen will be present in some proportion to the number of workers in key occupations using jackhammers and other powered handheld chipping tools, rock and concrete drillers, and other silica-generating equipment. OSHA presented these data in the PEA and requested comments, but did not receive any on this aspect of the analysis. Therefore, OSHA is retaining its estimates from the PEA, except as noted.

Examining jackhammers and other powered handheld chipping tools as an illustration of the use of these estimates for specific equipment categories, the construction laborer is a key occupation, and first-line supervisors and equipment operators are the secondary occupations. Because the applicable standard work crew (as specified in RSMeans, 2008) consists of a supervisor, an equipment operator, and four construction laborers, OSHA used a ratio of 1 to 4 (0.25, as shown in Table V-37)[57] for *each* of the secondary occupations: four laborers (key) to one supervisor (secondary), and four laborers (key) to one equipment operator (secondary). OSHA uses this 0.25 ratio to estimate the participation level for each of these secondary occupations relative to the key occupation in impact drilling.

In another example, for heavy equipment operators and ground crew laborers, ERG estimated that construction laborers are a secondary occupation and heavy equipment operators are the key occupation for standard work crews involving such equipment. The standard work crew in RSMeans (2008) calls for a heavy equipment operator and 0.5 construction laborers (in other words, the construction laborer is working with the heavy equipment operator half of the time). Therefore, ERG's cost model uses a ratio of 1 to 2 (0.5, as shown in Table V-37) to estimate the participation level of construction laborers relative to key occupations in the equipment category heavy equipment operators and ground crew laborers.

For some activities, the crew size and composition vary among the jobs defined in the equipment category. In those cases, OSHA used ERG determinations as to the most

[57] These estimates are ultimately derived from Table V-19.

representative crew composition and used that crew model to define the ratio of secondary to key occupations (ERG, 2007a).

The estimates of the number of FTE employees engaged in activities using silica-generating equipment are one of many factors that influence the final cost estimates. There are few data, however, on the breakdown of time spent by construction workers in various activities. The following discussion presents the basis for the time-on-task estimates for the key occupations as included in the PEA and the FEA (except where noted). OSHA presented most of these estimates for public comment in the PEA but did not receive any comments challenging them.

Rock and Concrete Drillers

A review of NIOSH reports covering rock and concrete drillers showed that over 75 percent of driller time was spent on actual drilling (NIOSH 1992a, Document ID 0911, NIOSH 1992b, Document ID 0910, NIOSH 1995, Document ID 0907).[58] Therefore, for the PEA and FEA, OSHA used 75 percent as the best indication of the time spent using dust-generating equipment for workers in this category.

Tuckpointers and Grinders

Grinding and tuckpointing are only two of the numerous jobs performed by brickmasons, cement masons, and their helpers. Workers in those trades are much more frequently performing bricklaying, cement work, and masonry construction. Where tuckpointers and grinders are being used, a review of the OSHA Special Emphasis Program reports revealed that the time spent using tuckpointers and grinders varied widely (see the technological feasibility analysis for this activity in Chapter IV of this FEA). In both the PEA and in this FEA, OSHA used ERG's estimate that 2.5 percent of the time for workers in each of the applicable occupations would be spent on using this equipment.

Heavy Equipment Operators and Ground Crew Laborers

For the final rule, heavy equipment operators and ground crew laborers were split into two categories in Table 1 based on how the heavy equipment and utility vehicles are being used, which reflects distinctions added in the final rule. This equipment is considered to either be used a) to abrade or fracture silica-containing materials (e.g., hoe-ramming, rock ripping) or used during the demolition of concrete or masonry structures; or b) for tasks such as grading and excavating but not including: demolition of concrete or masonry structures or abrading or fracturing silica-containing materials.

[58] This percentage is supported by updated data in NIOSH (1999b).

ERG estimated that workers using heavy equipment to abrade or fracture silica-containing materials or for demolition devoted only 2.5 percent of their time, on an FTE-equivalent basis, doing this work.

Key workers in the companion group using heavy equipment for grading and excavating often spend the bulk of their work shift on the equipment itself, engaged in construction work. OSHA Inspection Reports and other documentation consistently show that heavy equipment operators perform their tasks for more than 7 hours per shift (OSHA SEP Inspection Reports 122212079, 116179359; Greenspan, et al., 1995; NIOSH HETA 93-0696-2395, 1999; NIOSH, 1999b; NIOSH ECTB 233-120, 1999c). Nevertheless, the heavy equipment operator occupational category also includes operators of such equipment as pile drivers, cranes, and air compressors that are not generally associated with silica dust generation. For the PEA, OSHA used ERG's estimate of 75 percent for operating engineers and 50 percent for excavating and loading machine and dragline operators in this category to estimate the number of heavy equipment operators performing silica-generating activities. OSHA did not receive any comment on these estimates and has therefore has retained their substance for this FEA.

Hole Drilling Using Handheld or Stand-mounted Drills

While many workers might occasionally be assigned to drill holes in concrete, this equipment category represents a very small part of the activities of the occupational groups performing this work. ERG judged that carpenters, electricians, plumbers, sheet metal workers, and helpers (construction laborers) spend one percent of their time drilling holes in silica-containing materials in the affected industries. OSHA presented this estimate in the PEA and did not receive comment or alternate estimates and has therefore retained the estimate for this FEA.

Jackhammers and Other Powered Handheld Chipping Tools

OSHA estimated in the PEA that in the key occupation of construction laborers, relatively few use equipment in this category. In developing the estimate of time spent using equipment in this category for the PEA, ERG examined a snapshot of construction activities from the BLS publication, *Injuries to Construction Laborers* (BLS, 1986). That source presents a survey of injured construction workers and includes questions about their activities at the time they were injured. The survey indicated that 3 percent of construction workers were using jackhammers at the time they were injured. ERG judged that, while the survey was not intended to characterize typical construction activities, and a survey of injured workers introduces considerable potential bias into the observations, this estimate was useful as an observation of representative construction activities. ERG also judged that, because jackhammers are heavier, more cumbersome, and more powerful than much construction equipment, workers are probably injured more frequently while using jackhammers, on average, than when using all other construction equipment. Thus, the 3 percent figure is likely to be an upper bound of the amount of time spent using jackhammers and other powered handheld chipping tools. In the absence of other data, OSHA used ERG's estimate that 3 percent of laborers are using this equipment for the PEA. The Agency received no additional data or comment on this estimate and has therefore retained this estimate for the FEA.

Masonry and Concrete Cutters Using Portable Saws -- I

The key occupations using portable saws to cut masonry and concrete, namely brickmasons, blockmasons, stonemasons, and their helpers, spend, on average, a small share of their time cutting these materials with portable saws. In Table 1, OSHA notes three types of portable saws: 1) hand-held saws, 2) walk-behind saws, and 3) drivable saws. Each of those is encompassed in this analysis, although small-diameter handheld saws are addressed separately. According to OSHA and NIOSH reports, the workers in these occupations perform multiple masonry activities and might engage in cutting for only a small portion of their shift (OSHA SEP Inspection Report 300646510; NIOSH, 1999a) (Document ID 0084). Another glimpse of this activity can be gleaned from the BLS injury report for construction laborers, where 3 percent of workers were injured while breaking up or cutting concrete, asphalt, brick, rocks, etc.[59] For each of the applicable occupations, OSHA estimated in the PEA that 10 percent of the workers' time would be spent using the equipment in this category. The Agency received no comment on this estimate and has therefore retained this estimate for the FEA.

Masonry and Concrete Cutters Using Portable Saws – II - small diameter saws for cutting fiber-cement board

The task of using handheld power saws for cutting fiber-cement board (with blade diameter of 8 inches or less) was separated out in Table I in the final rule to recognize portable saws used for cutting cement fiberboard or cement fibersiding as a potential source of silica containing dust. OSHA judged that portable saws would be used by carpenters or their helpers to cut fiber-cement board and that, on average, they would spend 2.5 percent of their time using equipment in this category to cut the referenced materials.

Masonry Cutters Using Stationary Saws

[59] OSHA notes that these data are of uncertain value since they probably exclude most craft workers (i.e., masons) and may contain various other potential biases in injury data.

As noted earlier, OSHA and NIOSH surveillance publications report that saw operators perform multiple masonry cutting activities and might engage in cutting silica-containing materials for only a small portion of their shift (OSHA SEP Inspection Report 300646510; NIOSH, 1999a). For the PEA, OSHA used ERG's estimate that workers in mason occupations spend 10 percent of their time cutting silica-containing materials with stationary saws. The Agency received no comment on this estimate and has therefore retained this estimate for this FEA.

Millers Using Portable or Mobile Machines

In the PEA, ERG identified two key occupation groups where millers are using portable or mobile machines: (1) cement masons and (2) paving, surfacing, and tamping equipment operators. In response to comments (see, e.g. Document ID 3585, Tr. 3036; 4220, p. 9; 3756, Attachment 1), for the FEA, OSHA added a third key occupation group: terrazzo workers and finishers. Milling using this equipment represents a small share of the overall job duties of these applicable key occupations: in the PEA OSHA judged that 5 percent of all work for the first two occupation groups is spent using this equipment, and OSHA is retaining that estimate in the FEA because there were no comments challenging that estimate. OSHA estimates that terrazzo workers use the equipment about half as much as the other two occupation groups, so OSHA estimates that 2.5 percent of all work time spent by terrazzo workers and finishers will be spent using this equipment.

Rock Crushing Machine Operators and Tenders

According to information collected from ERG communication and OSHA SEP inspection reports, rock crushing machine operators spend most, if not all, of their shifts at and around the rock crushing process (Polhemus, 2000, Document ID 0958; Haney, 2001, Document ID 0721; OSHA SEP Inspection Report 2116507, Document ID 0186; OSHA SEP Inspection Report 300441862, Document ID 0030). OSHA estimated in the PEA that this occupational group spends 75 percent of its time using rock crushing machines and did not receive any comment on the estimate. OSHA has retained this estimate for the FEA.

Tunnel Boring

Underground workers perform both tunnel work and other types of construction work. The majority of these underground tasks still fall under Table 1 and have been accounted for elsewhere in the appropriate construction task analysis. However, a small amount of silica-generating underground construction work outside the scope of Table 1, primarily in tunnel boring, is expected to occur. The cost of engineering controls for this activity (to comply with the new PEL) is presented after the total engineering control costs to comply with Table 1 are presented.

SBAR Panel Comments on Key and Secondary Occupations

As stated in the comments during the Silica SBAR Panel process, one SBREFA commenter was "unable to reconcile ERG's statement that 'the amount of time . . . grinders and tuck-pointers perform grinding ranges widely, from about 1 hour per shift up to a full 8-hour shift (or longer)' [see the discussion on technological feasibility in Chapter IV of this FEA] with the 2.5% estimate in Table 4-8 [in the ERG report (2007a); Table V-26 in the PEA]" (Document ID 0004, p. 34, fn. 17 of memo). The commenter also asserted that masonry cutters use stationary saws approximately 20 to 30 percent of their working time (rather than 10 percent), and that masonry cutters use portable saws approximately 5 percent of their working time (rather than 10 percent) (Document ID 0004, p. 34, fn. 17 of memo).

In response, OSHA reiterated in the PEA that Table V-26 of the PEA showed the estimates of the full-time-equivalent number of workers in key and secondary occupations using equipment to perform silica-generating tasks. These occupations are taken from the BLS *Occupational Employment Survey* classification system and are much broader than the "masonry cutter" category referred to by the commenter, implying a lower percentage of time devoted to tasks involving masonry cutting.

OSHA did not receive further comment on this explanation. Therefore, OSHA has not changed these estimates in the FEA. For each occupation the estimates in Table V-37 in the FEA are meant to reflect the typical or average amount of a worker's time (over a year) devoted to the listed tasks.

FTE At-Risk Employment by Task Category

Tables V-38a and V-38b provide estimates, by occupation, of the full-time-equivalent (FTE) number of key and secondary workers, respectively, for each task category, using the percentages and ratios from Table V-37. These tables are relatively direct compilations from previous tables with adjustments needed, in a few cases, to assure that the industry-specific FTE occupational totals did not exceed the total occupational employment for any industry.

Table V-39 shows the corresponding estimates by NAICS code for the construction industry.

OSHA distributed FTE at-risk workers across NAICS codes according to the combination of task categories and occupational (key and secondary) categories (from BLS, 2012b) derived and updated by ERG for each industry group (ERG, 2007a, Document ID 1709).

For example, OSHA estimates (as shown in Table V-39) that the FTE of 26,004 construction workers use handheld or stand-mounted drills to drill into silica-materials. As shown in Table V-37, these workers can include carpenters, plumbers, electricians, sheet metal workers, or their helpers as well as construction laborers. Of these workers, 3,515 FTE workers were estimated to use handheld or stand mounted drills to drill into silica-containing material in the residential building industry, NAICS 2361. Table V-39 of this FEA also shows that, overall, 16,717 FTE-equivalent workers in the residential building industry performed work using equipment that can generate silica-containing dust, representing 3.2 percent of the industry's total employment of 519,070.
Overall, a full-time equivalent of 374,003 workers is estimated to use equipment to perform work on silica-containing materials in construction, ranging from 1,135 FTEs for rock crushing machine operators and tenders to 198,585 FTEs for heavy equipment operators and ground crew laborers (grading and excavating).

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on task percentages shown in Table V-37.

Total At-Risk Employment

In the PEA, OSHA used a relatively crude approach to convert the estimated number of FTE affected construction workers to the number at-risk construction workers. There, OSHA used a multiplier of 2 or 5, depending on the industry, to convert the number of FTEs to the number of at-risk workers (in Table V-37 of the PEA).

OSHA received several comments regarding the analysis used in the PEA as being too simplistic. Joseph Liss challenged OSHA's methodology:

> Even though OSHA estimates the number of workers needing training for silica exposure under the proposed rule by multiplying full-time equivalents by a factor of either 2 or 5, depending upon the sub-industry, the multiplicative factor for training purposes is likely to be much higher. For example, while paving, surfacing, and tamping operators spend a total of only 5% of their time on tasks exposed to silica, as estimated by ERG, it is not unlikely that many of the 51,857 workers in that industry sub-group will do silica-exposed work at some point, and, thus, require training. There are 823,737 construction laborers, and ERG estimated that 3% of their time is spent on silica-exposed work, but the severe turnover in that industry means firms may need to train many of those workers in silica safety procedures and health effects. OSHA estimates the nation's 575,000 residential construction workers spend 5% of their time on construction work and uses a multiplicative factor of two, thus assuming that only 10% of those workers require training and exposure monitoring. Costs may increase if the number of workers exposed increases, since OSHA requires training for all newly hired workers as well as all initial training for all workers exposed to silica (citations omitted) (Document ID 1950, p. 9).

Additionally, the Construction Industry Safety Coalition (CISC) submitted calculations to arrive at their own results of at-risk workers. They note:

> These percentages represent our quick judgement across both the key occupations and the secondary occupations that OSHA identifies as participating in the crew when the at-risk task is performed. If we had more time, we would like to make this judgement more carefully (Document ID 4032, Tab 6).

For this FEA, in response to comments, OSHA refined its process, as described below, to allow for a more nuanced approach to estimating the number of affected workers. As a result of this revised approach, the ratio of the estimated number of at-risk construction workers to the estimated number of FTE-affected construction workers increased from approximately three to one in the PEA to over five to one in this FEA. OSHA first assigned each of the affected NAICS construction industries into one of four subsectors in order to account for likely differences among specific industries with respect to the frequency with which silica-generating equipment is used. These subsectors are shown below in Table V-40a. Note that non-construction industries doing construction work—state and local governments and electric utilities are included in Subsector 3.

Table V-40a

NAICS Construction Industries by Subsector

Subsector Designation	NAICS	Industry
1	236100	Residential Building Construction
2	236200	Nonresidential Building Construction
3	237100	Utility System Construction
3	237200	Land Subdivision
3	237300	Highway, Street, and Bridge Construction
3	237900	Other Heavy and Civil Engineering Construction
4	238100	Foundation, Structure, and Building Exterior Contractors
4	238200	Building Equipment Contractors
4	238300	Building Finishing Contractors
4	238900	Other Specialty Trade Contractors

Source: US Census, http://www.census.gov/eos/www/naics/.

Second, because at-risk workers do not necessarily specialize in jobs that use equipment that generates silica-containing dust, ERG independently estimated the number of "affected" workers based on judgments of the share of workers in each occupation that would likely ever perform these tasks. These judgments were also made on a subsector-by-subsector basis. In most cases, costs for program requirements (but not for engineering controls) are based on the numbers of affected workers performing each task in a given industry. The estimated share of affected workers for the key occupations, taking into account the specific construction subsector and task, is shown in Table V-40b.

Using the FTE rates, secondary ratios, and affected rate parameters displayed in Table V-37, OSHA calculated, in Table V-39, that there are an estimated 374,003 FTEs affected by the rule. Table V-41 converts these FTEs to 2.02 million affected construction workers disaggregated by occupation based on 2012 County Business Pattern (CBP) (Census, 2012) total employment of 2.93 million in affected occupations in construction industries. Thus, as shown in Table V-41, about 68.9 percent of construction workers in affected occupations will be affected by the final rule. Table V-42 shows the same estimated number of affected workers, but disaggregated by NAICS industries and equipment category. There are an estimated 13.45 million workers total in the affected industries, meaning that about 15 percent of the workers in these industries are affected by the final rule. That percentage is misleading, however, because almost 7.7 million of total employment in affected industries (almost 60 percent) are employed in state and local governments, of which only 2 percent are affected by the final rule. When these public workers are removed, approximately 32 percent of the construction workers in affected private industries are affected by the final rule.

All of the above statistics do not include the estimated 11,640 at-risk abrasive blasters working in construction industries. Also, because some occupations are associated with the use of more than one equipment category, the “affected” totals are constrained to be less than or equal to the industry total for each at-risk occupation.

Table V-40b

Estimated Percentage of Affected Workers by Occupation, Task Area, and Construction Sector

Construction Subsector	Task No	Task	Occ. code	Occupation	Affected Rate

Labor Cost and Total Value of Work Performed Using Silica Exposure-Generating Equipment

To derive labor costs and project value for construction work done using the specified equipment where occupational exposure to silica is found, OSHA multiplied the mean hourly wage, as reported by OES (BLS, 2012b) for each affected occupation within each affected industry, by 2,000 hours. Then, to derive the total value of annual wages expended for work done using specified equipment to perform silica exposure-generating activities, OSHA multiplied that product by the number of affected full-time-equivalent employees. These estimates were then inflated to adjust for fringe benefits.[60] These loaded-wage costs, totaled by industry and equipment category, are summarized in Table V-43 as the annual labor value (or labor cost) of silica-generating projects. Thus for rock and concrete drillers, for example, OSHA estimated the labor share of the project value, or cost, was $1,568.5 million annually. Overall, OSHA estimated the labor value of all silica-generating construction work performed with the specified equipment to be $21.8 billion annually.

OSHA then converted the labor values for each industry and task category from Table V-43 to the total project value by dividing by the labor share of project costs. This conversion is possible because the labor share for each task category equals the labor value divided by project value, so dividing the labor value by the labor share generates an estimate of project value. The corresponding estimates of total project value for each industry and equipment category are shown in Table V-44. For example, for rock and concrete drillers, the labor share of costs was estimated at 53.1 percent (from Table V-36a).[61] The total project value for these drilling tasks was estimated, therefore, at 1.88 (1 divided by 0.531) times the labor value of $1,568.5 million—or $2,955 million annually. Overall, OSHA estimated the value of silica-generating construction work performed with the specified equipment at $41.2 billion. The values for specific equipment categories ranged from $136.2 million for rock crushing machine operators and tenders to $28.0 billion for heavy construction equipment operations-II.

The value of work performed using the specified equipment was then summed by NAICS industry to derive the total value of at-risk projects, a base from which OSHA calculated control costs associated with compliance with Table 1 or the final PEL.

---

[60] Bureau of Labor Statistics, Table 1, *Employer Costs for Employee Compensation*, (BLS, 2015). For civilian workers, wages and salaries comprised 68.4 percent of total compensation in the fourth quarter of 2014.

[61] Note that the baseline labor costs and project costs are the same for indoor and outdoor tasks. Only the control costs would be different.

Aggregate Control Costs in Construction to Comply with Table 1 or the New PEL

For the final rule, OSHA revised Table 1 to include separate engineering control and respirator requirements for tasks indoors or in enclosed areas ("indoor tasks") to provide a means of exhaust as needed to minimize the accumulation of visible airborne dust. As a result, indoor tasks will have an additional cost to reflect use of control equipment (e.g., a fan or "blower")[62] providing a means of exhaust as needed to minimize the accumulation of visible airborne dust. These additional indoor costs were included in Table V-34. However, to properly reflect these costs in the aggregate control costs in construction, OSHA had to add an additional methodological step. OSHA's Office of Technological Feasibility helped to develop estimates of the distribution of silica-related work disaggregated by the type of control equipment used, the duration of the task, and the location of the task (i.e., indoors or outdoors). The resulting distribution of silica-related work, which is later used to weight costs by the percentage of tasks performed indoors or outdoors, is displayed in Table V-45.

To derive estimates in Table V-46 of aggregate incremental compliance costs to meet the final Table 1, the total value of construction work using the specified equipment and requiring controls (in Table V-44) was multiplied by the percentage of incremental cost associated with the controls required for each equipment category (in Tables V-36a and V-36b), weighted by the percentage of work using each type of equipment performed outdoors and indoors (in Table V-45), and reduced by the percentage of baseline compliance.

Using the equipment category "hole drilling using handheld or stand-mounted drills" as an example, projects requiring additional engineering controls are estimated in Table V-36a to incur a 3.7 percent increase in total costs. As shown in Table V-44, the total annual value of the work done drilling holes using handheld or stand-mounted drills is estimated to be $179.82 million per year in the residential building construction industry (NAICS 2361). Baseline compliance is estimated to be 23.04 percent—derived from 52.4 percent of workers engaged in this task who are currently exposed below the PEL of 50 $\mu g/m^3$ (from Table III-8 in Chapter III of this FEA) multiplied by 44 percent baseline compliance for workers already below the PEL. After adjusting for baseline compliance, the annual incremental cost of silica controls in this industry is estimated to be $5.1 million (3.72% x (100% - 23.04%) x $179.82 million) as shown in Table V-46. Any construction work done using the specified equipment and involving both outdoor and indoor work (e.g., masonry and concrete cutters using portable saws-I) would be estimated in a similar fashion, but would have the added steps of compliance cost increases from both Tables V-36a and V-36b, weighted by the relative frequency of outdoor/indoor work locations from Table V-45.

OSHA performed this type of calculation for each construction work using equipment from each specified equipment category and NAICS industry code. As indicated in Table V-46, OSHA estimates that the incremental compliance costs for engineering controls (excluding tunnel boring and abrasive blasting) will total $386.4 million for construction work performed using the specified equipment affected by the final standard.

[62] Specifically, the FEA in Table V-32 estimates a cost of an electric blower (1,277 cfm) and 25 ft. of duct to reach the outside. Note that any additional respirator use required for indoor activities is addressed in a separate section.

As shown in Table V-46, the largest share of annualized engineering control costs, roughly 19 percent, is forecast for the tuckpointers and grinders equipment category ($74.7 million), while jackhammers and other handheld powered chipping tools and heavy equipment operators and ground crew laborers-II are expected to incur the next highest engineering control costs ($68.3 million and $67.4 million, respectively). Examining incremental control costs by NAICS industry for the new PEL of 50 μg/m^3, OSHA estimates that foundation, structure, and building exterior contractors (NAICS 2381) will incur the highest costs of any NAICS industry at $94.0 million per year. Other specialty trade contractors (NAICS 2389) and utility system construction (NAICS 2371) are also expected to incur sizable control costs to comply with the new Table 1 requirements ($63.1 million and $58.8 million, respectively). Almost half of the engineering control costs borne by foundation, structure, and building exterior contractors will involve work done using tuckpointers and grinders, whereas for other specialty trade contractors and utility system contractors, the equipment categories that accounted for the largest share of engineering control costs were, respectively, heavy construction equipment operators -II and rock and concrete drillers.

Control Costs for Construction Tasks Not Under Table 1

Abrasive Blasting

In the PEA, OSHA estimated that some abrasive blasting crews were not currently using all feasible engineering controls and added costs for wet methods for them to achieve the proposed PEL. OSHA did not receive comments on the PEA estimates of engineering control costs for abrasive blasting crews and has retained the same methodology to estimate costs for this FEA.

Consistent with what was done in the PEA, Table V-47a presents the unit costs and analytical assumptions applied in OSHA's cost analysis of controlling silica exposures during abrasive blasting operations. As shown in the table, after accounting for the number of affected workers, crew size, daily output, blasting cost per square foot, number of blasting days per year, and the percentage of crews using sand, OSHA estimates that baseline annual costs for sand blasting total $126.7 million. As in the PEA, ERG estimated that the incremental cost for wet blasting is 30 percent of baseline costs and that 50 percent of crews currently use wet methods. Therefore, the annual costs to comply with the final standard by using wet methods during sand blasting are expected to total $19.0 million, or $2,366 per worker for the approximately 8,033 workers exposed to silica dust.

Distributing these annualized costs by industry, OSHA estimates that employers in NAICS 238200, Building Finishing Contractors, will incur compliance costs of $12.1 million annually, while firms in NAICS 238900, Other Specialty Trade Contractors, will incur compliance costs of $6.9 million annually.

Table 47a

Engineering Costs for Abrasive Blasting Operations in Construction

Numbers of workers in blasting operations with exposures >50 μg/m^3			
238300	Building Finishing Contractors	5,124	
238900	Other Specialty Trade Contractors	2,909	
	Total	8,033	
Blasting crew size		4	ERG estimate based on Means, 2008
Ouput per day (square ft.)		1,500	ERG estimate based on Means, 2008
Blasting cost per square foot (dry blasting)		$2.10	ERG estimate based on Means, 2008; inflated to 2012
Blasting days per year		100	ERG estimate
Percent of blasting crews using sand		20.0%	ERG estimate
Annual costs of sand blasting		$126,723,549	
Incremental cost for wet blasting		30.0%	ERG estimate based on Means, 2008
Share of blasting currently with wet methods		50.0%	ERG estimate
Cost of requiring all sand blasting to use wet methods		$19,008,532	
Cost per blasting worker		$2,366	
Costs by Industry			
238300	Building Finishing Contractors	$12,125,288	
238900	Other Specialty Trade Contractors	$6,883,244

Tunnel Boring

Tunnel boring is not included on Table 1 of the final rule. An employer engaged in tunnel boring must comply with the PEL of 50 μg/m^3 specified in §1926.1153(d). Employers in tunnel boring must already comply with the ventilation and dust suppressant requirements in subpart S of Part 1926 (Underground construction), which would have allowed those employers to meet the previous PEL of 250 μg/m^3. Therefore, OSHA calculates the additional controls necessary to reduce exposures from the preceding PEL to the new PEL of 50 μg/m^3.

In most cases, employers are able to reduce exposures to the preceding PEL by providing suction at the drill head, removing the dust as soon as it is generated. The technological feasibility chapter of this FEA demonstrates that employers can do so by extending the existing suction controls as the drill head progresses. There are limits on these extensions, however, and the amount of worker exposure can increase if the suction is not extended frequently enough to keep it at the drill head. This extension does not require additional machinery, but it is likely to require the employer to invest more labor time to extend the suction device more frequently to meet the new PEL than previously necessary to meet the preceding PEL. The Agency has estimated in Table V-47b the control costs for tunnel boring using the same cost methodology applied in the PEA (see Tables V-21 and V-24 in the PEA) to calculate the incremental cost as a percentage of baseline control costs (0.013 percent). The rest of the calculations in Table V-47b reflect 2012 data on the number of affected FTE tunnel workers and 2012 hourly wage rates. The resulting estimate of annualized incremental control costs for tunnel boring is about 0.02 million.

Table V-48 of the FEA just adds the abrasive blasting and tunnel boring control costs in construction above to the control costs for Table 1 tasks presented in Table V-46.

Table V-47b Estimated Annualized Control Costs for Underground Tunneling Workers

Representative Job description		Tunnel construction, bored tunnels, including mucking; 20' in diameter, rock excavation (average cost; assumes 100 feet/day)	
Daily Costs [a]		Cost	Share
	Labor	$16,125	15.00%
	Equipment	$91,375	85.00%
	Total	$107,500	100.00%
Control measure		Supplemental spray points in dust control system: Install 3 additional spray points on material handling equipment.	
Daily control cost [b]		$13.96	
Incremental control cost		0.013%	
FTE Tunnel workers [c]		2,067	
Hourly labor rate per worker (including fringes) [d]		$25.36	
Annual labor value of tunneling tasks ($M)		$114.8	
Total value of tunneling work ($M)		$765.3	
Percent needing controls		22.22%	
Incremental control costs ($M)		$0.02

Adjustment for Self-Employed Workers on a Multi-employer Worksite

The OSH Act provides authority for OSHA to regulate employers for the protection of their employees. Because sole proprietors without employees, referred to as "self-employed workers" for the purposes of this discussion, are not "employers" under the Act, OSHA cannot require them to comply with the silica standard. On a multi-employer worksite, however, their silica activities could expose employees protected by the Act to respirable crystalline silica.

Employers must still protect their employees from exposure to silica in accordance with the standard, whether it is generated by work performed by their own employees or by the work performed by a sole proprietor not regulated by the Act (see the summary and explanation of the written exposure control plan requirements in paragraph §1926.1153(g)(1)(iv)). Under OSHA's multi-employer citation policy (CPL 02-00-124), employers of workers who may be exposed to silica are considered "exposing employers" who have a duty to protect their employees, even from hazards they do not correct themselves. However, the controlling employer, the employer in overall charge of the worksite or project, also has a duty to exercise reasonable care to prevent and detect violations of the silica standard on the multi-employer worksite. The silica standard does not limit the means by which either employer may fulfill this duty, and in many cases the issue may be resolved if the work schedule does not place the self-employed worker in the same area of the worksite at the same time as employees, thereby avoiding the need for additional measures.

As discussed in Chapter III of the FEA, CISC requested that the Agency account for the costs arising from self-employed workers separately based on the theory that self-employed workers will use the controls necessary to comply with Table 1 to reduce exposures to others when working on a multi-employer worksite where employees are present (Document ID 4217, p. 80). CISC identified several reasons why this might happen, including self-interested recognition of "Table 1 specifications as the safe way to perform their work"; demands by construction general contractors that anyone working on their site, whether self-employed or not, conform to regulatory requirements; and demands by nearby employers that their employees "not suffer increased silica exposures from inappropriate practices by self-employed workers."

While these are not costs that OSHA typically includes in its analysis, OSHA recognizes that Table 1 is unique among OSHA standards, and that it is possible that controlling employers on a multi-employer construction worksite may assume some costs of engineering controls—either by providing the controls or by reimbursing the self-employed persons for the costs of the controls through increased fees—when they cannot resolve the issue through simple scheduling choices. Therefore, OSHA is estimating the additional cost of the engineering controls in that scenario.

In order to estimate the number of self-employed persons in construction, CISC's contractor, Environomics, Inc., did the following:

> The U.S. Census Bureau, in Revised 2008 Nonemployer Statistics Reflecting 2009 Methodology Changes, provides information on the number of self-employed individuals ("nonemployers") working in each of the 4-digit construction industries (total of 2.52 million self-employed construction workers), but no further information on the occupations of these self-employed workers. In order to estimate the number of self-employed workers in each of the various at-risk construction occupations that OSHA identified and that we added, we simply assumed that these 2.52 million "nonemployers" are distributed among occupations within each construction NAICS in the same proportion as employed workers are distributed among occupations within the NAICS (Document ID 4217, p. 80).

Note that the Census data that Environomics used provides detail on self-employed persons by 4-digit NAICS construction industries but not by occupation. Hence, in the absence of occupational data, Environomics simply assumed that the number of self-employed persons by occupation was proportional to the number of employees by occupation—which implies that the ratio of the number of self-employed persons to employees was the same for each occupation. Using this database and approach, Environomics estimated that the ratio of self-employed persons to employees for all occupations affected by the rule was 40.1 percent (1,811,009 self-employed relative to 4,519,889 employees). Based on the full-time-equivalent (FTE) number of workers—which, in OSHA's estimation methodology, determines the amount of engineering control equipment used— Environomics calculated that the ratio of FTE self-employed persons to FTE employees for all occupations affected by the rule was 35.7 percent.

Having reviewed the Environomics self-employment analysis, the Agency has concluded that the occupation of the self-employed persons is a much more relevant factor for estimating costs than the 4-digit construction industry in which self-employed persons work. Therefore, for its analysis, OSHA has chosen to rely on data from the 2013 BLS Current Population Survey, with the goal of estimating the ratio of the number of self-employed persons to the number of employees by occupation. Table V-49 below presents data from the 2013 BLS Current Population Survey (BLS, 2013) with the focus on the ratio of the self-employed to the non-self-employed (i.e., employees).[63] Note that this table includes many occupations that do not involve silica exposure (e.g., boilermakers, paperhangers, glaziers) and others that are not covered by OSHA (e.g., mining machine operators; roof bolters, mining—covered by MSHA).

[63] The absolute number of self-employed and employed in construction by occupation from this survey is not, itself, relevant for this analysis. What matters is the ratio of self-employed to non-self-employed in construction where the estimates of both types of workers are derived from a single source.

Table V-49

Self-Employment in Construction Occupations

Occ. Code	Occupation	Workers in All Construction Occupations [a] Self-employed	Non-Self-Employed	Total	Ratio of Self-Employed to Non-Self-Employed
47-1011	First-Line Supervisors of Construction Trades and Extraction Workers	114,000	517,000	631,000	22.1%

	Totals	**1,358,000**	**5,897,000**	**7,255,000**	**23.0%**

[a] Source: BLS (2013). These employment estimates are based on a household survey and include individuals working in construction as well as non-construction industries. Self-employment statistics by occupation and industry are not available.

Table V-50 presents the same data as shown in Table V-49, but restricted to just those occupations where OSHA estimated that workers are potentially exposed to hazardous levels of respirable crystalline silica. One thing that is immediately obvious in this table is the very wide variation from occupation to occupation in the ratio of the self-employed to the employed, with the ratio ranging from 0 percent to 47.53 percent. This wide variation is clearly incompatible with the assumption made by Environomics that the ratio of the number of self-employed to employees is the same for all occupations. Table V-50 also shows that average ratio of self-employed to employees over all construction occupations involving silica exposure (when the ratio is allowed to vary by occupation) is 22.82 percent when weighted by the number of employees (as compared to 40.1 percent as estimated by Environomics).

As noted above, in OSHA's methodology, the amount of engineering control equipment used is based on the FTE number of workers. In Table V-51, OSHA multiplied the FTE rate for each occupation (from Tables V-38a and V-38b) by the number of self-employed workers and employees in that occupation (from Table V-48). As shown in Table V-51, there are an estimated 69,461 FTE self-employed workers in at-risk occupations, relative to the total of 377,913 FTE employees in at-risk occupations. In other words, the number of at-risk FTE self-employed workers is 18.38 percent of the number of at-risk FTE employees (as compared to 35.7 percent as estimated by Environomics).

The analysis of the number of self-employed persons conducted by Environomics stopped at this point. However, as OSHA explained in Chapter III of this FEA, self-employed workers are not required to comply with the final rule and are only likely to do so in two situations: (1) where self-employed workers are generating silica dust while working in a multi-employer construction worksite such that their activities could expose the employees of others, and (2) where the host employer (or competent person) is unable to schedule the self-employed worker's activities or location so as to prevent the exposure or overexposure of other, covered workers. The Agency does not have data on the likelihood of either of these two conditions. OSHA judges that self-employed workers work at multi-employer construction sites at the same times as others a minority of their worktime, and work even less frequently within the same area such that covered employees could be exposed. Nevertheless, OSHA is conservatively estimating here that they do so 50 percent of the time. OSHA also judges that the host contractor (with the assistance of the competent person) would be able to schedule the self-employed workers' activities or location so as to prevent the exposure or overexposure of other, covered workers a majority of the time. This makes sense because self-employed workers are often used on multi-employer sites because they possess special skills not otherwise available onsite. Therefore, their work frequently could be performed at a different time or location from the other work. In any case, for costing purposes, OSHA is conservatively estimating that the work of self-employed persons cannot be isolated in time or space so as to prevent the exposure or overexposure of other, covered workers 50 percent of the time that those self-employed workers are on the multi-employer worksite.

Based on these estimates, OSHA calculates that only 25 percent of the at-risk work of self-employed workers would meet the conditions in which a host or controlling employer would incur engineering control costs to mitigate the exposures to employees on the site. At the bottom of Table V-51, OSHA has accordingly reduced the number of FTE self-employed workers using equipment to perform silica-dust-producing work relative to the number of FTE at-risk employees to 25 percent of the earlier estimate of 18.38 percent. OSHA therefore concludes that the number of FTE at-risk self-employed workers imposing costs on host employers is equal to 4.60 percent of the number of FTE at-risk employees. This result is shown at the bottom of Table V-51.

Finally, in Table V-52, OSHA increased the estimates of the control costs for work performed using the specified equipment in construction presented in Table V-48 by 4.60 percent to include the engineering control costs that would be incurred by host or controlling employers to control the exposures caused by self-employed workers. This increases the annualized cost of engineering controls needed in construction to comply with the final rule from $405.5 million to $423.4 million.

Table V-50

Self-Employment Statistics

Occ. Code	Occupation	Workers in At-Risk Occupations [a] Self-employed	Non-Self-Employed	Total	Ratio of Self-Employed to Non-Self-Employed
47-1011	First-Line Supervisors of Construction Trades and Extraction Workers	114,000	517,000	631,000	22.05%

Respiratory Protection Costs

This section presents OSHA's estimate of the costs for construction employers to comply with the respiratory protection requirements of the final rule. Contained below is an overview of the estimated costs associated with respirator use presented in the PEA, comments received on the preliminary estimates and OSHA's response to those comments, the changes made in this FEA, and finally the estimated costs associated with respirator use as required by the final rule.

PEA Estimates of Respiratory Protection Costs

In the PEA, employers in the construction sector whose workers were exposed to respirable silica above the proposed PEL were assumed to adopt the appropriate task-specific engineering controls and, where required, respirators prescribed in Table 1 and paragraph (g)(1) in the proposed standard.

In developing the estimates of respirator costs for the PEA, respirator requirements were identified for each of the tasks evaluated in the engineering control cost analysis. Where respirator requirements varied among different control methods that could be used for a given task, the respirator type associated with the most commonly selected control method was used. Respirator costs by Table 1 task were calculated assuming 4 hours or less of use for 50 percent of workers and more than 4 hours of use for the other 50 percent of workers. The annualized cost per worker, derived by ERG in an earlier respirator study conducted for OSHA (ERG, 2003), was estimated to be $570 per year (in 2009 dollars) to use a half-mask nonpowered air-purifying respirator and $638 per year (in 2009 dollars) to use a full-face nonpowered air-purifying respirator. These unit costs reflected the annualized cost of respirator use, including accessories (e.g., filters), training, fit testing, and cleaning.

OSHA utilized a baseline compliance rate of 56 percent based on a NIOSH respirator survey (NIOSH/BLS, 2003) and as calculated in the PEA. Using the annualized unit respirator costs, and accounting for baseline respirator use, the PEA estimated that the cost of respirator use in construction was $80.8 million annually.[64]

[64] Note that these respirator costs did not include the costs of disposable respirators used in regulated areas or as part of an access control plan. The costs for these disposable respirators were separately estimated as part of the costs of a regulated area or an access control plan.

Comments and Responses on PEA Estimate of Respiratory Protection Costs

OSHA received only a few comments on the issue of respirator use in construction and associated costs.

The Interlocking Concrete Pavement Institute (ICPI), whose members include manufacturers of segmental pavement systems and paver installation contractors, estimated that for construction employers, "[a]dditional respirator costs could be up to $1,000 to $2,000 per year per employee, and cost a firm $1,000s per year in total" (Document ID 2246, p. 3). ICPI provided no further data on their method for calculating those costs, such as what elements they considered to be part of the cost of respirator use, how many workers would be using what type of respiratory protection, and the cost of respirators. It is therefore impossible for OSHA to further evaluate ICPI's estimates or to compare them to OSHA's estimates.

The General Contractors Association of New York estimated that a fit test and qualifying medical exam would cost $275 per worker and that respirators would cost $250 per worker per year (Document ID 2314, p. 2). This estimate is in line with OSHA's estimates, which are presented in more detail below.

Kellie Vazquez, with Holes Incorporated, submitted that "with the reduction of the PEL and our historical data, every equipment operator will be required to have a PAPR respirator" and included cost data for OSHA to consider (Document ID 2338, p. 5). Holes Incorporated equipment operators, as OSHA understands it, engage in a variety of silica-related tasks, and the need to wear a respirator depends on the requirements specified in Table 1 for each task. For example, one of Holes Incorporated's tasks, core drilling, would require no respiratory protection if wet methods are used.

In both the PEA and FEA, OSHA estimated respirator use in construction based on Table 1 requirements, which in turn depend on the type of task performed, the duration of the task, and the location of the task (indoors or outdoors). The number of equipment operators requiring respirators under the final rule depends on the tasks that they perform and whether Table 1 requires respirator use for those tasks (type, duration, and location). OSHA has therefore costed respirator use according to the respirator requirements specified in Table 1.

SBAR Panel Comments on Respiratory Protection Costs

A SBREFA commenter questioned how the Agency determined the full-time-equivalent (FTE) number of at-risk construction workers who are exposed above the PEL

(Document ID 0968, p. 18). The PEA noted that aggregate respirator costs were estimated for *all* workers at risk above the proposed PEL, by task and industry. The total number of at-risk workers was derived from estimates in Table 4-9 (full-time equivalent workers by occupation and task) and Table 4-22 (profile of worker exposures to crystalline silica in construction) in ERG (2007a).[65] In the FEA, a similar methodology was used to estimate aggregate respirator costs for all workers—with respirator equipment costs based on FTE usage and respirator fit testing and training costs based on the number of workers engaging in Table 1 tasks that require respirator use. This is shown in Table V-60 later in this section.

Another commenter asserted that the Agency's respirator analysis was based on two incorrect assumptions: (1) a condensed group of FTE employees wear a respirator full-time rather than a larger pool of workers wearing respirators on an intermittent basis; and (2) the respirators are shared among workers who do not perform silica-generating tasks full-time (Document ID 0004, p. 29 of memo). In response to these criticisms, OSHA emphasizes that, in both the PEA and the FEA, estimates of total respiratory protection compliance costs are based on respirators for *all* workers at risk above the PEL of 50 $\mu g/m^3$.[66] Furthermore, as discussed below, OSHA estimates that most workers in construction will use disposable N95 respirators, which are not shared. As indicated above, total respirator equipment costs are based on FTE usage, but, because workers can use disposable N95 respirators, the FTE approach is fully compatible with workers wearing respirators on an intermittent basis. (A small percentage of workers in construction are estimated to wear non-disposable respirators, but those workers would typically be frequent or full-time respirator users who are not expected to share their respiratory protection equipment.) It makes no difference in equipment costs if one worker wears disposable respirators full-time for a year or ten workers wear disposable respirators part-time such that their usage totals one full-time equivalent year of usage. With respect to respirator fit testing and training, however, individual worker usage matters, and OSHA accounts for that by basing fit testing and training costs on the number of workers (not FTEs) engaged in Table 1 tasks that require respirator use.

Final Estimates of Respiratory Protection Costs

Paragraph (e) of this final rule requires that when respiratory protection is required, employers provide each employee an appropriate respirator that complies with the requirements of paragraph (e) and also with 29 CFR 1910.134. This final rule requires respiratory protection where specified by Table 1 (paragraph (c) of the rule) or, for tasks

[65] Total workers at risk above the PEL were referred to as "adjusted full-time-equivalent workers" or "adjusted workers at risk" in ERG (2007a).

[66] This is explained in the note to Table 4-28 in ERG (2007a).

not listed in Table 1 or where the employer does not fully and properly implement the engineering controls, work practices, and respiratory protection described in Table 1, during the installation or implementation of engineering and work practice controls when employees are exposed above the PEL; during tasks, such as certain maintenance and repair tasks, for which engineering and work practice controls are not feasible and employees are exposed above the PEL; and in situations where all feasible engineering and work practice controls have been installed and such controls are not sufficient to reduce exposures to or below the PEL. The final rule also requires, where respirator use is required, that the employer institute a respiratory protection program in accordance with 29 CFR 1910.134.

Changes in Table 1 entries in the final rule have resulted in revised respirator requirements for certain tasks relative to Table 1 in the PEA. These include:

- Stationary masonry saws—The requirement for a half-mask respirator (APF 10) for >4 hours/day was removed.
- Vehicle-mounted drilling rigs for concrete and rock—The requirement for a half-mask respirator (APF 10) for >4 hours/day for concrete was removed.
- Hand-operated jackhammers and chipping hammers—A requirement for a respirator with APF 10 when used indoors or in an enclosed area for ≤4 hours/day was added.
- Handheld grinders for mortar removal—The requirement for respiratory protection was revised from APF 25 to APF 10 for ≤4 hours/day.
- Handheld grinders for uses other than mortar removal—The requirements for a half-mask respirator (APF 10) outdoors and for ≤4 hours/day indoors were removed.
- Walk-behind milling machines and floor grinders—The requirement for a half-mask respirator (APF 10) for >4 hours/day was removed.
- Crushing machines—All requirements for respirators were removed.
- Milling machines – All requirements for respirators were removed.
- Dowel drilling rigs for concrete – New entry in Table 1 with respirator requirement (APF 10).

The methodology for estimating the costs to construction employers of respiratory protection in this FEA is largely similar to the methodology employed in the PEA. OSHA has updated the profile numbers that serve as input to the model (i.e., the number of employees, the number of establishments, and wage rates) and has updated all costs to reflect 2012 dollars. The PEA estimated that, with the exception of workers who are entering regulated areas,[67] all workers in construction who would need respirators with an APF of 10 would use non-disposable, half-face respirators. The FEA, in contrast, estimates that 10 percent of workers needing respirators will use elastomeric half-face respirators and 90 percent will use disposable N95 respirators. That is because the final rule clarifies that both disposable and non-disposable respirators are available with an APF of 10.[68] Where an APF of 25 is required by Table 1, OSHA assumes that an elastomeric full-face respirator will be used.

According to OSHA's Respiratory Protection Standard, employers whose workers are required to wear respirators during the course of their job duties must establish a written respiratory protection program. The required elements are presented earlier in this section as part of the discussion of respiratory protection costs for general industry and maritime employers.

For this FEA, OSHA estimated the costs for developing a respiratory protection program, the costs for annual fit testing, the costs for equipment (which includes the cost for respirators, any necessary accessories, and cleaning where non-disposable respirators are used), and the costs of annual training. The costs for medical clearance required by the Respiratory Protection Standard are included as part of medical surveillance costs, and recordkeeping costs are included in the respirator program costs.

Similar to general industry, OSHA estimates that a human resources manager or equivalent with an hourly wage rate of $74.97 will be responsible for developing the respiratory protection program and providing the appropriate recordkeeping (BLS, 2012b). As in the PEA, the Agency estimates that a large employer with 500 or more employees will take 8 hours to develop this program and provide the appropriate recordkeeping, and employers of all other sizes will take 4 hours. In addition, as in the PEA, OSHA estimates that it will take half as much time (2 hours for small and medium employers and 4 hours for large employers) to review and update the respirator plan (including appropriate recordkeeping), and that 20 percent of establishments will do so in any given year. The unit costs for respiratory protection program development and updating in construction are displayed in Table V-53 below.

[67] The final rule contains no regulated area provisions in construction.

[68] In Table 1 for the proposed construction rule, the stated requirement was for a "half-mask (10)," with "(10)" referring to the APF, while in the final rule the stated requirement is simply for an "APF 10." As a result, in the PEA in support of proposal, the OSHA economists erroneously assumed that disposable N95 respirators would not satisfy the "half-mask (10)" requirement and only estimated costs for non-disposable half-mask respirators.

Table V-53: Respirator Program Unit Costs in Construction

		Establishment Size		
		Small (<20)	**Medium** (20-499)	**Large** (500+)
Respirator users per establishment with respirators		2	4	6
Program development (hours)				
	Hours	4	4	8
	Labor value	$297	$297	$594
Program Updates				
	Hours	2	2	4
	Labor value	$149	$149	$297
Establishments updating program				
	Per year	20.0%	20.0%	20.0%
Compliance rate		56.0%	56.0%	56.0%

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA (2016), and BLS (2012b).

The Respiratory Protection Standard requires that, before a worker is required to use a respirator with a negative or positive pressure tight-fitting facepiece, the employee must be fit-tested with the same make, model, style, and size of respirator that will be used (29 CFR 1926.103, referencing 29 CFR 1910.134). OSHA estimates that qualitative fit testing will be performed by a supervisor on groups of four employees. This fit testing is estimated to take a total of one hour total for each employee and fifteen minutes of a supervisor's time per-employee (one hour divided by the four employees in the group). The total cost per-employee for fit testing in construction is shown below in Table V-54.

Table V-54: Fit Testing in Construction - Qualitative

Testing group size	4
Employee hours	1
Supervisor hours	0.25
Loaded employee hourly wage	$31.63
Loaded supervisor hourly wage	$44.04
Cost per employee	$42.64

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA (2016), and BLS (2012b).

OSHA revised Table 1 for this final rule. Whereas the PEA judged that workers needing respirators with an APF of 10 would use reusable half-face elastomeric respirators, this FEA reflects that workers performing Table 1 tasks requiring a respirator with an APF of 10 will be able to use either disposable N95 filtering facepiece respirators or reusable half-face respirators. For this FEA, OSHA has estimated that 90 percent of workers in construction who need respirators with an APF of 10 will use a disposable N95 respirator and that 10 percent will use an elastomeric reusable half-face respirator. This is because very few workers in construction engage in tasks requiring respirator use full-time. Under those circumstances, disposable respirators are both more convenient to use and much less expensive than reusable respirators. As in the PEA, OSHA judges for this FEA that any workers needing respirators with an APF of 25 will use an elastomeric full-face respirator to meet the requirements of this final rule.

The unit equipment costs for each type of respirator are shown in Table V-55 below. OSHA estimates that, for cost purposes in construction, respirator use for one FTE employee is equivalent to respirator use every workday for that worker. However, in practice, respirator use for individual workers may vary from day to day and during any particular day. Hence, respirator fit testing and training costs are based on the number of employees performing tasks requiring respirator use and not on the number of respirators used. The employer could choose to supply disposable N95 respirators, which the employee would replace every day but which would need no cleaning or additional accessories, or a reusable elastomeric half-mask respirators, which can be used for two years but which will require daily cleaning and additional accessories[69] that will need to be replaced regularly.

[69] OSHA's respirator costs are based on estimates of the annual costs of respirator use derived in an earlier study (ERG, 2003). These costs include not only the purchase cost of the respirator itself, but the ancillary costs of accessories (e.g., filters) and other costs associated with respirator cleaning and required training and fit testing. The 2003 estimates were based on a unit cost of $3.57 for a replacement pair of filters for half-mask negative-pressure air-purifying respirators. In the PEA, these were extrapolated to an annual cost of $285.52 per year (and inflated to $333.07 in 2009 dollars), erroneously assuming that the filters would be changed 80 times a year, or roughly every 3 days for a working year of approximately 240 days. For this FEA, OSHA corrected these estimates to reflect a construction working year of approximately 150 days, with filters changed 50 times a year, or roughly every three days.

In the PEA cost analysis, respirator costs from the 2003 study were used, but inflated from 2003 to 2009 dollars using the implicit price deflator for this period. For this FEA, those costs have again been adjusted for inflation to 2012 dollars, resulting in an annual cost for filters of $184.70. OSHA's internal research, reported on page V-170 the PEA, showed that filter prices have not, in fact, increased since 2003, and might well have declined, at least for the N95 particulate filters used for silica protection. Thus, it is possible that OSHA has overestimated the cost for accessories for reusable respirators in this FEA.

Table V-55: Respirator Unit Costs in Construction

Equipment	Disposable Filtering Facepiece	Elastomeric Half-Mask Respirator	Elastomeric Full-Face Respirator
Equipment Cost (each)	$1.05	$32.74	$269.78
Equipment Service Life (years)	1	2	2
Annualized Equipment Cost	$1.05	$17.11	$140.99
Accessory Cost	0	$184.70	$184.70
Accessory Service Life (years)	1	1	1
Annualized Accessory Cost	$0.00	$184.70	$184.70
Total Annualized Equipment Costs	$1.05	$201.81	$325.69
No. per year	150	1	1
Total Annualized Cost	**$157.75**	**$201.81**	**$325.69**

Workers who are provided with reusable respirators will need to clean those respirators. OSHA estimates that this will happen weekly and take five minutes (0.08 hours) of the worker's time. On a yearly basis this will cost $79.08 for a worker in construction who uses a non-disposable respirator. These costs are shown below in Table V-56.

Table V-56: Respirator Cleaning Costs in Construction (non-disposable only)

Cleaning	
Frequency per year	30
Time (hours)	0.08
Loaded employee wage	$31.63
Yearly cost	$79.08

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on OSHA (2016) and BLS (2012b).

The final cost component of a respirator program is training workers in respiratory hazards and in the proper use of respiratory protection. OSHA estimates that this training will take two hours and that it will be provided by a supervisor to a group of four employees at a time. The total per-employee cost for training on respiratory hazards and respirator use will be equal to two hours of the worker's wage plus one half hour of the supervisor’s wage (two hours of supervisor time total divided among the four workers). The unit costs for this training are shown below in Table V-57.

Table V-57: Respirator Training Costs in Construction

Class size	4
Employee training hours	2
Supervisor training hours	0.5
Loaded employee hourly wage	$31.63
Loaded supervisor hourly wage	$44.04
Cost per employee	$85.28

Table V-59 shows, by task and NAICS industry, the aggregate respirator costs for workers requiring respirators, as prescribed in Table 1. Table 1 does not specify respirators for some tasks, such as heavy equipment operators, hand-held hole drilling, and some other categories of workers. Also, abrasive blasting helpers and underground tunnel workers are not covered in Table 1. Table V-59 does not show any costs for abrasive blasting helpers and underground tunnel workers. Costs for these workers are included in Table V-60.

The number of FTE construction workers needing respirators, and the number of employees who will be wearing respirators sometime during the year (and who are therefore subject to the training and fit testing requirements of this provision) is presented below in Table V-60. Table V-60 also aggregates unit costs and calculates the costs for providing equipment, the programmatic costs associated with respirator use, and the total costs to each industry for respiratory protection requirements. As previously noted, Table V-60 includes respiratory protection costs for abrasive blaster helpers[70] (within NAICS 238300 and NAICS 238900) and underground tunnel workers (within NAICS 237300)—as justified in the technological feasibility analysis presented in Chapter IV of this FEA—even though there are no Table 1 tasks that cover them.

As previously explained, the costs in Table V-60 have been adjusted, both in the PEA and in this FEA, to take into account OSHA's estimate—consistent with the findings from the NIOSH Respirator Survey (NIOSH 2003)—that 56 percent of employees in the construction sector whose exposures are high enough that they would need respirators under the final silica rule are already using respirators that would bring them into compliance. The total cost of respiratory protection in the construction sector decreased from about $84.0 million in the PEA to about $22.4 million in the FEA. This reduction is due to a decline in the number of workers in construction from 2006 to 2012, and to the revisions to Table 1 that significantly reduced the occasions when respirator use would be required under the final rule.

Table V-60 also indicates the extent of respirator use expected in construction as a result of the final rule. Of the approximately 2.0 million workers in construction affected by the final rule (from Table III-13 in Chapter III of this FEA), approximately 265,000 (or about 13 percent) will be required to wear respirators at some point during the year. At any point in time during a construction workday, approximately 24,000 workers (from the FTE total in Table V-60) will be required to wear respirators to comply with the final silica rule.

[70] Abrasive blasters in construction, but not their helpers, already have respiratory protection in accordance with existing OSHA standards.

Exposure Assessment Costs

Overview of regulatory requirement

Paragraph (d) requires employers who do not fully and properly implement the engineering controls, work practices, and respiratory protection described in Table 1 to assess the exposure of each employee who is or may reasonably be expected to be exposed to respirable crystalline silica at or above the action level in accordance with either the performance option in paragraph (d)(2)(ii) or the scheduled monitoring option in paragraph (d)(2)(iii) of the standard. Under the performance option, the employer must assess the 8-hour TWA exposure for each employee on the basis of any combination of air monitoring data or objective data sufficient to accurately characterize employee exposures to respirable crystalline silica.

Under the scheduled monitoring option (termed the "periodic" monitoring option in the proposal), the employer must perform initial monitoring to assess the 8-hour TWA exposure for each employee on the basis of one or more personal breathing zone (PBZ) air samples that reflect the exposures of employees on each shift, for each job classification, in each work area. Where several employees perform the same job tasks on the same shift and in the same work area, the employer may sample a representative fraction of these employees in order to meet this requirement. In representative sampling, the employer must sample the employee(s) who are expected to have the highest exposure to respirable crystalline silica. Under the scheduled monitoring option, requirements for periodic monitoring depend on the results of initial monitoring. If the initial monitoring indicates that employee exposures are below the action level, no further monitoring is required. If the most recent exposure monitoring reveals employee exposures to be at or above the action level but at or below the PEL, the employer must repeat monitoring within six months of the most recent monitoring. If the most recent exposure monitoring reveals employee exposures to be above the PEL, the employer must repeat monitoring within three months of the most recent monitoring.

Under paragraph (d)(2)(iv), employers must reassess exposures whenever a change in the production, process, control equipment, personnel, or work practices may reasonably be expected to result in new or additional exposures at or above the action level, or when the employer has any reason to believe that new or additional exposures at or above the action level have occurred. Also, paragraph (d)(2)(v) requires employers to ensure that samples taken are evaluated in accordance with the procedures in Appendix A of the final standard.

In addition, paragraph (d)(2)(vi) requires the employer to individually notify each affected employee in writing of the results of an exposure assessment conducted in accordance with paragraph (d)(2) of that section or post the results in an appropriate location accessible to all affected employees.

Paragraph (d)(2)(vii) requires the employer to provide affected employees or their designated representatives the opportunity to observe any monitoring.

PEA cost estimates

In the PEA, the costing methodology and unit costs were identical to those used in general industry and maritime with the exception that construction industry wages are used to calculate productivity losses and recordkeeping costs.

As with general industry and maritime, OSHA assumed that establishments performing exposure monitoring would require the assistance of an outside consulting industrial hygienist (IH) to obtain accurate results because the testing protocols were judged to be too challenging for firms to adequately perform using their own staff. OSHA also estimated in the PEA that, on average, there are four workers per work area.

In the PEA, OSHA expected that many employers, aware that their operations exposed their workers to silica levels above the proposed PEL, would simply choose to comply with Table 1 and avoid the costs of conducting exposure assessments. For purposes of estimating costs, however, OSHA conservatively estimated exposure monitoring costs by assuming all employers would follow the scheduled monitoring option, rather than the performance option, to comply with paragraph (d)(2). While this likely resulted in an overestimation of costs because the scheduled monitoring option has more stringent requirements than the performance option, OSHA chose this approach because of insufficient data about how many employers would choose the performance option.

In addition to the initial exposure monitoring, OSHA, for costing purposes, estimated that exposure monitoring would be conducted twice a year where initial or subsequent exposure monitoring reveals that employee exposures are at or above the action level but at or below the PEL. For initial exposures above the PEL, OSHA judged that all employers in construction would choose to comply with Table 1 and therefore would not have to conduct periodic exposure monitoring. For the PEA, OSHA judged that approximately 15 percent of workers whose initial exposure or subsequent monitoring was at or above the action level would require resampling.

Further, OSHA estimated in the PEA that an IH would spend one day, at a cost of $500, to obtain the following number of PBZ samples: 2 for establishments with fewer than 20 employees; 6 for establishments with 20-499 employees; and 8 for establishments with 500 or more employees. In addition, OSHA estimated that analysis of each sample would cost $133.38 in lab fees and shipping costs. When combined with the IH fee, the cost per PBZ sample was projected to range from $195.88 to $383.38 (depending on establishment size).

In the PEA, the Agency indicated that it was not aware of any published studies presenting data on the frequency with which employee-designated representatives observe exposure monitoring but stated its belief that in some cases union officials are given the opportunity to observe monitoring at no direct cost to the employer. For these reasons, in the PEA, OSHA included no additional cost for this provision (Document ID 1720, p. V-181).

OSHA also accounted for the estimated 30-minute loss in employee time while attaching the pump and the 15 minutes required for recordkeeping, which includes recording the sampling results and notifying the employee of the sampling results. The loss in employee time was multiplied by an average employee hourly wage rate, including fringe benefits, to estimate the associated cost. The recordkeeping time was multiplied by a manager's hourly wage rate, including fringe benefits, to estimate the associated costs. Overall, in the PEA, OSHA estimated that unit costs in construction would range from approximately $227.98 to $415.98 per sample. OSHA believed that some establishments in construction were conducting exposure monitoring but had no evidence to estimate how many establishments were doing so. The Agency therefore conservatively estimated that no establishments in construction were currently conducting exposure monitoring and assumed no current compliance with the proposed exposure monitoring requirements.

Comments and responses on exposure monitoring

OSHA received a number of comments on the costs of exposure monitoring, with some commenters stating that OSHA had underestimated costs and others stating that OSHA had overestimated costs. As OSHA has retained the same cost methodology and unit costing used in general industry and maritime for construction, some of the relevant comments from that section are again discussed below. Note, however, that many of the construction industry comments are moot points in that, in the final rule, almost all silica-generating tasks would fall under Table 1 and require no exposure monitoring at all if employers fully and properly implement the engineering controls, work practices, and respiratory protection specified by Table 1. Sampling would be only conducted under rare conditions (as subsequently discussed) as the expectation is that most establishments will be complying with Table 1 protocols.

Robert Matuga, from the National Association of Home Builders (NAHB), commented that:

> [Trade contractors] also work on multiple jobsites in a day, sometimes three to four, and their tasks and work conditions vary. …. In this instance, an industrial hygiene firm would be required to take multiple tests at multiple jobsites in a single day. These jobsites can be spread over a large geographic area covering fifty miles or more. Because of these conditions, exposure monitoring would be a constant ongoing activity (Document ID 2334, p. 6).

OSHA disagrees with NAHB's assertion that exposure monitoring would be a constant activity. Most or all of these establishments would choose to follow Table 1, negating the need for monitoring. For establishments who would be performing tasks on Table 1 but not using Table 1, OSHA expects that the reason would likely be the availability of objective data (e.g., provided by professional trade or industry associations) showing that the exposures are below the threshold for engineering controls (or exposure monitoring) requirements to apply.

Commenters also disagreed with the estimate of 15 percent of workers requiring reassessment. In particular, in his testimony, Jack Waggener, speaking for URS, testified that:

> For the periodic monitoring, OSHA, who we believe is unrealistically low, assumed that 15 percent of the workers would be over the action level and that no worker would be over the PEL. We expect many people to be over the PEL and many more people to be over the action level (Document ID 3582, Tr. 2019).

The Agency believes that Mr. Waggener simply misunderstood the Agency's methodology here. OSHA estimated that there would be an additional 15 percent of those at or over the action level performing additional testing due to a change in the production, process, control equipment, personnel, or work practices may reasonably be expected to result in new or additional exposures at or above the action level. OSHA was not suggesting that only 15 percent of worker exposures would be over the action level and none over the PEL.

Additionally, the American Foundry Society (AFS) asserted that the percentage of exposure sampling should be increased by 25 percent for reassessment based on experience (Document ID 2379, Attachment 3, p. 35). OSHA does not have strong evidence to dispute the AFS estimate, so the Agency has adopted AFS's 25 percent estimate for this FEA.

Under paragraph (d)(2)(vii)(B) of the final rule, the employer must provide any required PPE at no cost to the observer. One commenter, the Korte Company, asserted that OSHA had omitted the cost of PPE for an employee's designated representative during observation of monitoring "without regards to whether or not the representative is trained or qualified to be wearing the required PPE" (Document ID 3230, p.1). In response, OSHA would like to make several points. In most cases, observation of monitoring is expected to occur during the set-up and at the end of the exposure monitoring—where a respirator would not be required. Exposure monitoring is expected to occur relatively infrequently in construction under the final rule because OSHA expects most employers to rely on Table 1, which does not require exposure monitoring. OSHA judges that when exposure monitoring is conducted, observation of monitoring is typically a relatively rare occurrence. In most cases, designated representatives have experience in observing monitoring, often in the presence of chemicals for which respirators would be required; therefore, the designated representatives would be expected to be trained and qualified to wear a respirator and may own their own respirators with an APF of at least 10. For these reasons, OSHA has not included additional exposure monitoring costs for PPE during observation of monitoring.

Alternatives to hiring an industrial hygienist

Please see the discussion under this identical subheading (Alternatives to hiring an industrial hygienist) earlier in this chapter of the FEA in "General Industry and Maritime: Exposure Assessment Costs."

Cost of industrial hygienist

Please see the discussion under this identical subheading (Cost of industrial hygienist) earlier in this chapter of the FEA in "General Industry and Maritime: Exposure Assessment Costs." Note that only the IH exposure monitoring cost of $2,500 applies in the construction sector.

Laboratory fees

Please see the discussion under this identical subheading (Laboratory fees) earlier in this chapter of the FEA in "General Industry and Maritime: Exposure Assessment Costs."

When the laboratory fee is combined with the IH fee, the direct cost per PBZ sample in construction is projected to range from $452.77 to $1,390.27—depending on establishment size. This is an increase from the range of $195.88 to $383.38 estimated in the PEA.

Other unit costs

OSHA did not receive comment on the other exposure monitoring unit costs in the PEA and has retained them in the FEA. These include the costs to reflect a 30-minute loss in employee time while attaching the pump and the 15 minutes required for recordkeeping, including recording the sampling results and notifying the employee of the sampling results. The only difference from the PEA to the FEA is that these costs were updated to 2012 dollars. The loss in employee time was multiplied by the employee's hourly wage rate, including fringe benefits, to estimate the associated cost. The recordkeeping time was multiplied by a manager's hourly wage rate, including fringe benefits, to estimate the associated costs.

Summary of updated unit costs

Overall, in the FEA, OSHA estimated that the total unit costs of an exposure sample for either initial or periodic monitoring in construction would range from approximately $487.15 to $1,424.65 (depending on establishment size). This is an increase from the range of $227.98 to $415.48 estimated in the PEA.

Aside from updating the costs to reflect 2012 dollars, the only changes to the unit costs of exposure monitoring in construction are due to the increased unit cost of a PBZ sample based on the increased cost to hire an IH consultant, as explained above.

Table V-61 shows the unit costs and associated assumptions used to estimate the cost of an exposure assessment in construction.

Table V-61
Exposure Assessment - Construction
Assumptions and Unit Costs

Costs and Parameters				**Comments/Assumptions**
Direct Costs by Establishment Size				
	Small (<20)	Medium (20-499)	Large (500+)	
Initial Monitoring				
IH fees/PBZ sample	$1,250.00	$416.67	$312.50	Consulting CIH - cost per sample. Assumes IH fee of $2,500 for 2, 6, and 8 samples for small, medium, and large
Scheduled Monitoring (Construction and hydraulic fracturing				
	$1,250.00	$416.67	$312.50	Consulting CIH - cost per sample. Assumes IH fee of $2,500 for 2, 6, and 8 samples for small, medium, and large
Lab Fees and shipping cost	$140.27	$140.27	$140.27	Lab fees per sample (EMSL Laboratory, 2000) and OSHA estimates. Inflated to
Total - per PBZ sample - Initial	$1,390.27	$556.94	$452.77	
Total - per PBZ sample - Scheduled, Construction (and Hydraulic Fracturing)	$1,390.27	$556.94	$452.77

Number of Exposure Samples Taken Annually

Changes from the proposed to the final rule have resulted in a significant reduction in OSHA's estimate of the annual number of samples taken by construction employers. In the PEA in support of the proposal, OSHA estimated that all employers in construction would perform initial exposure assessments and that exposure monitoring would be conducted (a) twice a year where initial or subsequent exposure monitoring revealed that employee exposures are at or above the action level but at or below the PEL, and (b) four times a year where initial or subsequent exposure monitoring reveals that employee exposures are above the PEL.

For the final rule, employers following Table 1 are not required to engage in initial or subsequent exposure monitoring for those construction workers engaged in tasks on Table 1. Therefore, OSHA is only estimating scheduled semi-annual exposure monitoring (for expected exposures at or above the action level but at or below the PEL) and scheduled quarterly exposure monitoring costs (for expected exposures above the PEL) for tunnel workers (in NAICS 237300) and scheduled quarterly exposure monitoring costs (for expected exposures above the PEL) for abrasive blasters (in NAICS 238300 and 238900) because those operations are not listed on Table 1. In addition, OSHA is estimating that some small fraction of employers—1 percent—will choose to conduct initial sampling to investigate the possibility that exposures are so low (below the action level) that Table 1 need not be followed. A larger estimate would, in reality, probably reflect larger cost *savings*, not larger costs, because the exposure monitoring estimated to occur for employees working under Table 1 may allow employees to be scoped out of the rule because their exposures are below the action level and, therefore, actually be indicative of avoided compliance costs relative to the costs that OSHA has estimated in this FEA. However, the Agency has made no such adjustment.

OSHA also notes that the National Association of Manufacturers (NAM) argued that in order to "demonstrate results meeting the 95 percent confidence limit […] it would be necessary to take 20 or more samples under substantially identical conditions" (Document ID 2380, Attachment 2, p. 17). OSHA disagrees with NAM's justification for the extensive sampling and has discussed the 95-percent-confidence-interval issue in greater detail in the Summary and Explanation section of the preamble concerning general industry and maritime compliance with the PEL. OSHA therefore estimated that employers would not need to repeat sampling in order to achieve any particular confidence level.

Existing Compliance Rate

Dr. Ruth Ruttenberg on behalf of the AFL-CIO noted that OSHA's costs for exposure monitoring assumed that employers are not already conducting exposure monitoring and contended that OSHA is therefore overestimating the costs of compliance because those employers already engaging in exposure monitoring would not need to incur additional costs to comply with the new exposure monitoring requirements (Document ID 2256, Attachment 4, p. 5). The Agency agrees that it is very likely that some employers already conduct exposure monitoring, but concludes that there is not sufficient evidence in the record as to how many establishments currently conduct exposure monitoring. Therefore, for costing purposes for the FEA, as in the PEA, OSHA has conservatively assumed no current compliance with the exposure monitoring requirements.

Conclusion

Based on the unit costs of exposure monitoring presented in Table V-61, OSHA provides, in Table V-62a and Table V-62b, the estimated annual exposure monitoring costs for construction, by NAICS industry and size of establishment (since exposure monitoring unit costs vary by the size of the establishment), for the final rule. As shown, the combined costs of the exposure monitoring requirements for construction are an estimated $16.5 million annually.

Table V-62a Annualized Exposure Monitoring Costs: Construction

NAICS	Industry	Workers: Initial Sampling	Workers: Semi-annual Sampling	Workers: Quarterly Sampling	Costs: Initial Sampling	Costs: Semi-annual Sampling	Costs: Quarterly Sampling	Total
Small (<20)

Medical Surveillance Costs

The medical surveillance requirements in the construction standard are generally the same as those in the general industry and maritime standard, although the triggers for the requirements are different. The methodology for calculating the costs of the medical surveillance requirements in the construction standard is therefore largely the same as that used for the general industry standard, but OSHA presents the costs for each standard separately. OSHA requested comments on the estimated costs in the PEA, but the comments, which are addressed in the following discussion, did not provide a persuasive argument that the Agency should use alternative costs in its final estimates. Accordingly, based on the rationale provided in the PEA and consideration of the issues identified in the following discussion and the record as a whole, OSHA has decided to maintain the same unit cost structure and time requirements used in the PEA. The only change from the PEA to the FEA was to update unit costs from 2009 to 2012 dollars.

Explanation of Medical Surveillance Provision

Paragraph (h) of the final standard requires the employer to make available medical surveillance for each employee who will be required under the rule to use a respirator for 30 or more days per year. This is a change from the proposed standard, which required medical surveillance for workers exposed to respirable crystalline silica above the PEL of 50 $\mu g/m^3$. The Summary and Explanation section of the preamble on medical surveillance provides a discussion of the rationale for this change.

Medical surveillance will include an initial (baseline) medical examination and periodic examinations. The initial medical examination must be made available to the employee within 30 days after initial assignment, unless the employee has received an equivalent medical examination within the last three years. The periodic medical examination must be made available to the employee at least every three years, or more frequently if recommended by the physician or licensed health care professional (PLHCP).

In accordance with paragraph (h)(2) of the final standard, the initial medical examination will consist of (1) a medical and work history, (2) a physical examination with special emphasis on the respiratory system, (3) a chest x-ray interpreted and classified according to the International Labour Office (ILO) International Classification of Radiographs of Pneumoconioses by a NIOSH-certified B Reader, (4) a pulmonary function test administered by a spirometry technician with a current certificate from a NIOSH approved course, (5) testing for latent tuberculosis (TB) infection, and (6) any other tests deemed appropriate by the PLHCP. In accordance with paragraph (h)(3) of the final standard, the contents of the periodic medical examinations are the same as those for the initial examination, with the exception that testing for latent TB infection is not required. However, consistent with what was done in the PEA (without subsequent comment), OSHA medical experts in the Office of Occupational Medicine and Nursing estimated that the PLHCP will recommend testing for latent TB during the periodic medical examination for 20 percent of construction workers (Document ID 1720, p. V-191).[71]

Note that the relevant language in both the proposed and final rule requires "the employer to make medical surveillance available for each employee…" For costing purposes, in both the PEA and FEA, OSHA assumed that all eligible employees would take advantage of the medical surveillance made available by the employer. In fact, to the extent that this is not true, OSHA will have overestimated the cost to employers of the medical surveillance provision. As evidence illustrating less than 100 percent employee participation, the record includes a study of miner participation rates in medical surveillance programs indicating that participation over the time span of the study ranged from 25 percent to 41.7 percent (Document ID 3998, Attachment 15; see also Document ID 3587, Tr. 3616-3617).

PEA estimates of unit costs

As presented in Table V-39 of the PEA, OSHA's medical experts in its Office of Occupational Medicine and Nursing provided estimates in 2009 dollars of the following medical costs: a complete medical and work history, a triennial review and updating of health history, a physical examination by a PLHCP, a chest x-ray, the classification of a chest x-ray by a NIOSH-certified B Reader, a pulmonary function test, an examination by a specialist (defined in the standard as an American Board Certified Pulmonary Disease or Occupational Medicine Specialist), other necessary tests (the medical experts estimated that these would likely be required by 10 percent of examined workers), and a latent TB test (Document ID 1720, p. V-187). OSHA also used the research and expertise of staff from its Office of Occupational Medicine and Nursing and from OSHA's contractor, ERG, to provide preliminary estimates in the PEA for how much time each medical activity would take, and requested comment on those estimates. These estimates included, for each employee, 120 minutes for the health history survey and exam, including x-ray; 30 minutes to review the health history; 60 minutes for the physical exam and tests, including pulmonary function but excluding x-ray; 30 minutes for the chest x-ray. OSHA also estimated 5 minutes for the reading of the latent TB test

[71] The 20-percent estimate for the construction sector is higher than the 15-percent estimate for general industry and maritime because OSHA's medical experts judged that workers in the construction sector would have a higher percentage of workers who recently lived in or visited foreign countries with elevated tuberculosis rates.

(return visit to receive results); and 60 minutes for an examination by a specialist (Document ID 1720, pp. V-187-191).

The PEA also accounted for round-trip travel costs necessary to see an off-site physician. Off-site travel time for a construction worker was estimated to be 90 minutes—as opposed to 60 minutes for an employee in general industry or maritime—for medical surveillance at any off-site location because OSHA expected that construction workers would be more likely to work in remote locations. OSHA further enumerated in the PEA the percentage of employees seeing an off-site physician by establishment size. For the initial examination, it was estimated that 20 percent of employees in small establishments (with fewer than 20 employees), 75 percent in medium-sized establishments (with 20 – 499 employees), and 100 percent in large establishments (with 500 or more employees) would see an on-site physician. For new hires, OSHA had estimated that the percentages of on-site medical examinations will decrease to 10 percent of employees in small establishments, 50 percent in medium establishments, and 90 percent in large establishments because OSHA expects that physicians would be less willing to travel to an establishment for the fewer patients that new hires represent. For the construction sector, OSHA also estimated a hiring rate[72] of 64.0 percent (utilizing 2008 data from the Bureau of Labor Statistics Job Openings and Labor Turnover Survey) and judged that 40 percent of new hires would require an initial health screening (the other 60 percent of new hires would have previous job experience covered by either the general industry and maritime standard or the construction silica standard such they would have had a compliant health screening within the prior three years). OSHA did not receive comment on this 40 percent estimate, other than from commenters questioning whether it accounted for persons who would not need to be re-screened, which it does. The initial screening for current employees was estimated to range in cost from $389.38 to $424.94 per employee, depending on establishment size, and the initial screening for new hires was estimated to range in cost from $393.82 to $429.38 per employee, again depending on establishment size.

Comments and Responses on Medical Surveillance

Unit costs

[72] In the PEA, OSHA in some cases referred to this rate as the separations rate, but in fact the Agency was using the hiring rate reported by BLS. Because the regulatory analysis is based on steady-state economic conditions, the separations rate, the hiring rate, and the turnover rate are effectively identical.

A frequent criticism expressed by commenters was that OSHA had underestimated the costs for the construction sector associated with the medical surveillance provision. See, e.g., comments from the Leading Builders of America (Document ID 2269, p. 18) and Fann Contracting, Inc. (Document ID 2116, Silica Comments 1, p. 18). However, the Leading Builders of America did not offer alternative estimates for the Agency to consider and Fann Contracting's only alternative estimate was an observation that travel time in Arizona could take many hours. While the Agency recognizes that there will be instances where the travel time for a particular construction worker would be greater than what OSHA has estimated in its unit costs, there will be other instances when the travel time is much less, considering that this estimate represents a national average for construction workers. Logically, more rural, geographically dispersed jobs are likely to require more travel time to medical facilities; this is offset, however, by the concentration of jobs in other areas with available nearby medical services. Note, however, that travel time was estimated to be 90 minutes for construction workers versus 60 minutes for workers in general industry or maritime to reflect the anticipated larger percentage of jobs in rural or remote areas. Further, as discussed in the general industry section, after reviewing other OSHA rulemakings, OSHA concludes that it is likely being conservative and overestimating the amount of travel time necessary and will revisit the issue in future rulemakings. For example, the asbestos in construction rule only includes 30 minutes of travel round trip for medical examinations. However, because the record was not further developed in this rulemaking, OSHA is not now reducing its estimate from the PEA.

A number of commenters from the construction sector provided specific cost estimates for initial medical examinations that were consistent with, or less than, OSHA's estimates of $389.38 to $424.94 per employee. In some cases, the submitted cost estimates were bundled with costs representing other provisions of the standard. The Associated General Contractors of Michigan (AGCM) commented that "[t]he cost of training and medical health evaluations for each individual worker would cost more than $300 per person" (Document ID 2265, Attachment 2, p. 2). The American Subcontractors Association reported average member estimates of $250 to $300 per employee for the required medical examinations (Document ID 2187, p. 7). The General Contractors Association of New York commented that "[t]he average cost of a single fit test and doctor exam to qualify employees for work is $275" (Document ID 2314, p. 2). The Precast/Prestressed Concrete Institute (PCI) stated that "fit testing and associated medical clearance for one worker [would] cost between $75 and $400, depending on location" (Document ID 4029, p. 3). Note that OSHA judged that the medical and work history required by the medical surveillance provisions of the final rule could also provide respirator fitness results required by the RPP, but for costing purposes for the final rule, the Agency assumed no current compliance with the health evaluation requirements for RPP in the final rule.

Eric Olson, from the Western Construction Group, commented that "the local [occupational medicine clinic] stated that this evaluation would cost approximately $150 per person because of the x-ray requirement… [s]o the financial impact of the average union mason in St. Louis at $36 per hour is $222 per worker" (Document ID 2183, pp. 3-4). Peter Soyka of Soyka & Company LLC reviewed OSHA's proposal for James Hardie Building Products, Inc. and found OSHA's medical surveillance unit costs "unrealistically low" (Document ID 2322, Attachment G, p. 16). Mr. Soyka indicated that to arrive at his estimate he "retained OSHA's existing methodology … adjust[ed] this number to 2012 dollars, applied this average cost to the corrected number of affected workers" and "used a three-year amortization period to annualize the costs of medical surveillance" (Document ID 2322, Attachment G, p. 28). Mr. Soyka arrives at an average annualized cost per at-risk worker of $229.40, which is only slightly higher than OSHA's estimated annualized cost of about $226 (Document ID 2322, Attachment G, Appendix A, p. A-4). In conclusion, OSHA estimated in the PEA that medical surveillance would cost between $389 and $425 per worker for initial screening (annualized cost of $226), depending on establishment size, which is comparable with the estimates presented above by the PCI and James Hardie Building Products and is higher than the estimates provided above by the ACGM, the Western Construction Group, and the General Contractors Association of New York.

Mr. Toscas of the Precast/Prestressed Concrete Institute (PCI) also argued that "an additional employee may also be needed to manage the new [medical surveillance] program at a cost of $50,000 - $60,000 per year" (Document ID 2276, p. 10). It was not explained why an employer would need to hire a new employee to manage a medical surveillance program; the actual performance of the medical surveillance would be performed by medical staff, which has already been captured as an employer expense. The administrative element of keeping track of when employees are due for another medical examination or related information is a simple administrative task, as is any potential recordkeeping. Many OSHA rules require medical examinations and medical surveillance, including 29 CFR 1910.1027 (Cadmium), 29 CFR 1910.1026 (Chromium VI), and 29 CFR 1926.1101 (Asbestos), and OSHA has never estimated costs for adding a medical surveillance manager. To OSHA's knowledge (and no evidence has been presented otherwise in this record), employers have been able to meet the requirements of these rules without having to hire additional employees for administrative oversight.

Total costs

Some commenters used the Agency's cost estimates to provide an independent calculation of the costs. In its post-hearing comment, the CISC submitted calculations relating to the costs of the medical surveillance provision (Document ID 4023, Silica Cost Analysis, spreadsheet tab 16). These calculations, however, did not provide new information on the unit costs related to medical surveillance. The NAHB, commented that “[i]f each construction employee required only one screening per year at $377.77, the total cost would be roughly $1.2 billion” (Document ID 2296, p. 18). OSHA does not take issue with the unit cost. However, as widespread as silica exposure is in construction, the Agency estimates that less than forty percent of all construction workers have jobs that are potentially at risk for any silica exposure (see Table III-9 of this FEA). And of those, only construction workers required to wear respirators for 30 or more days per year would need to be offered medical surveillance. Unlike in the proposal, OSHA has included Table 1 in the final rule as a separate means of compliance for the majority of silica-generating tasks likely to arise in construction, and most of those tasks would not require respirator use under normal conditions. Additionally, as in the proposal, the final rule generally requires employers to offer full medical screenings for all affected workers initially and then every three years— not annually, as implied by the NAHB’s estimates.

Current compliance

Although OSHA believes that some affected establishments in construction currently provide some medical testing to their silica-exposed employees, there was significant testimony in the record that many employers would at least have to make changes to their existing practices in order to comply with the new standard (See, e.g., Document ID 3580, Tr. 1535; Document ID 3585, Tr. 3004). Therefore, for costing purposes, the Agency assumed no current compliance with the health screening requirements of the rule. Given this assumption, OSHA is likely overestimating costs as the Agency believes there are currently establishments in construction that utilize medical testing for silica-exposed employees.

Employee Turnover

For the PEA, OSHA estimated a hiring rate in the construction sector of 64.0 percent (utilizing 2008 data from the Bureau of Labor Statistics Job Openings and Labor Turnover Survey) and judged that 40 percent of new hires would require an initial health screening. OSHA did not receive comment on this 40 percent estimate, other than from commenters questioning whether it accounted for persons who would not need to be re-screened, which it does.

A concern among the commenters was that the amount of turnover in the construction industry rendered the medical surveillance requirement impractical, or at least very expensive. For example, NAHB commented that "in both home building and remodeling, workforce is transitory by nature and there is a very high rate of turnover in the workforce" (Document ID 2296, p. 44). Kelli Vazquez, from Holes Incorporated, presented cost estimates for her company based on an assumption that every new hire will need an initial exam (Document ID 2338, p. 6). The FEA does take into account a high turnover rate in construction. For the FEA, in order to estimate turnover rates in construction, OSHA (2016) used the hiring rate of 70.3 percent in construction as estimated in 2012 by the Bureau of Labor Statistics (BLS, 2012a), as opposed to the 64.0 percent rate from the PEA, which was based on the older 2008 data from the same source. As specified in paragraph (h)(2) of the rule, employees who had received a medical examination that meets the requirements of this section within the previous three years would be exempt from undergoing a second "initial" medical examination. Therefore, not all new hires would require initial medical testing even if they otherwise qualified for such testing as measured by foreseeable respirator use alone. However, as explained in the discussion of the costs of the general industry standard, OSHA lacks sufficient data to identify the percentage who would remain in silica construction jobs but would not require re-testing. Therefore, the Agency is not changing its estimate that 100 percent of current affected employees and 40 percent of new hires (reflecting the large percentage of construction workers who are rehired in the construction sector) who meet the criteria for receiving medical surveillance will be tested in the initial year after promulgation of this final rule.

Final cost estimates

In summary, OSHA's estimates of the unit costs presented in this FEA for medical surveillance in the construction sector are broadly consistent with the estimates put forth by the Agency in the PEA. The comments on this issue did not identify significant issues with OSHA's methodology or estimates in the PEA or provide a persuasive argument that the Agency should use alternative costs in its final estimates. OSHA explained the basis for each of those estimates in the PEA, and the same basis applies in the FEA. The only change from the PEA to the FEA was to update unit costs from 2009 to 2012 dollars.

As in the PEA, OSHA estimated separate costs for current employees and for new hires as a function of the employment size (i.e., 1-19, 20-499, or 500+) of affected establishments. Table V-63 presents ERG's unit cost data and modeling assumptions used by OSHA to estimate medical surveillance costs. As shown in Table V-63, the estimated unit cost of the initial health screening for current employees in construction ranges from $428.55 to $466.50 and includes direct medical costs, the opportunity cost of worker time (i.e., lost work time, evaluated at the worker's 2012 hourly wage, including fringe benefits) for offsite travel and for the initial health screening itself, and recordkeeping costs. As in the PEA, the variation in the unit cost of the initial health screening by employment size is due entirely to differences in the percentage of workers expected to travel offsite for the health screening. In general, OSHA expects that the larger the establishment, the more likely it is that the selected PLHCP would provide the health screening services at the establishment's worksite. As was done in the PEA, OSHA estimates that, on average, 20 percent of establishments with fewer than 20 employees, 75 percent of establishments with 20-499 employees, and 100 percent of establishments with 500 or more employees will have the initial health screening for current employees conducted onsite.

The unit cost components of the initial health screening for new hires in construction are identical to those for existing construction employees with the exception that the percentage of workers expected to travel offsite for the health screening will be somewhat larger, as explained above. As shown in Table V-63, the estimated unit cost of the initial health screening for new hires in construction ranges from approximately $433.29 to $471.25.

The periodic medical examination would occur every three years, or more frequently if recommended by the PLHCP. As previously noted, the contents of the periodic medical examination are identical to those for the initial examination, with the exception that testing for latent tuberculosis infection is not required.

The estimated unit cost of periodic health screening includes direct medical costs, the opportunity cost of worker time, and recordkeeping costs for the employer. As shown in Table V-63, these unit costs vary from roughly $428.55 to $466.50 every third year. The variation in the unit cost is due entirely to differences in the percentage of workers expected to travel offsite for the periodic health screening. OSHA estimated that the share of workers traveling offsite, as a function of establishment size, would be the same for the periodic health screening as for the initial health screening for existing employees.

Table V-63

Medical Surveillance and TB Testing - Construction Industry

Assumptions and Unit Costs

Coverage: All employees using respirators

Screening Tool	Cost	Initial	Periodic	Comments/Assumptions
Direct Costs				
Complete medical and work history	$36.94	Yes	NA	Assumed one third of physical exam cost
Periodic review and updating of health history	$36.94	NA	Yes	Assumed one third of physical exam cost
Physical examination by PLHCP [a]	$110.83	Yes	Yes	Evaluation and office consultation including detailed examination ($100, inflated to 2012).
Chest x-ray [a]	$88.24	Yes	Triennial	Radiologic examination (a single posteroanterior radiographic projection) ($62.97; inflated to 2012). Costs include consultation and written report.
Chest X-ray classified by a NIOSH-certified B Reader [a]	$43.44	Yes	Triennial	Average of three estimates provided by B Readers to ERG, inflated to 2012.
Pulmonary function test [a]	$60.62	Yes	Triennial	Spirometry, including reports showing graphical displays and numerical results for measurements of Forced Vital Capacity (FVC), Forced Expiratory Volume in One Second (FEV1), and FEV1/FVC ($43.26; inflated to 2012).
Examination by a specialist [b]	$210.89	Yes	NA	Office consultation and evaluation by a specialist ($158.07; inflated to 2012)

Percentage of employees tested in initial year			
Current Employees	100.0%		
New Hires	40.0%		
Percentage of employees recommended for periodic TB testing [c]	20.0%		

[a] Typical charge based on ERG contacts with occupational health providers.

[b] Mean expense per office-based physician visit to a specialist for diagnosis and treatment, based on data from the 2004 MEPS. Inflated to 2009 levels using the consumer price index.

[c] The corresponding table in the PEA erroneously referred to this as annual TB testing. This typographical error did not impact the costs in the PEA.

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis.

The final rule requires employers in the construction sector to make medical surveillance available to each employee who will be required to use a respirator under this section for 30 or more days per year. The Agency applied this requirement to the unit costs to estimate total health screening costs. Based on a ten-year time horizon, OSHA estimated the total annualized costs in construction for health screenings (to include initial health screenings for existing employees and new hires and periodic health screenings) as required by the final rule. These estimates, disaggregated by affected NAICS industry, are presented in Table V-64.

Finally, OSHA estimated the unit cost of a medical examination by a specialist for those employees found to have signs of silica-related disease (1/0 or higher on the ILO scale) or are otherwise referred by the PLHCP. As shown in Table V-63, the estimated unit cost of a medical examination by a specialist is $364.23. This cost includes direct medical costs, the opportunity cost of worker time, and recordkeeping costs, including the cost of the employer's time to make a referral to a specialist. In all cases, regardless of establishment size, OSHA anticipates that the worker will spend 90 minutes in travel-time cost to travel offsite to receive the medical examination by a specialist.

Based on Buchanan et al. (2003), OSHA estimated that, for those workers in construction under medical surveillance (required by the final rule to wear a respirator for 30 or more days per year), there would be 445 new cases of silicosis a year (based on an x-ray of silica-exposed employees classified as 1/0 or higher) identified by medical surveillance.[73] For the purpose of estimating costs, OSHA assumes that the PLHCP would refer the employee to a specialist only if the employee was diagnosed with silicosis. ERG distributed these disease cases among industries in proportion to the number of workers currently exposed above the PEL of 50 $\mu g/m^3$. Table V-65, which multiplies the unit cost by the number of referred workers, shows the total annualized cost in the construction sector of medical examinations by a specialist.

Table V-66, which combines total health screening costs and the total costs of medical examinations by a specialist, shows the aggregate annual cost in construction, by NAICS industry, for the medical surveillance requirements in the rule. Combined over all affected NAICS construction industries, the estimated cost of these medical surveillance requirements is $66.7 million annually.

[73] OSHA has estimated many more specialist referrals in general industry and maritime than in construction even though many more workers in construction, relative to those in general industry and maritime, are estimated to receive medical surveillance. There are two reasons for this: (1) Only 38 percent of workers in construction with current exposures above the PEL will have medical surveillance (which is triggered by respirator use as specified in Table 1) whereas 100 percent of workers at or above the action level will have medical surveillance. (2) The relationship between exposure and silicosis is much stronger in GI/M because the exposure is typically full-time in GI/M and part-time in construction.

Table V-64: Annualized Health Screening Costs: Construction

NAICS	Industry	Using Respirator	Initial Screening	Screening for New Hires	Triennial Screening	Total Cost of Examinations	Total Cost of TB Testing	Total Cost

Familiarization Costs and Costs of Communication of Silica Hazards to Employees

In this section, OSHA presents its cost estimates for two employer information activities arising from the silica final rule: (1) employer familiarization with the final rule, and (2) training on, and communication of, respirable crystalline silica hazards to employees as required by the final rule.

Familiarization Costs

OSHA did not estimate any employer familiarization costs in the PEA in support of the proposed rule. However, for the same reasons explained in the discussion of familiarization costs for employers in general industry and maritime, OSHA is including familiarization costs in this FEA for employers in the construction sector. As was done for general industry and maritime, OSHA's estimate of familiarization costs for construction reflects the total familiarization time, costed at a supervisory wage, for each covered employer and is a function of establishment size. OSHA estimates that the average familiarization time will be the same as needed in general industry work: 4 hours per covered employer with fewer than 20 employees; 8 hours per covered employer with 20 to 499 employees; and 40 hours per covered employer with 500 or more employees. These estimates represent an average familiarization time for an establishment of a given size and, as a result, it is expected that some establishments will spend less time on familiarization than estimated here (e.g., if worker exposure never meets or exceeds the action level) and some will spend more time on familiarization than estimated here.

OSHA notes that, in addition to its other purposes, the familiarization time will help supervisors to prepare or select training to provide to other supervisors and to other employees of the firm. Although the construction standard has several differences from the general industry standard, OSHA anticipates that the average familiarization time will not vary significantly from the general industry standard. In fact, the familiarization time may be over-estimated in construction because many employers will be able to save time by identifying their activities on Table 1 and following the specific guidance that OSHA has provided for complying with the standard with respect to those activities. However, for this FEA, OSHA anticipates that the average familiarization times in construction, general industry, and maritime will not vary appreciably. Commenters who argued in favor of OSHA including familiarization costs did not suggest that one standard would require more familiarization time than the other.

Table V-67 shows the unit cost by establishment size for employers in construction to become familiar with the final rule. Note that for an establishment of any given size, the unit cost in construction is higher than the unit cost for general industry and maritime because the supervisor wage is higher in construction. Table V-68, which multiplies the unit familiarization costs per construction establishment from Table V-67 by the corresponding number of affected establishments, displays OSHA's estimate of the annualized familiarization costs of the final rule in the construction sector, by NAICS industry.[74] For the construction sector, the total annualized familiarization cost of the final rule is $13.8 million.

Table V-67

Familiarization - Construction
Assumptions and Unit Costs

Cost Category	**Cost**			**Comments/Assumptions**
	Small (<20)	Medium (20-499)	Large (500+)	
Hours per establishment	4.0	8.0	40.0

Costs for Training on, and Communication of, Silica Hazards to Employees in Construction

Paragraphs (i)(1) and (i)(2) of the final construction rule parallel paragraphs (j)(1) and (j)(3) of the general industry standard, and includes hazard communication under paragraph (i)(1) and employee information and training under paragraph (i)(2). Most of the comments received on the general industry rule were applicable to the construction rule as well because they addressed types of costs or unit costs. OSHA has therefore estimated the costs for training in the same way and for the same reasons as discussed earlier in the section on general industry, although certain cost components, such as the average supervisor and employee wages, are different in construction and general industry. As with the general industry standard, the hazard communication required under paragraph (i)(1) is already required and costed under OSHA's hazard communication standard (HCS) (29 CFR 1910.1200, made applicable to construction through 29 CFR 1926.59). Therefore, OSHA has estimated no costs for compliance with this paragraph of the final silica rule. The silica construction standard includes a requirement for a competent person, but the costs for competent persons to receive training are estimated and discussed in the cost section on the written exposure control plan.

Training requirements in the construction rule

Employers covered by the standard are required to include respirable crystalline silica in the program established to comply with the HCS. The employer must ensure that each employee has access to labels on containers of crystalline silica and safety data sheets, and is trained in accordance with the provisions of the HCS and paragraph (i)(2) of the respirable crystalline silica standard. The employer must also ensure that at least the following hazards are addressed: Cancer, lung effects, immune system effects, and kidney effects.

Paragraph (i)(2) of the construction standard requires that employers ensure that each employee who is covered by this section can demonstrate knowledge and understanding of at least the following: (A) the health hazards associated with exposure to respirable crystalline silica; (B) specific tasks in the workplace that could result in exposure to respirable crystalline silica; (C) specific measures the employer has implemented to protect employees from exposure to respirable crystalline silica, including engineering controls, work practices, and respirators to be used; (D) the requirements of the silica rule; (E) the identity of the "competent person" designated by the employer in accordance with the requirements of the standard and (F) the purpose and a description of the silica medical surveillance program. This requirement applies to existing employees, newly hired workers who would require training before starting work, workers who change jobs within their current workplace or are assigned new tasks or exposure protection, and any covered worker an employer believes needs additional training. As this is a performance standard, there is not a specified hours-of-training requirement; the amount of silica training an employee receives will depend on what is required for employees to demonstrate knowledge and understanding of the subjects listed under paragraphs (i)(2)(i)(A)-(F).

A few commenters from the construction sector provided specific comments on OSHA's estimate of training time. For example, Fann Contracting, Inc. considered OSHA's estimates reasonable and noted that it already provides training classes and could work in silica without a significant problem:

> OSHA's cost estimates of training employees on respirable crystalline silica-related hazards is probably not too far off …. Fann Contracting, Inc. has 26 actual training classes it offers to its employees * * * It would be easy for Fann Contracting, Inc. to change the required health and safety related topic in its OSHA 10 hour training, which all employees are required to attend within three months of being hired, from asbestos … to safety and health related hazards of silica (Document ID 2116, Attachment 1, p. 21).

Kellie Vazquez, from Holes Incorporated, testified that the training on the silica hazards in her firm consists of employees watching a video, going over a booklet, and taking a test on the materials presented. She reported that this training took "an hour or two" (Document ID 3580, Tr. 1389). While Ms. Vazquez did not clarify whether the training provided by her firm exceeded the requirements of the OSHA standard or would be representative of the minimum training time for other employers in the construction industry, OSHA notes that its estimate of one hour for training time is not inconsistent with the Holes Incorporated estimate. George Kennedy, from the National Utility Contractors Association, estimated the instructor's charge to be $20.00 per hour and stated that training the employees is "likely to take 3-to-4 hours to train each employee," (Document ID 2171, p. 5). Mr. Kennedy did not provide any further explanation as to what this time estimate entails or specify whether that training time would encompass information already required (and costed) under OSHA's hazard communication standard. OSHA also notes that Mr. Kennedy estimated a training professional's wage of $20 per hour, while the Agency used an hourly wage more than twice that amount—over $44 an hour for a construction supervisor.

OSHA has explained the basis for its estimate of one hour of training time for the general industry standard, and is not persuaded that employees would require any significant increase in training time in order to comply with the construction standard. OSHA updated the wage rates to 2012 wage rates for the supervisor who will be providing the training and the workers who will be receiving the training (shown below in Table V-69). The Agency has reviewed its baseline training estimates in light of the comments discussed in the general industry analysis and additional comments submitted by employers in the construction sector. In particular, some commenters in the construction sector, such as the International Union of Bricklayers and Allied Craftworkers, provided anecdotal evidence that many employers are already training their employees regarding silica (Document ID 2329, p. 5).

Commenter Joseph Liss disagreed with OSHA's multiplier for determining the number of employees requiring training because the "multiplicative factor for training purposes is likely to be much higher" than the FTE multiplied by a factor of 2 or 5, depending on the sub-industry (Document ID 1950, p. 9). OSHA has reviewed the comment submissions and revised the estimation procedures by developing occupation- and industry-specific estimates of the ratio between the number of affected workers and the associated number of FTEs.

Mr. Liss also questioned the methodology of the training cost calculation in the PEA, including job seasonality and the turnover rate in construction (Document ID 1950, p. 9). Mr. Liss commented that OSHA had not included initial training for all of the full-time-equivalent (FTE) workers exposed to silica (Document ID 1950, p. 9). Mr. Liss's analysis appears to contain two errors: (1) his use of OSHA's unit costs for initial training failed to recognize that the costs reported in Table V-44 of the PEA were annualized costs, not total costs; (2) OSHA did not estimate costs for FTE workers but did in fact account for the initial training costs for all workers contributing to the FTE work estimates. Those costs can be seen in the PEA on Table V-44 and can be found in the FEA in Table V-70. Finally, OSHA accounted for the seasonality and turnover in the construction industry by incorporating the BLS hiring rate[75] of 64.0 percent in the PEA (BLS, 2008) and 70.3 percent in the FEA (BLS, 2012a). A breakdown of OSHA's training cost methodology, including turnover in the construction industry, can be found in Table V-69.

The training requirements are generally the same under the construction standard as under the general industry standard, and OSHA generally used the same approach in determining the costs for training under the construction standard (note that "competent person" training is costed separately with the costs for the written exposure control plan.) As with the cost estimates for the general industry rule, OSHA concludes that the

[75] In the PEA, OSHA in some cases referred to this rate as the separations rate, but in fact the Agency was using the hiring rate reported by BLS. Because the regulatory analysis is based on steady-state economic conditions, the separations rate, the hiring rate, and the turnover rate are effectively identical.

additional silica training required in the final rule is sufficiently specific to the provisions of the final rule that baseline silica training would make only a minor contribution to employer compliance with the (additional) training required in the final rule. Therefore, for this FEA, OSHA is assuming no baseline respirable crystalline silica training in construction (other than that already required under the HCS), but that a full hour of training, on average, will be required for all covered workers. This removal of baseline respirable crystalline silica training in estimating training costs has the effect, by itself, of increasing the effective training costs for construction in the FEA relative to the PEA by 33 percent (from an average training time, per employer, from 45 minutes to 60 minutes). OSHA again recognizes that this change will likely lead to an overestimation of training costs for some employers.

Otherwise, OSHA did not change the unit cost parameters used in the PEA. For example, for costing purposes, in the PEA, OSHA assumed that all new hires would receive the full silica training from their new employer. OSHA has maintained this assumption in the FEA despite the fact that many new hires in construction may have been previously employed in the same industry and in some cases by the same establishment, so that they might have already received respirable crystalline silica training sufficient to comply with part or all of the training requirements specified in the final rule. The only unit cost difference between the PEA and the FEA is that the estimate of unit training costs has been inflated from 2009 to 2012 dollars. In addition, the hiring rate in the construction sector—used to estimate the amount of new hire training—increased from 64.0 percent (2008 data used in the PEA) to 70.3 percent (2012 data used in the FEA) in construction.

Also, as was done in the PEA, OSHA developed estimates of average class sizes as a function of establishment size. For training of current employees (i.e., initial training), OSHA is adopting the same estimated class sizes as in the general industry analysis, which are also the same as used in the PEA: 5 workers for establishments with fewer than 20 employees; 10 workers for establishments with 20 to 499 employees; and 20 workers for establishments with 500 or more employees. For new-hire training, OSHA estimated an average class size of 2 workers for establishments with fewer than 20 employees; 5 workers for establishments with 20 to 499 employees; and 10 workers for establishments with 500 or more employees.

The unit costs of training for this FEA are summarized below in Table V-69. As shown, OSHA has estimated the annualized cost (annualized over 10 years) of initial training to be between $4.21 and $4.99 per employee and the annual cost of new hire training at between $38.14 and $55.76 per employee, depending on establishment size.

Table V-70 summarizes OSHA's estimate of the annualized costs, by NAICS industry, of the training requirements in the final standard for the construction sector. This estimate is based on the assumption that all workers in the construction sector who are within the scope of the final standard would receive the required silica training. Combined over all NAICS construction industries, the cost of the training requirements is $76.1 million annually.

Table V-71 summarizes for the construction sector, by NAICS industry, the annualized costs of employer familiarization and employee training for the final rule. For the construction sector, combined over all NAICS industries, the annualized cost of employer familiarization and employee training for the final rule is $89.9 million annually.

Written Exposure Control Plan

A written exposure control plan provision was not included in the silica proposal, and no costs for a written exposure control plan were estimated in the PEA. Paragraph (g) of the final standard for the construction sector contains requirements for a written exposure control plan. The Summary and Explanation section of the preamble provides a thorough explanation of the reasoning behind the inclusion of the written exposure control plan provision in the final standard.

As specified in paragraph (g)(1) of the construction standard, an employer must establish and implement a written exposure control plan that contains at least the following elements: (i) a description of the tasks in the workplace that involve exposure to respirable crystalline silica; (ii) a description of the engineering controls, work practices, and respiratory protection used to limit employee exposure to respirable crystalline silica for each task; (iii) a description of housekeeping measures used to limit employee exposure to respirable crystalline silica; and (iv) a description of the procedures used to restrict access to work areas, when necessary, to minimize the number of employees exposed to respirable crystalline silica and their level of exposure, including exposures generated by other employers or sole proprietors. Under paragraph (g)(2), the employer must review and evaluate the effectiveness of the written exposure control plan at least annually and update it as necessary. Under paragraph (g)(4), the employer must designate a competent person to make frequent and regular inspections of job sites, materials, and equipment to implement the written exposure control plan.

Developing, reviewing, and updating a written exposure control plan

OSHA has estimated the cost of a written exposure control plan for the construction sector using the same time estimates (but sector-specific supervisory wages) as for the general industry/maritime requirement: 1 hour for establishments with fewer than 20 employees, 4 hours for those establishments with between 20 and 499 employees, and 16 hours for those establishments with 500 or more employees. OSHA estimated that 1 hour would be sufficient for very small establishments because there is, on average, slightly more than 1 worker covered by the standard per very small establishment in construction. As with the requirement in general industry, the Agency believes that the number of employees in the establishment serves as a reasonable proxy for the amount of time required to develop the written exposure control plan. The Agency expects this to be especially true in construction, as construction sites often involve workers performing several different tasks, requiring more coordination and planning. In addition, the employer may need to make some provision in the plan to limit access of persons not engaged in respirable crystalline silica-generating tasks to certain areas in certain situations.

OSHA further determined that the additional supervisory time needed to review and evaluate the effectiveness of the plan and to update it as necessary will also be based on establishment size. OSHA is estimating 0.5 hours for establishments for fewer than 20 employees, 2 hours for those with between 20-499 employees, and 8 hours for those with 500 or more employees to perform the annual review and update.

Although OSHA did not include the written exposure control plan in the proposal, OSHA received comments confirming that a written exposure control plan provision would be simple and inexpensive to create. The International Union of Bricklayers and Allied Craftworkers noted that “creating control plans is simple and cost effective for all contractors” because of the availability of online tools such as the Center for Construction Research and Training's Work Safely with Silica website (Document ID 2329, p. 5).

The annualized unit costs to develop, review and evaluate, and update the written exposure control plan, presented in Table V-72, have been applied to the employers in the construction sector covered by the standard—in all, 534,133 establishments with fewer than 20 employees, 59,744 establishments with between 20 and 499 employees, and 560 establishments with 500 or more employees. The annualized costs, broken out by NAICS construction industry, are shown in Table V-73. For the construction sector, the total annualized cost of developing, reviewing, and updating the written exposure control plan is $22.4 million.

Table V-72: Unit Costs for Developing a Written Exposure Control Plan in Construction

Develop exposure control plan

	Small (<20)	Medium (20-499)	Large (500+)	
Time to develop plan (hours)	1.0	4.0	16.0	
Annualized cost for plan development	$6.27	$25.08	$100.33	Annualized one-time cost to develop plan. Valued at weighted average of supervisors' hourly wage rate for affected construction industries of $44.04 per hour. Wages include fringe benefits. (BLS, 2012b).
Time for annual review and updating (hours)	0.5	2.0	8.0	
Annual review cost	$22.02	$88.09	$352.35	Annual cost to review plan. Valued at weighted average of supervisors' hourly wage rate for affected construction industries of $44.04 per hour. Wages include fringe benefits. (BLS, 2012b)
Total annualized cost	$28.29	$113.17	$452.69

Implementing the access restriction provision of the written exposure control plan

In construction, there is no regulated area requirement, and employers may be faced with new costs due to activities necessary to implement the written exposure plan as they move from site to site. OSHA has therefore included costs for implementation, in addition to the costs for development of the plan, for construction employers. Paragraph (g)(4) requires the employer to designate a competent person to implement the plan, and OSHA has addressed the additional costs for training the competent person after the discussion of the implementation costs.

Paragraph (g)(1)(iv) requires that the written exposure control plan include provisions to restrict access to work areas, when necessary, to minimize the number of employees exposed to respirable crystalline silica and their level of exposure, including exposures generated by other employers or sole proprietors. The competent person has two broad options to restrict access to work areas when necessary: (1) notifying or briefing employees, or (2) direct access control. The direct access control component is similar to the written access control plan included in the PEA, which OSHA has replaced with the written exposure control plan in the final rule. While the requirements for the written exposure control plan are more performance-oriented and thus should provide more flexibility for employers and reduce the cost of compliance, OSHA has estimated the costs of these options using, where appropriate, comparable components of the regulated area and written access control plan costs estimated in the PEA.[76]

Employee Notification or Briefing

For the employee notification or briefing option, OSHA estimated that, on average, it will take the competent person 15 minutes (0.25 hours) per job to revise the briefing plan, that each job will last 10 work-days, and that there are 150 construction working days in a year (Document ID 1709, p. 4-6). OSHA further estimated that it will take the competent person 6 minutes (0.1 hours) to brief each at-risk crew member (where an at-risk crew member could be an employee, a contractor, a subcontractor, or other worker under the control of the competent person) and that each crew consists of 4 at-risk workers

[76] For example, the time needed to identify and set up the direct access control area was estimated to be the same as the time needed to identify and set up the regulated area. Many costs in the PEA were not included here—for example, the costs for disposable clothing and extra respirators—because the written exposure control plan provisions do not require them.

(Document ID 1720, Table V-19, pp. V-108-112). As shown in Table V-74, the annual cost of the briefing option is $105.25 per at-risk crew member.[77]

Marcus Kuizenga, of James Hardie Building Products, Inc., commenting on OSHA's estimates for communication under the regulated area and written access control plan requirements in the PEA, stated that OSHA had estimated costs only to communicate to employees, but not to subcontractors at the same worksite (Document ID 2322, Attachment 1, p. 177). The Agency's preliminary estimate in the PEA encompassed communication to all at-risk workers at a worksite, where a worker could be an employee, a contractor, a subcontractor, or other worker under the control of the employer. OSHA assumed that each worker's employer, and not necessarily the general contractor at a worksite, would be responsible for employee communication. This all-inclusive group of workers requiring communication under the requirements in the proposed rule for regulated work areas and written access controls is the same group that would require job briefings under the written exposure control requirements in the final rule (although some of these workers will be addressed through direct access controls rather than job briefings).

For the FEA, OSHA is retaining the underlying assumptions used in the PEA. Despite the fact that there may be employees of many different employers at a worksite, OSHA did not increase the crew size for its estimates in the FEA both because subcontractors are likely to have their own competent person (which means that costs for the employee briefing provision to be implemented for the subcontractor's workers will be borne by the subcontractor and not the contracting employer) and because in many situations the workers generating the silica dust are the only ones at the jobsite at the time. This latter point was noted in the case of granite countertop installation in a comment by Tony Zimbelman representing the National Association of Homebuilders (Document 2334, pp. 5 and 7).

Direct Access Control

For the direct access control option, OSHA has estimated that, in addition to developing the overall written exposure control plan, it will take the employer, on average, 15 minutes (0.25 hours) per job to revise the plan concerning direct access control in order to tailor it to the specific conditions of the worksite and, again, that each job will last 10 work-days and that there are 150 construction working days in a year. Thus, OSHA estimates that, on average, each employer would implement direct access control 15 times per year over a total of 3.75 hours per year. OSHA then multiplied the number of

[77] The per worker cost is equal to the total cost for job briefing divided by the number of workers per crew times the number of jobs per year.

hours by the supervisory hourly wage to determine the cost per job, and divided this cost by the crew size of 4 to obtain the cost per worker.

For the direct access control option, OSHA has also added the cost of signage and tape for constructing physical barriers: 100 feet of hazard tape (per job) and three warning signs. OSHA presented these costs in the PEA as the cost of materials to establish a regulated area. Because the Agency received no comment on these costs and because, functionally, the act of establishing a restricted access area and a regulated area are the same, these costs were used for this FEA estimate of the cost of materials to establish a restricted access area. These costs are presented in Table V-74. As also shown there, the annualized cost of the direct access control option is $71.40 per at-risk crew member.[78] In developing an alternative cost model, Mr. Kuizenga added costs through a productivity penalty

> associated with wearing personal protective equipment (PPE) and/or observing the boundaries of access control areas, because it is simply not realistic to believe that work can be conducted as quickly and efficiently while wearing PPE as with normal work clothing and equipment or while taking a more circuitous path to reach and work on different areas within a work site (Document 2322, p. 190).

Mr. Kuizenga also included costs for the controlled access area to be established three times on each project, and estimated that a project would take sixty days and that workers would work 250 days per year (Document 2322, pp. 189-190). OSHA disagrees with all of these assumptions and the resulting additional cost estimates. As has been previously explained in the discussion of engineering control costs in construction, workers in construction are estimated to work an average of 150 days a year, not 250. More importantly, the written exposure control plan included in this final rule does not require those entering the controlled access area to wear PPE. In addition, the access restrictions need to be implemented only under certain circumstances, such as when Table 1 tasks that require workers to wear a respirator are being performed. Finally, Mr. Kuizenga's industry, residential building construction, would only infrequently involve Table 1 tasks that require a respirator.

Kellie Vasquez, of Holes Incorporated, also suggested that there might be a productivity penalty for her workers associated with access control plans:

---

[78] The per-worker cost is equal to the competent person cost per job to identify and set up the controlled access area divided by the number of workers per crew times the number of jobs per year plus the per worker per year cost of materials.

> My equipment operators are the first ones to arrive onsite to review the site conditions. They have enough room on their trucks for the equipment necessary to cut concrete and perform their duties but they do not have room on their trucks to carry equipment to set up these areas (Document 2338, Attachment 1, p. 5).

Ms. Vazquez's comment was directed at regulated area and controlled access plan requirements in the proposed rule. These requirements were not included in the final construction standard; the related requirement in the final construction standard is for a written exposure control plan. However, restricted access as needed to comply with the written exposure control plan can be accomplished by a job briefing as well as through the use of access control materials. For that reason, the difficulties Ms. Vazquez envisions need not arise in the final rule.

As discussed in the Summary and Explanation section of the preamble concerning the written exposure control plan, restricting access is necessary where respirator use is required under Table 1 or when an exposure assessment reveals that exposures are in excess of the PEL, or in other situations identified by the competent person.[79] On the other hand, when exposure to respirable crystalline silica is being successfully contained by engineering controls and work practices specified in Table 1 and no respirator use is required by Table 1, implementation of access control procedures is not required.

OSHA assumed that, in restricting access, half the time employers would use the briefing option and the other half of the time they would use direct access control. Consequently, as shown in Table V-74, the annualized cost of restricting access to work areas is $88.33 per at-risk crew member.[80]

The annualized unit costs for the competent person to implement the written exposure control plan to restrict access to work areas, presented in Table V-74, have been applied to the covered employers in the construction sector with workers using respirators required by Table 1 and where workers are performing abrasive blasting and tunneling work. The annualized costs, broken out by NAICS construction industry, are shown in Table V-75. For the construction sector, the total annualized cost for the competent person to implement the written exposure control plan is $2.7 million.

---

[79] In addition, as explained in the Summary & Explanation, the written exposure control plan must also provide for situations where employees could encounter potential overexposures generated by unusual circumstances, such as excessive exposures generated by other employers or sole proprietors.

[80] This weighted average is equal to the per employee cost per briefing times 50 percent plus the per employee cost of direct access control times 50 percent.

Table V-74: Unit Costs for Implementing Access Restriction Provisions of a Written Exposure Control Plan in

Option 1: Job Briefing			
Revise plan for specific job (hours)	0.25	$11.01	Per job. Valued at supervisor's wage
Communication of plan provisions (hours)	0.1		Per job. Value of supervisors' and workers' time for briefing on job specific site-control provisions.
Communication of plan provisions (cost, supervisor wage)		$4.40	Per job. Valued at supervisor's wage
Communication of plan provisions (cost, crew wage)		$12.65	Crew members; based on crew size assumption below
Total cost per crew for implementing plan through job briefing (per job)		$28.07	
Option 2: Direct Access Control			
Access control materials (per crew)			
Hazard tape per job (100 ft)		$6.03	(Lab Safety Supply, 2010, inflated to
Warning signs (3)		$78.86	$25.30 per sign (Lab Safety Supply, 2010, inflated to 2012)
Warning signs - annualized cost		$30.05	Assumes 3 year life
Total annualized costs		$120.44	Based on job frequency and crew size assumptions below
Material cost per worker (per year)		$30.11	
Supervisor time to identify and set up direct access control areas (hours)	0.25	$11.01	Per job
Job Frequency and Crew Size Assumptions			
Share of jobs requiring direct access control measures	50.0%		Estimated by ERG
Average crew size (workers)	4		Estimated by ERG
Average job length (days)	10		Estimated by ERG
Working days per year	150		Based on comments during SBAR Panel
Per-worker costs for plan implementation or direct access control implementation			
Annual cost per worker - briefing only		$105.25	
Annual cost per worker – direct access control only		$71.40	
Weighted average annual cost per worker		$88.33

Training the competent person

As specified in paragraph (g)(4) of the final standard, a competent person must carry out the responsibilities of implementing the written exposure control plan. As defined in the standard, "competent person" means an individual who is capable of identifying existing and foreseeable respirable crystalline silica hazards in the workplace and who has authorization to take prompt corrective measures to eliminate or minimize them, as well as has the knowledge and ability necessary to fulfill the responsibilities set forth in paragraph (g) of the standard. Employers in construction are already required, under Subpart C—General Safety and Health Provisions; 1926.20(b)(1) and (2), to initiate and maintain programs as may be necessary to comply with the safety and health provisions of that Part. These programs, if necessary, must include provisions for a competent person, designated by the employer, to perform "frequent and regular inspections of the job sites, materials, and equipment."

OSHA has utilized the competent person provision in other construction standards, such as 1926.1127, Cadmium, and 1926.1101, Asbestos, so the Agency expects that there is widespread familiarity with both the concept and the responsibilities of competent person in the construction sector. As in other OSHA construction rules, a major purpose of the competent person provision in this final silica standard is to identify who has the responsibility for inspections of the job sites, materials, and equipment. Thus, OSHA expects that most employers will have training programs in place to produce competent persons, and the cost of training someone will only be a relatively small marginal increase in the overall training cost.

OSHA does not anticipate any additional costs beyond training costs to be associated with the requirement that a competent person implement the written exposure control plan. Any corrective measures involving control equipment that result from the inspections performed by the competent person would be covered under the maintenance and repair costs that OSHA has already estimated as part of the costs for engineering controls.

In paragraph (e) of the proposed rule, employers had the option of controlling access through either a regulated area or a written access control plan. The role of the competent person was limited to the implementation of a written access control plan, which required the competent person to have the "knowledge and experience necessary to identify in advance tasks or operations during which exposures are reasonably be expected to exceed the PEL" (78 FR 56443, Sept. 12, 2013). Comments on competent person costs focused on the cost of training the competent person. Because the competent person would need to have a similar knowledge base and skill set to implement the written exposure control plan as required by the final rule, OSHA has treated the comments on competent person training as directly relevant to training under the final rule.

CISC opposed the inclusion of the competent person provision as unnecessary but also believed that a competent person, if required by the final standard, would not need additional training. Bradford Hammock, representing the CISC, commented that:

> An individual's experience, job training, and silica awareness training, in the CISC's view, will provide the capabilities envisioned by OSHA for a competent person with respect to crystalline silica. For silica in construction, the CISC respectfully believes that no specific training for a "competent person" is required (Document ID 2319, p. 128).

Other commenters disagreed, indicating that the training required by the proposed competent person provision was insufficient. The International Union of Operating Engineers (IUOE) suggested requiring that each competent person receive “specific hands on training on the engineering controls and work practices associated with the employee’s tasks, including the applicable work practices” (Document ID 2262, pp. 38-39). Additionally, Tom Nunziata, from the Laborers’ International Union of North America Training and Education Fund, testified that:

> Because by definition the competent person is one who is capable of identifying an existing, predictable respirable crystalline silica hazards in the surroundings or working conditions, and has the authorization to take prompt corrective measures to eliminate them, it is imperative that they have a detailed knowledge in the safe operation of the tools and engineering controls being employed on the job, and be capable of identifying when the controls are not functioning or being employed properly (Document ID 3589, Tr. 4221).

While the competent person provision does not specify a training requirement, the competent person is required to possess the knowledge and skills to perform the functions required by the standard. For that reason, the Agency expects that many employees designated as competent persons will undergo some training for the position. IUOE commented that competent persons should have at least “the same level of training for those workers performing silica dust-generating tasks, including hands-on training addressing the safe operation of tools and associated engineering controls” (Document ID 3589, Tr. 4221). OSHA agrees that the competent person will need training to, among other things, be able to ensure the safe operation of all tools used in silica-generating activities and implement the applicable controls. However, OSHA expects the competent person to require more training than the average worker since the competent person will need to have knowledge of all tools and silica-generating processes on the worksite.

Therefore, the Agency is estimating that each competent person will, on average, undergo two hours of training—in addition to the one hour of silica training estimated for all construction employees.

Because employers in construction are already required to have a competent person to comply safety and health provisions of Subpart C—General Safety and Health Provisions; 1926.20(b)(1) and (2), OSHA expects that each establishment will already have a competent person program in place. OSHA is therefore not including additional costs for the administration or management of a competent person program because the Agency expects employers will already be familiar with the concept of a competent person. The specific number of competent persons at each establishment would be determined by establishment size. Based on OSHA's knowledge of the typical crew, worksite, and workflow in the construction industry, the Agency estimates that, on average, there will be 1 competent person for each establishment with fewer than 20 employees,[81] 5 competent persons for each establishment with 20-499 employees, and 10 competent persons for each establishment with 500 or more employees.

OSHA expects that competent persons will be trained by a supervisor, presumably one who went through the process to become familiar with the requirements of the respirable crystalline silica standard, or by a combination of supervisory and/or technical staff that are familiar with the operation of the engineering controls. While the competent persons are not required to be supervisors and some of the staff providing the training may not be supervisors, OSHA is using a supervisor's wage to estimate the costs for time spent by both the trainers and the trainees in order to provide the upper cost limit, realizing that the cost for establishments who do not designate supervisors as the competent person will be lower.

The annualized cost for an employer to provide competent person training, by establishment size, is shown in Table V-76. The total cost for competent person training, by NAICS construction industry, is shown in Table V-77. For the construction sector, the total annualized cost for training the competent person to perform the responsibilities laid out in the final rule is $15.0 million.

[81] The Agency expects that most establishments have at least two competent persons, with one serving as back-up on any particular shift. However, establishments with fewer than 20 employees have an average of only about one affected worker. Hence, if that worker were unavailable, there would be no one left to engage in a silica-generating task, and a back-up competent person would be unnecessary. Alternatively, if some of these very small establishments have two or more affected workers, there will be others with no affected workers (and OSHA will have overestimated the number of affected establishments).

Table V-76: Unit Costs for Competent Person Training in Construction

	Small (<20)	Medium (20-499)	Large (500+)	
Persons per establishment	1.0	5.0	10.0	
Training time (hours)	2.0			Assumes all are trained in the same class. Time for the trainer and trainee valued at the supervisor wage (BLS, 2012b)
Total cost per establishment	$176.18	$528.53	$968.97	
Annualized cost	$20.65	$61.96	$113.59

*Any railroad costs calculated for the construction sector have been incorporated in general industry costs for NAICS 482110.

The annualized unit costs for the written exposure control plan have been applied to the employers in construction covered by the standard. These annualized costs, broken out by NAICS construction industry, are shown in Table V-78. Combined over all affected construction industries, the estimated annualized cost of the written exposure control plan provision is $40.1 million, which includes an annualized cost of $22.4 million to develop the written exposure control plan, $2.7 million to implement the access restriction provisions of the plan, and $15.0 million for competent person training.

Table V-78: Total Annualized Costs of Exposure Control Plan in Construction

NAICS	Industry	Total Exposure Control Plan Development Cost	Exposure Control Plan Implementation Cost	Total Competent Person Cost	Total Annual Exposure Control Plan Cost
236100	Residential Building Construction	$4,566,974	$124,783	$3,261,405	**$7,953,162**

Combined Construction Control, Respirator, and Program Costs

Table V-79 summarizes the engineering control costs, respirator costs, and program costs of the rule for the construction sector. Annualized compliance costs in construction are expected to total $659.0 million, of which $423.4 million are for engineering controls, $22.4 million are for respirators, and $213.2 million are to meet the ancillary provisions of the rule. These ancillary annual costs consist of $16.5 million for exposure monitoring; $66.7 million for medical surveillance; $89.9 million for familiarization and training; and $40.1 million for the written exposure control plan.

Table V-B-1 in Appendix B presents estimated compliance costs by NAICS industry code and program element for small entities (as defined by the Small Business Administration) in construction, while Table V-B-2 presents estimated compliance costs, by NAICS code and program element, for very small entities (fewer than twenty employees) in construction.

Table V-79: Annualized Compliance Costs for Construction Employers Affected by OSHA's Silica Standard (2012 Dollars)

NAICS	Industry	Control Costs	Respirators	Exposure Assessment	Medical Surveillance	Control Plan	Training & Familiarization	Total
236100	Residential Building Construction	$23,741,539	$2,661,194	$620,700	$8,082,550	$7,953,162	$11,885,853	**$54,944,997**

TOTAL COST SUMMARY

As shown in Table V-80, annualized compliance costs associated with the rule are expected to total $1,029.8 million. Table V-80 also provides total annualized costs for general industry, maritime, and construction separately, by major provision or program element included in the rule. This table shows that engineering control costs represent 64 percent of the costs of the standard for general industry and maritime and 64 percent of the costs of the standard for construction. Considering other leading cost categories, costs for exposure assessment and for medical surveillance represent, respectively, 22 percent and 8 percent of the costs of the standard for general industry and maritime; costs for training and familiarization and for medical surveillance represent, respectively, 14 percent and 10 percent of the costs of the standard for construction.

While the costs presented here represent the Agency's best estimate of the costs to industry of complying with the rule under static conditions (that is, using existing technology and the current deployment of workers), OSHA recognizes that actual costs could be somewhat higher or lower, depending on the Agency's possible overestimation or underestimation of various cost factors. In Chapter VII of this FEA, OSHA provides a sensitivity analysis of its cost estimates by modifying certain critical unit cost factors. Beyond this sensitivity analysis, OSHA notes that its cost estimates do not reflect the possibility that, in response to the rule, industry may find ways to reduce compliance costs.

This could be achieved in three ways. First, in construction, 36 percent of the estimated costs of the rule (all costs except engineering controls) vary directly with the number of workers exposed to silica. However, as shown in Table III-5 in this FEA, more than five times as many construction workers will be affected by the rule as will the number of full-time-equivalent construction workers necessary to do the work. This is because most construction workers currently doing work involving silica exposure perform such tasks for only a portion of their workday. In response to the rule, many employers are likely to assign work so that fewer construction workers perform tasks involving silica exposure; correspondingly, construction work involving silica exposure will tend to become a full-time job for some construction workers.[82] Were this approach fully implemented in construction, the actual cost of the rule would decline because employers would have to

[82] There are numerous instances of job reassignments and job specialties arising in response to OSHA regulation. For example, asbestos removal and confined space work in construction have become activities performed by well-trained specialized employees, not general laborers (whose only responsibility is to identify the presence of asbestos or a confined space situation and then to notify the appropriate specialist).

comply with the ancillary provisions of the final rule for fewer workers.[83] However, these workers would be subject to the full protections of the final rule.

Second, industry could demonstrate that certain construction activities result in exposures below the action level under any foreseeable conditions—in which case, workers engaged only in those silica-generating activities would not be subject to the requirements of the final rule. For example, an employer could make this demonstration by using objective data developed for short-term, intermittent tasks involving limited generation of silica dust. In estimating the costs for this final rule, however, OSHA included all costs, including ancillary costs as appropriate, associated with short-term intermittent silica tasks.

Third, the costs presented here do not take into account the possible development and dissemination of cost-reducing compliance technology in response to the rule.[84] One possible example is the development of safe substitutes for silica sand in activities such as abrasive blasting operations, repair and replacement of refractory materials, foundry operations, and in the railroad transportation industry. Another is expanded use of automated processes which would allow workers to be isolated from the points of operation that involve silica exposure (such as tasks between the furnace and the pouring machine in foundries and at sand transfer stations in structural clay production facilities). Yet another example is the further development and use of bags with valves that seal effectively when filled, thereby preventing product leakage and worker exposure (for example, in mineral processing and concrete products industries). Probably the most pervasive and significant technological advances, however, will likely come from the integration of compliant control technology into standard production equipment. Such advances would both increase the effectiveness and reduce the costs of silica controls when compared to retrofitted production equipment. Possible examples include local exhaust ventilation (LEV) systems attached to portable tools used by grinders and tuckpointers; enclosed operator cabs equipped with air filtration and air conditioning in

[83] OSHA expects that such a structural change in construction work assignments would not have a significant effect on the benefits of the rule. As discussed in Chapter VII of this PEA, the estimated benefits of the rule are relatively insensitive to changes in average occupational tenure or how total silica exposure in an industry is distributed among individual workers.

[84] Evidence of such technological responses to regulation includes Ashford, Ayers, and Stone (1985), OTA (1995), and OSHA's regulatory reviews of existing standards under § 610 of the Regulatory Flexibility Act ("610 lookback reviews"). On the other hand, supplemental evidence from Harrington et al. (2000) finds that OSHA does not systematically overestimate costs on a per-unit basis; nevertheless, the authors provide several examples of OSHA's overestimation of costs due to technological improvements.

industries that mechanically transfer silica or silica-containing materials; and machine-integrated wet dust suppression systems used, for example, in road milling operations.[85]

OSHA has decided not to include in its analysis any possible cost-reducing technological advances or worker specialization because the technological and economic feasibility of the rule can easily be demonstrated using existing technology and employment patterns. However, OSHA believes that actual costs, which will incorporate any future developments of this type, will likely be lower than those estimated here.

[85] A dramatic example from OSHA's 610 lookback review of its 1984 ethylene oxide (EtO) standard is the use of EtO as a sterilant. OSHA estimated the costs of then existing add-on controls for EtO sterilization, but in response to the standard, improved EtO sterilizers with built-in controls were developed and widely disseminated at about half the cost of the equipment with add-on controls. (See OSHA, 2005.) Lower-cost EtO sterilizers with built-in controls did not exist, and their development had not been predicted by OSHA, at the time the final rule was published in 1984.

Table V-80: Annualized Compliance Costs for Employers in General Industry, Maritime, and Construction Affected by OSHA's Silica Standard (2012 Dollars)

Industry	Engineering Controls	Respirators	Exposure Assessment	Medical Surveillance	Exposure Control Plan	Regulated Areas	Training & Familiarization	Total
General Industry	$228,014,496	$10,389,419	$78,620,499	$29,004,870	$4,065,164	$2,617,814	$5,945,116	**$358,657,378**
Maritime	$10,079,555	$104,287	$1,130,235	$680,718	$66,922	$19,322	$72,112	**$12,153,151**
Construction	$423,362,684	$22,390,518	$16,490,605	$66,667,933	$40,141,004	Not Applicable	$89,918,502	**$658,971,248**
Total	**$661,456,736**	**$32,884,224**	**$96,241,339**	**$96,353,520**	**$44,273,091**	**$2,637,136**	**$95,935,731**	**$1,029,781,777**

COSTS UNDER ALTERNATIVE PEL (100 $\mu G/M^3$) SCENARIO

Appendix V-C presents, for analytical purposes, costs for an alternative PEL of 100 μg/m^3. Total annualized compliance costs under this alternative are $649.3 million. Table V-C-1 displays costs for general industry, maritime, and construction by each program element. Table V-C-2 shows total costs by NAICS industry code for all affected general industry and maritime establishments, for business entities in general industry and maritime defined as small by the Small Business Administration, and for very small business entities in general industry and maritime (those with fewer than twenty employees). Table V-C-3 shows total costs by NAICS industry code for all affected construction establishments, for business entities in construction defined as small by the Small Business Administration, and for very small business entities in construction (those with fewer than twenty employees). The costs in Table V-C-3 reflect the assumption that all employers in construction would use Table 1 to comply with the alternative rule. Some employers, however, may find it less expensive not to use Table 1—in which case, these costs will be lower than OSHA's estimates.

COSTS UNDER ALTERNATIVE DISCOUNT RATES

An appropriate discount rate[86] is needed to reflect the timing of costs after the rule takes effect and to allow conversion to an equivalent steady stream of annualized costs.

Alternative Discount Rates for Annualizing Costs

Following OMB (2003) guidelines, OSHA has estimated the annualized costs of the rule using separate discount rates of 3 percent and 7 percent. Consistent with the Agency's own practices in recent proposed and final rules,[87] OSHA has also estimated, for benchmarking purposes, undiscounted costs—that is, costs using a zero percent discount rate.

Summary of Annualized Costs under Alternative Discount Rates

In addition to using a 3 percent discount rate in its main cost analysis, OSHA estimated compliance costs, in Appendix V-D, using alternative discount rates of 7 percent and zero percent. Table V-D-1 and V-D-2 in Appendix V-D present total costs at a 7 percent discount rate for both (1) all employers by major industry category and program element, and (2) affected employers by NAICS industry code and employment size class (all establishments, small entities, and very small entities). Tables V-D-3 and V-D-4 present the same breakdowns of total costs estimated at a zero percent discount rate.

As shown in Appendix V-D, the choice of discount rate has only a minor effect on total annualized compliance costs, with annualized costs increasing from $1,029.8 million using a three percent discount rate to $1,056.1 million using a seven percent discount rate, and decreasing to $1,011.6 million using a zero percent discount rate.

TIME DISTRIBUTION OF COSTS

OSHA analyzed the stream of (unannualized) compliance costs, by industry sector, for the first ten years after the rule takes effect under the simplifying assumption that no provisions of the rule are phased in. As shown in Table V-81, total compliance costs are expected to peak in Year 1 totaling almost $1.5 billion. After that, costs are estimated to decline and remain relatively flat after the initial set of capital and program start-up expenditures has been incurred. Costs are projected to rise somewhat in Year 4 as a result of the triennial medical examinations and in Year 6 because of a second cycle of control equipment purchases in construction for short-term,

[86] Here and elsewhere throughout this FEA, unless otherwise noted, the term "discount rate" always refers to the real discount rate—that is, the discount rate net of any inflationary effects.

[87] See, for example, 71 FR 10099, the preamble for the final hexavalent chromium rule.

intermittent work. Thereafter there are fluctuations but no strong trend. OSHA notes that the differences between costs for Year 1 and costs for subsequent years are narrower than might otherwise be the case due to (1) the expectation that, in the construction sector, a large percentage of control equipment will be rented (leading to constant annual expenses for the rented control equipment) rather than purchased as capital in Year 1; and (2) the expectation that the only engineering controls needed in the maritime sector will be wet methods, which do not require capital expenditures. On the other hand, the ancillary provisions are expected to have a relatively large number of initial costs (mainly labor rather than capital) in Year 1.

Table V-81: Distribution of Compliance Costs by Year for Establishments Affected by the Silica Standard (2012 Dollars)

Year	Engineering Controls	Program Requirements	Total
General Industry			
1	$351,150,221	$226,474,187	$577,624,408
2	$88,019,935	$96,902,383	$184,922,318
3	$88,335,426	$96,902,383	$185,237,809
4	$88,019,935	$128,722,760	$216,742,695
5	$88,335,426	$102,868,704	$191,204,130
6	$97,750,338	$103,313,313	$201,063,651
7	$88,335,426	$119,936,421	$208,271,847
8	$88,019,935	$106,068,901	$194,088,835
9	$88,335,426	$106,068,901	$194,404,327
10	$88,019,935	$115,223,631	$203,243,565
Maritime			
1	$3,508,723	$5,103,417	$8,612,140
2	$2,061,181	$1,479,402	$3,540,584
3	$2,061,181	$1,479,402	$3,540,584
4	$2,061,181	$2,221,245	$4,282,426
5	$2,061,181	$1,618,498	$3,679,679
6	$3,508,723	$1,503,124	$5,011,848
7	$2,061,181	$2,016,405	$4,077,586
8	$2,061,181	$1,693,105	$3,754,287
9	$2,061,181	$1,693,105	$3,754,287
10	$2,061,181	$1,906,534	$3,967,715
Construction			
1	$494,322,820	$404,082,164	$898,404,984
2	$402,508,839	$90,472,782	$492,981,621
3	$402,508,839	$90,472,782	$492,981,621
4	$402,508,839	$124,698,143	$527,206,982
5	$402,508,839	$100,096,954	$502,605,793
6	$494,322,820	$98,584,007	$592,906,827
7	$402,508,839	$112,807,735	$515,316,574
8	$402,508,839	$103,671,225	$506,180,065
9	$402,508,839	$103,671,225	$506,180,065
10	$402,508,839	$108,391,817	$510,900,656

APPENDIX V-A
Background Data Supporting OSHA's Analysis of Control costs for General Industry and Maritime

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime

Sector/Job Category	Control Requirements	Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
Cut stone						
Sawyer	Control other dust sources in area	Addressed by other controls	NA	NA	NA	No cost estimated
	Rigorous housekeeping- capital	HEPA vacuum	NA	$937	100%	Nilfisk, 15 gallon capacity
	Rigorous housekeeping- labor	Labor costs	NA	$997	100%	Additional 10 minutes/day
	Manage slurry-assumed included in housekeeping costs	No incremental costs	NA	NA	NA	No cost estimated
	Pre-wash stone to be cut	Labor	NA	$499	100%	5 min/wrkr/day
	Improve drainage	Plumbing enhancements	NA	$7,592	100%	ERG estimate based on discussions with contractors
	Increase water use at saw blade	Extra saw maintenance	NA	$499	100%	5 min/worker/day;Equipment has water capabilties
	Enclose saw	Build enclosure	NA	$230	100%	8x8x8 dust partition, with plastic sheeting, assumes 5 year life (Means, 2003)
	Exhaust saw	LEV	645	$3,394	100%	Based on saw LEV (e.g., pg. 10-158, 159, 160, ACGIH, 2001)
Fabricator	Use water fed equipment	No cost, most tools have water capability	NA	NA	NA	No cost estimated
	Manage slurry-assumed included in housekeeping costs	No incremental costs	NA	NA	NA	Assumes no incremental costs
	Rigorous housekeeping- capital	HEPA vacuum	NA	$937	100%	Nilfisk, 15 gallon capacity
	Rigorous housekeeping- labor	Labor costs	NA	$997	100%	10 min/wrkr/day
Splitter/ chipper	Use work practices to position work near duct	Judged to be a negligible cost	NA	NA	NA	Work practices adjustments judged to be negligible cost.
	Rigorous housekeeping- capital	HEPA vacuum	NA	$937	100%	Nilfisk, 15 gallon capacity
	Rigorous housekeeping- labor	Labor costs	NA	$997	100%	Additional 10 minutes/day
	Pre-wash stone	Labor	NA	$997	100%	10 min/wrkr/day
	Use flexible trunk LEV for hand chipping	Flexible trunk LEV	600	$3,158	100%	Granite cutting and finishing;pg. 10-94 (ACGIH, 2001)
	Tool-mounted LEV for hand-held chipping tools	Shroud and vacuum	NA	$812	100%	Proventilation.com

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category	- Control Requirements	Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
	Keep floors wet; wash down with high pressure hose	Already costed (see sawyers)	NA	NA	NA	High-pressure hose and floor trough installation
Machine operator	Control other dust sources in area	Addressed by other controls	NA	NA	NA	No cost estimated
	Rigorous housekeeping- capital	HEPA vacuum	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Rigorous housekeeping- labor	Labor costs	NA	$997	100%	Additional 10 minutes/day
	Wash stone before and after each process	Add misters to conveyor line	NA	$281	100%	Judged to require 8 hrs of shop labor,$200 in materials to fabricate; 2-year life
	Keep conveyor clean and damp	Addressed in other	NA	NA	NA	No cost estimated
	Management of dust-carrying water	Included in housekeeping	NA	NA	NA	No cost estimated
	Enclose machinery	Build enclosure in machine shop	NA	$168	100%	8x8x8 enclosure, plastic sheeting, from Means, 2003. Five-year life.
	Exhaust trimming machine	LEV	500	$2,631	100%	Based on abrasive cut-off saw; (pg. 10-134) (ACGIH, 2001)
Abrasive Blaster	For use of maintained, interlocked, ventilated glove-box cabinet	Cost of maintaining blast cabinet	NA	$1,287	100%	Assumes 50% increase in maintenance costs (of up to $2,000) and purchase of new cabinets (25%) at $8,000/cabinet (Norton, 2003), or addit. interlocks at $1,800/cabinet (Heastrup, 2003).
	Use only non-silica blasting media	Neglible incremental cost	NA	NA	100%	Manufacturer calls indicted no use of sand, and neglible cost difference
	Increase blasting cabinet ventilation	Incremental LEV	1,225	$6,447	100%	Judged to require an increase in CFM for a 7x7 booth, approximately 25% of ACGIH recommended 100 cfm per square ft of opening, or 4900 cfm in total.
	Use HEPA vacuums for machine cleaning	Vacuum replaces compressed air cleaning	NA	$937	100%	Judged to create a negligible impact on labor requirements for cleaning

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category	Control Requirements	Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
Flat glass						
Material Handler	Automated and ventilated unloading equipment	Not costed	NA	NA	NA	No cost estimated
	Conveyor enclosures	Limit dust and spills	NA	$901	100%	ERG estimates based on discussions with industrial ventilation consultants
	Conveyor ventilation	LEV	4,900	$25,787	100%	Per 200 ft of conveyor enclosure (Pg. 10-70, ACGIH)
Batch Operator	Conveyor enclosures	Limit dust and spills	NA	$901	100%	ERG estimates based on discussions with industrial
	Conveyor ventilation	LEV	4,900	$25,787	100%	Per 200 ft of conveyor enclosure (Pg. 10-70, ACGIH)
	LEV for batch operator workstation	LEV	1,050	$5,526	100%	Bin & hopper ventilation and unvented mixers (pg. 10-69, ACGIH, 2001)
	Dust suppressants	Use commercial dry suppressants	NA	$676	100%	Oil-based sawdust sweeping compound
	Substitute wider HEPA vacuum use for compressed air	HEPA available, requires more labor	NA	$1,010	100%	10min/wrker/day
	HEPA vacuums	Small HEPA needed	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Half mask respirator		NA	$520	NA	Annual cost of respirator use
Other glass

	Dust suppressants	Use commercial dry	NA	$676	100%	Oil-based sawdust sweeping compound
	Substitute wider HEPA vacuum use for compressed air	HEPA available, requires more labor	NA	$1,096	100%	10 min/wrker/day
	HEPA vacuums	Small HEPA needed	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Half mask respirator		NA	$520	100%	Annual cost of respirator use
Concrete I						
	Yard dust suppression	Wetting with yard hose	NA	$1,647	100%	Per facility; 2 year life. .25 hour of labor time per day per worker
	Enclosed cabs	Retrofit with cab or replacement equip	NA	$7,365	100%	Per machine. Assumes 35% annual maintenance costs
Material handlers	LEV for blender and hoppers	LEV	1,050	$5,526	100%	Per ACGIH design parameters (pg. 10-69; ACGIH, 2001)
	Improved housekeeping - HEPA vacuum	HEPA vacuum cost	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Improved housekeeping - additional labor	Labor cost	NA	$1,024	100%	10 min/wrker/day
Mixer operators	Wet methods to clean equipment	Additional cleaning time	NA	$1,024	100%	Per day/per operator
	LEV for bag opening stations	LEV with bag dumping station	1,513	$7,962	75%	Bag opening station; pg. 10-19) (ACGIH, 2001)
	Ventilated control room and HEPA filter	LEV	200	$3,123	25%	ERG estimates based on Means and ACGIH
	Dust control for adjacent operations	Addressed by other controls	NA	NA	NA	No cost estimated

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category - Control Requirements		Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
Forming operators	LEV for forming operator workstations	Moveable LEV duct	600	$3,158	100%	See similar control for granite cutting and finishing; p.10-94 (ACGIH, 2001)
	Initial thorough cleaning	Cost per square foot, per facility	NA	$0	100%	ERG estimate. One time cleaning
	Improve housekeeping - capital	HEPA vacuum cost	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Improve housekeeping - labor	Additional cleaning time	NA	$1,024	100%	10 min/wrker/day
Abrasive blasting operators	Use wet process	Shop built sprayer	NA	$133	80%	Assumes 2-year life
	Use alternative blast media	Use of more expensive non-silica media	NA	$5,156	20%	Based on 220,000 square feet of coverage per year per crew of 4
	Half mask respirator		NA	$520	100%	Annual cost of respirator use
Finishing operators	Work concrete green	Penalty for overall productivity	NA	$2,393	100%	Assumes 5% productivity penalty per worker
	Use wet process	Shop built sprayer	NA	$133	50%	Assumes 2-year life
Finishing operators	LEV where wet methods are infeasible	Shroud and vacuum	NA	$988	50%	Proventilation.com
Packaging operators	LEV for bag filling stations	LEV with bag filling station	1,500	$7,894	100%	Bag filling station (pg. 10-15, ACGIH, 2001)
	Extended polyethylene bag valves to reduce dust release	Use bags with dust-control feature	NA	$4,915	100%	Assumes 5 bags per minute; 200 days a year
Concrete II						
Production worker	Enclosed ventilation equipment		NA	$901	100%	ERG estimates based on discussions with industrial ventilation consultants
	Conveyor ventilation	LEV	4,900	$25,787	100%	Per 200 ft of conveyor enclosure (Pg. 10-70, ACGIH)
	Improved maintenance on process equipment enclosures	Additional maintenance	NA	$554	100%	Incremental cost for annual maintenance
	Improved maintenance		NA	$571	100%	0.5 hr additional maintenance time per week per production worker
	Initial thorough cleaning	Cost per square foot, per facility	NA	$0	100%	ERG estimate. One time cleaning
	Improved area cleanup with HEPA	Equipment cost	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Enhanced housekeeping with HEPA vacuums	Additional labor time	NA	$997	100%	Additional 20 minutes/day

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category	Control Requirements	Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
	Ventilated bag dumping stations with bag compactor	LEV	1,513	$7,962	100%	Bag opening station; (pg. 10-19, ACGIH, 2001)
Pottery						
Material Handler	Well-ventilated bag dumping stations	LEV	1,513	$7,962	100%	Bag opening station; (pg. 10-19) (ACGIH, 2001)
	Ventilated cab enclosures	Retrofit with cab or replacement equip	NA	$7,365	100%	ERG estimate based on vendor interviews.
	Apply LEV to conveyors in material handling area	LEV	10,000	$52,626	100%	ERG estimates based on discussions with industrial ventilation consultants
	Initial thorough cleaning	Cost per square foot, per facility	NA	$0	100%	ERG estimate. One time cleaning
	Improve housekeeping - capital	HEPA vacuum cost	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Improve housekeeping - labor	Additional cleaning time	NA	$961	100%	10 min/wrker/day
Forming Line Operator	LEV- hand grinding bench controls	LEV	1,400	$7,368	100%	Welding ventilation bench hood (pg. 10-149, ACGIH
	Eliminate compressed air (switch to vacuum)	HEPA vacuum plus additional time	NA	$1,474	100%	Includes 5 incremental minutes per day.
	Reduce dust generation during mold parting (redesign talc bag)	Cost judged negligible	NA	NA	NA	No cost estimated
Finishing operator	LEV- hand grinding bench controls	LEV	2,400	$12,630	100%	Hand grinding bench (pg. 10-135, ACGIH, 2001)
	Wet finishing	Option not costed	NA	NA	NA	Assume 5% penalty
Coatings preparer	Well-ventilated bag dumping stations	LEV	1,513	$7,962	100%	Bag opening station; pg. 10-19) (ACGIH, 2001)
	Well-ventilated or enclosed, automated systems for charging mixing equipment with glaze materials	LEV	1,050	$5,526	100%	Bin & hopper ventilation and unvented mixers (pg. 10-69, ACGIH, 2001)
	Eliminate compressed air	Covered by improved housekeeping	NA	NA	0%	No cost estimated
	Improve housekeeping - capital	HEPA vacuum cost	NA	$1,304	100%	Nilfisk, 15 gallon capacity

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category	Control Requirements	Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
	Improve housekeeping - labor	Additional cleaning time	NA	$961	100%	10 min/wrker/day
Coatings Operator	Substitute low silica content inputs	Option not costed	NA	NA	NA	No cost estimated
	Improved LEV for spray booths and enclosures	Increased airflow, additional CFM	250	$622	100%	Increment judged adequate for spray booth
	Spray booth maintenance	Booth repairs	NA	$240	100%	Annual incremental costs of $100 materials plus 4 hours maintenance time [a]
Paint						
Material handler	No overexposure	No control needed	NA	NA	NA	No cost estimated
Mixer operator	Ventilated bag dumping stations with bag compactor	LEV	1,513	$7,962	100%	Bag opening station; pg. 10-19) (ACGIH, 2001)
Struc clay						
Material Handler (Loader Operators	Enclosed, ventilated cab	Retrofit with cab or replace equipment	NA	$7,365	100%	Per machine
	Rigorous housekeeping- capital	HEPA Vacuum	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Rigorous housekeeping- labor	Housekeeping - labor	NA	$961	100%	10 min/wrker/day
	Improve cab maintenance and keep windows closed	Use existing cabs for dust control	NA	$788	100%	Judged to be incremental cost equal to one-half normal maintenance cost
	Cover conveyors in material handling area	Conveyor covers	NA	$901	100%	ERG estimates based on discussions with industrial ventilation consultants
	Apply LEV to conveyors in material handling area	LEV	10,000	$52,626	100%	ERG estimate of CFM requirements. See supporting write up.
Material Handler (Produc-tion Line Handlers)	Use low-silica gravel	Option not costed; substitutes available	NA	NA	NA	No cost estimated
	Misters on conveyor line	Water spray to suppress dust	NA	$2,305	100%	Assumes 100 ft. length of conveyor in this area
	Exhaust LEV and clean air island (CAI)	LEV	4,000	$21,050	100%	Assumes clean air island plus 1500 cfm.

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category	Control Requirements	Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
Material Handler (Post-Production	Misters on conveyor line	Water spray to suppress dust	NA	$2,305	100%	Assumes 100 ft. length of conveyor in this area
	Improved dust suppression	hose spraying 0.25/hr/day 250 days/yr	NA	$1,647	100%	Per facility; 2 year life. .25 hour of labor time per day per worker
	Improve housekeeping - capital	HEPA vacuum cost	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Improve housekeeping - labor	Additional cleaning time	NA	$961	100%	10 min/wrker/day
Grinding Operators Forming Line operators (Pug mill operators)	Ventilated control room and HEPA filter	LEV	200	$3,123	100%	ERG estimates based on Means and ACGIH
	Control room improvements and repairs	In-house repairs	NA	$263	100%	ERG estimate
	Enclosures with LEV for grinding equipment	LEV	17,000	$89,464	100%	One half of the total 34,000 cfm estimated by Knutson for a medium sized brick facility
	Purchase additional HEPA vacuums	HEPA vacuum	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Enhanced housekeeping with HEPA vacuums	Labor costs	NA	$961	100%	10 min/wrker/day
	Cover conveyors in grinding area	Conveyor covers	NA	$901	100%	ERG estimates based on discussions with industrial ventilation consultants
	Dust suppression for raw materials	Dust suppression activity	NA	$676	100%	Use of oil-based sawdust dust suppressant
	Tightly sealed storage units	Option not costed	NA	NA	NA	No incremental costs estimated
	Initial thorough cleaning	Cost per square foot, per facility	NA	$0	100%	ERG estimate of costs per square foot of floorspace
	Half mask respirator	Respirator	NA	$520	100%	Annual cost of respirator use
	Enclosed and ventilated pug mill equipment	LEV	6,000	$31,576	100%	Estimated by Knutson. See "Brick Manufacturing.xls"
	Initial thorough cleaning	See grinding operator	NA	NA	NA	No cost estimated
	Misters on conveyor line	Misting	NA	$2,305	100%	National Environmental Services Company (Kestner, 2003). [a]
	Improve housekeeping - capital	HEPA vacuum cost	NA	$1,304	100%	Nilfisk, 15 gallon capacity

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category - Control Requirements		Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source

Production operator	Process enclosure	Enclose conveyors and equip	NA	$901	100%	200 ft of conveyor enclosure
	Enhanced ventilation	Conveyor ventilation	700	$3,684	100%	ACGIH LEVestimate
	Rigorous housekeeping- capital	HEPA vacuum	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Rigorous housekeeping- labor	Incremental labor costs	NA	$1,693	100%	Addit. 10 minutes/day
Material handler	No additional controls required	NA	NA	NA	NA	Controls for production operator suffice
Mineral processing						
Production Worker	Enclosed ventilation equipment (conveyors)	Conveyor cover; 200'	NA	$901	33%	ERG estimates based on discussions with industrial ventilation consultants
	Conveyor ventilation	LEV	4,900	$25,787	33%	ACGIH LEV estimate, conveyor belt ventilation
	Improved maintenance on process equipment enclosures	Additional maintenance	NA	$560	33%	Incremental cost for annual maintenance
	Improved maintenance	Labor costs	NA	$571	33%	0.5 hr additional maintenance time per week per production worker
	Initial thorough cleaning	Cost per square foot, per facility	NA	$0.018	33%	ERG estimate based on docket submissions and industry contacts
	Improved area cleanup with HEPA	Equipment cost	NA	$1,304	33%	15 gal HEPA vacuum; 5 year life
	Enhanced housekeeping with HEPA vacuums	Additional labor time	NA	$997	33%	Additional 20 minutes/day
	Ventilated bag dumping stations with bag compactor	LEV	1,513	$7,962	33%	Bag opening station; (pg. 10-19, ACGIH, 2001)
Dental equipment						
	Ventilated bag dumping stations with bag compactor	LEV	1,513	$7,962	100%	Bag opening station; (pg. 10-19, ACGIH, 2001)

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category - Control Requirements		Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
Productio	Enclosed and ventilated mixing equipment	LEV	1,050	$5,526	100%	Mixer & muller hood (pg. 10-87, ACGIH, 2001)
	Increased LEV maintenance	Additional cost per operator	NA	$409	100%	Assumes 1 hour additional maintenance time per operator per month
	Workstation modifications to reduce spillage	Judged to be negligible cost	NA	NA	NA	No cost estimated
Asphalt						
Facility Operator	Enclosed and ventilated control booths	LEV	200	$3,123	100%	ERG estimate based on Means, 2003, ACGIH, 2001
	Control dust from adjacent processes	No additional cost	NA	NA	NA	No cost estimated
Front-end loader operator	Enclosed cabs	Retrofit with cab or replacement equip	NA	$7,365	100%	ERG estimate based on vendor interviews.
Mainten-ance worker	No overexposures	Additional controls not needed	NA	NA	NA	No cost estimated
Quality control worker	No overexposures	Additional controls not needed	NA	NA	NA	No cost estimated
Refractory repair						
	Portable exhaust ventilation	LEV	400	$2,105	33%	Moveable exhaust hoods example: pg. 10-93 (ACGIH, 2001)
Refractory Worker	Wet methods for chipping tools	Shop-built water feed	NA	$242	33%	ERG estimate. $200 in annual costs [a]
	LEV for chipping tools	LEV	600	$3,158	33%	Granite cutting and finishing; (pg. 10-94, ACGIH, 2001)
	Improved maintenance for spay guns	Labor costs	NA	$372	100%	Assumes 1 hour additional maintenance time per operator per month

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category - Control Requirements		Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
	Half mask respirator	Respirator	NA	$520	100%	Annual cost of respirator use
Ready mix						
Material handler	Yard dust suppression	Wetting with yard hose	NA	$5,894	100%	From concrete; 2 year life
	Enclosed cabs	Retrofit with cab or replacement equip	NA	$7,365	100%	From concrete
Batch operator	No overexposures	No controls necessary	NA	NA	NA	No cost estimated
Mainten-ance operator	Wet methods to clean equipment	Additional cleaning time	NA	$1,024	100%	From concrete. 10 mins per day, 250 days
Quality control	No overexposures	No controls necessary	NA	NA	NA	No cost estimated
Truck Driver	Wet methods for drum cleaning	Water fed chipping equipment	NA	$242	100%	ERG estimate of annual retrofit costs
	Ventilation for drum cleaning	Forced ventilation	NA	$386	100%	5 year life
	Half mask respirator	Respirator	NA	$520	100%	Annual cost of respirator use
Iron						
Sand Systems Operator	LEV, mixer & muller hood	LEV	1,050	$7,962	100%	Mixer & muller hood (pg. 10-87, ACGIH, 2001); Formerly required clean-air island, but not called out in techfeas; dropped from costs
	Conveyor enclosures	200 feet, ventilated (7 take-off points)	4,900	$26,273	100%	One take-off point at-least every 30', 7 overall.
	Bin and hopper ventilation	LEV	1,050	$5,526	100%	CFM from Solburg worksheet. (ACGIH, 2001; p. 10-69)
	Bucket elevator ventilation	LEV	1,600	$8,420	100%	Based on Knutson specs
	Screen ventilation	LEV	1,200	$6,315	100%	Based on Knutson specs
	Substitute silica-free materials	Option not costed, other	NA	NA	NA	No cost estimated

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category	Control Requirements	Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
Molder	Upgraded sand handling equipment - covered elsewhere	No cost	NA	NA	NA	No cost estimated
	Upgrade or install LEV	LEV	1,050	$5,526	100%	ERG estimates based on discussions with industrial ventilation consultants
	Rigorous housekeeping- capital	HEPA vacuum	NA	$1,304	100%	Nilfisk, 15 gallon capacity
	Rigorous housekeeping- labor	Labor costs	NA	$1,041	100%	10 min/wrker/day
	Eliminate compressed air	Included in rigorous housekeeping	NA	NA	NA	No cost estimated
Coremaker	Eliminated compressed air	Additional labor time	NA	$1,041	100%	10 min/wrker/day
	Enclosed conveyors, covered elsewhere	No cost	NA	NA	NA	No cost estimated
	Non-silica cores and core coatings	Option not costed, other controls sufficient	NA	NA	NA	No cost estimated
	Initial thorough cleaning	Costed below	NA	NA	NA	No cost estimated
Furnace operator	Control dust releases from adjacent processes - covered elsewhere		NA	NA	NA	No cost estimated
	Well-maintained furnace emission control system	Maintenance	NA	$650	100%	20 hours addtional maintenance time per year
	Operator booths or cabs	Based on clean-air island costs	2,500	$13,157	100%	Based on clean air island costs for structural clay
	Minimize dust generated by sand contamination of scrap	Option not costed	NA	NA	NA	No cost estimated
Pouring operator	Control dust from adjacent processes - covered elsewhere	No cost	NA	NA	NA	No cost estimated
	Operator booths or cabs	Based on clean-air island costs	2,500	$13,157	100%	Based on clean air island costs for structural clay
	Physical isolation of pouring area (create a pouring room)	Option not costed	NA	NA	NA	No cost estimated
	Modify ventilation system to reduce airflow from other areas into the pouring area	Option not costed	NA	NA	NA	No cost estimated

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category	Control Requirements	Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
Shakeout Operator	Improve existing ventilation system efficiency (very large castings)	Double-draft shake-out table	28,800	$151,563	100%	Based on Solberg costs for shakeout conveyor
	Improve existing ventilation system efficiency	Shakeout enclosing hood	7,040	$37,049	100%	Based on ACGIH design parameters for ventilated enclosing hood (pg. 10-23, ACGIGH, 2001); 4'x4' openings
	Partially enclose process	Enclosed, ventilated shakeout conveyor	10,000	$52,626	100%	Based on Solberg costs for shakeout conveyor
	Control emissions from associated operations - covered elsewhere	No cost	NA	NA	100%	No cost estimated
	Half mask respirator	Respirator	NA	$520	100%	Annual cost of respirator use
Knockout Operator	Installing and improving LEV	Small knockout table	1,350	$7,105	100%	Based on ACGIH design parameters for hand grinding table (pg. 10-135), ACGIH, 2001), 4'x6'
	Installing and improving LEV	Large knockout table	4,800	$25,261	100%	Based onACGIH design parameters for ventilated cut-off saw (pg. 10-134, ACGIH, 2001, 2'x3' opening)
	Installing and improving LEV	Ventilated abrasive cutoff saw	1,500	$7,894	100%	No cost estimated
	Reduce residual sand on castings	Option not costed	NA	NA	NA	No cost estimated
	Automate knockout process	Option not costed	NA	NA	NA	No cost estimated
	Half mask respirator	Respirator	NA	$520	100%	Annual cost of respirator use
Abrasive Blasting Operator	Improved maintenance for blasting cabinet	Maintenance	NA	$1,287	100%	Assumes 50% increase in maintenance costs (of up to $2,000) and purchase of new cabinets (25%) at $8,000/cabinet (Norton, 2003), or addit. interlocks at $1,800/cabinet (Heastrup, 2003).
	Half mask respirator	Respirator	NA	$520	100%	Annual cost of respirator use
	LEV for workstations	Hand grinding bench	3,750	$19,735	100%	Consultant Solberg estimate for hand grinding bench
	LEV on hand tools	LEV	200	$794	100%	Consultant Solberg estimate for hand tools

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category - Control Requirements		Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
Cleaning/ Finishing Operator	Eliminate compressed air (switch to vacuum)	HEPA vacuum plus additional time	NA	$1,474	100%	15 gal vacuum and 5 extra minutes per day
	Substitution with non-silica materials	Option not costed	NA	NA	NA	No cost estimated
	Process automation	Option not costed	NA	NA	NA	No cost estimated
	Wet methods	Option not costed	NA	NA	NA	No cost estimated
	Pre-cleaning with automated equipment	Option not costed	NA	NA	NA	No cost estimated
Material Handler	Enclosed, ventilated cab	Retrofit with cab or replace equipment	NA	$7,365	100%	Per machine
Mainten-ance Operator	Use low silica refractory	Option not costed	NA	NA	NA	No cost estimated
	LEV for chipping tools	Dust collector with HEPA vacuum	NA	$988	100%	5 year life
	Pre-wetting lining to be removed	Additional labor	NA	$3,382	100%	2 hours per week
	Maintaining moisture level in the refractory applied	Additional labor	NA	$1,691	100%	1 hour per week
	Also, use of precast refractories and automated equipment for powdered refractory materials	Option not costed	NA	NA	NA	No cost estimated
Housekeeping Worker	Initial thorough cleaning	Cost per square foot, per facility	NA	$0.02	100%	ERG estimate based on docket submissions and industry contacts
Nonferrous sand casting foundries						
Sand Systems Operator	LEV, mixer & muller hood	LEV	1,050	$7,962	100%	Mixer & muller hood (pg. 10-87, ACGIH, 2001); Formerly required clean-air island, but not called out in techfeas; dropped from costs

Knockout Operator	Installing and improving LEV	Small knockout table	1,350	$19,735	100%	Based on ACGIH design parameters for portable grinding table pg. 10-136), ACGIH, 2001), 3'x3' opening
	Installing and improving LEV	Large knockout table	4,800	$794	100%	Based on ACGIH design parameters for hand grinding table (pg. 10-135), ACGIH, 2001), 4'x6'
	Installing and improving LEV	Ventilated abrasive cutoff saw	1,500	$1,474	100%	Based onACGIH design parameters for ventilated cut-off saw (pg. 10-134, ACGIH, 2001, 2'x3' opening)
	Reduce residual sand on castings	Option not costed	NA	NA	NA	No cost estimated
	Automate knockout process	Option not costed	NA	NA	NA	No cost estimated
	Half mask respirator	Respirator	NA	$520	100%	Annual cost of respirator use

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category	Control Requirements	Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
Abrasive Blasting Operator	Improved maintenance for blasting cabinet	Maintenance	NA	$1,287	100%	Assumes 50% increase in maintenance costs (of up to $2,000) and purchase of new cabinets (25%) at $8,000/cabinet (Norton, 2003), or addit. interlocks at $1,800/cabinet (Heastrup, 2003).
	Half mask respirator	Respirator	NA	$520	100%	Annual cost of respirator use
Cleaning/ Finishing Operator	LEV for workstations	Hand grinding bench	3,750	$19,735	100%	Consultant Solberg estimate for hand grinding bench
	LEV on hand tools	LEV	200	$794	100%	Consultant Solberg estimate for hand tools
	Eliminate compressed air (switch to vacuum)	HEPA vacuum plus additional time	NA	$1,474	100%	15 gal vacuum and 5 extra minutes per day
	Substitution with non-silica materials	Option not costed	NA	NA	NA	No cost estimated
	Process automation	Option not costed	NA	NA	NA	No cost estimated
	Wet methods	Option not costed	NA	NA	NA	No cost estimated
	Pre-cleaning with automated equipment	Option not costed	NA	NA	NA	No cost estimated
Material Handler	Enclosed, ventilated cab	Retrofit with cab or replace equipment	NA	$7,365	100%	
Mainten-ance Operator	Use low silica refractory	Option not costed	NA	NA	NA	No cost estimated
	LEV for chipping tools	Dust collector with HEPA vacuum	NA	$988	100%	5 year life
	Pre-wetting lining to be removed	Additional labor	NA	$3,382	100%	2 hours per week
	Maintaining moisture level in the refractory applied	Additional labor	NA	$5,526	100%	1 hour per week
	Also, use of precast refractories and automated equipment for powdered refractory materials	Option not costed	NA	NA	NA	No cost estimated

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category - Control Requirements		Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
House-keeping Worker	Initial thorough cleaning	Cost per square foot, per facility	NA	$0.018	100%	No cost estimated
Landscaping						
Land-scaping and Grounds-keeping Workers	Wet methods	Labor costs	NA	$468	100%	Assumes 0.25 hours extra time per day for 100 days
Brick and stone-masons	Masonry saw dust control	Labor costs	NA	$749	100%	Assumes 5% productivity penalty for using wet methods for 100 days per year
Railroads						
Ballast Dumper	Spray system for right-of-way maintenance vehicles	Costs estimated per rail car.	NA	NA	NA	
Machine Operator	Spray system for right-of-way maintenance vehicles	Costs estimated per rail car.	NA	NA	NA	
Captive cut stone I						
Fabricator	Use water fed equipment	No cost, most tools have water capability	NA	NA	NA	No cost estimated
	Manage slurry-assumed included in housekeeping costs	No incremental costs	NA	NA		No cost estimated
	Rigorous housekeeping- capital	HEPA vacuum	NA	$937	100%	Nilfisk, 15 gallon capacity
	Rigorous housekeeping- labor	Labor costs	NA	$997	100%	10 min/wrker/day

Table V-A-1: Detailed Exposure Control Requirements, Analytical Assumptions and Sources for the Cost Data Applied in OSHA's Analysis of Control Costs in General Industry and Maritime (continued)

Sector/Job Category - Control Requirements		Control Description	LEV CFM	Annualized Cost (a)	Applicability [b]	Estimate Source
Captive cut stone II						
Fabricator	Masonry saw dust control	Labor costs	NA	$749	100%	Assumes 5% productivity penalty for using wet methods for 100 days per year
	Use water fed equipment	No cost, most tools have water capability	NA	NA	NA	No cost estimated
	Manage slurry-assumed included in housekeeping costs	No incremental costs	NA	NA	NA	No cost estimated

Substitute low silica content inputs	Option not costed	NA	NA	NA	NA	NA	NA	NA	NA	No cost estimated
Improved LEV for spray booths and enclosures	Increased airflow, additional CFM	250	$3,334	$231	$622	4	$156	2	$311	Increment judged adequate for spray booth
Spray booth maintenance	Booth repairs	NA	NA	$240	$240	4	$60	2	$120	Annual incremental costs of $100 materials plus 4 hours maintenance time [a]
Paint										
Material handler										
No overexposure	No control needed	NA	NA	NA	NA	NA	NA	NA	NA	No cost estimated
Mixer operator										

Table V-A-2: Unit and Annualized Costs and Model Specifications for Silica Engineering Controls Applied in OSHA's Cost Analysis for General Industry and Maritime (continued)

Sector/Job Category - Control Requirements	Control Description	LEV CFM	Unit Cost	Operating Cost	Annualized Cost (a)	Workers per	Cost per worker	Workers per Control	Cost per worker	Estimate Source
Ventilated bag dumping stations with bag compactor	LEV	1,513	$20,180	$5,597	$7,962	4	$1,991	2	$3,981	Bag opening station; pg. 10-19) (ACGIH, 2001)
Structural Clay										
Material Handler (Loader Operators)										
Enclosed, ventilated cab	Retrofit with cab or replace equipment	NA	$15,762	$5,517	$7,365	4	$1,841	2	$3,682	Per machine
Rigorous housekeeping- capital	HEPA Vacuum	NA	$3,633	$511	$1,304	4	$326	2	$652	Nilfisk, 15 gallon capacity
Rigorous housekeeping- labor	Housekeeping - labor	NA	NA	$961	$961	1	$961	1	$961	10 min/wrker/day
Improve cab maintenance and keep windows closed	Use existing cabs for dust control	NA	NA	$788	$788	4	$197	2	$394	Judged to be incremental cost equal to one-half normal maintenance cost
Cover conveyors in material handling area	Conveyor covers	NA	$4,147	$415	$901	4	$225	4	$225	ERG estimates based on discussions with industrial ventilation
Apply LEV to conveyors in material handling area	LEV	10,000	$133,375	$36,990	$52,626	4	$13,157	4	$13,157	ERG estimate of CFM requirements.
Material Handler (Production Line Handlers)										
Use low-silica gravel	Option not costed; substitutes available	NA	NA	NA	NA	NA	NA	NA	NA	No cost estimated

Table V-A-2: Unit and Annualized Costs and Model Specifications for Silica Engineering Controls Applied in OSHA's Cost Analysis for General Industry and Maritime (continued)

Sector/Job Category - Control Requirements	Control Description	LEV CFM	Unit Cost	Operating Cost	Annualized Cost (a)	Workers per	Cost per worker	Workers per Control	Cost per worker	Estimate Source
Misters on conveyor line	Water spray to suppress dust	NA	$10,609	$1,061	$2,305	4	$576	4	$576	Assumes 100 ft. length of conveyor in this area
Exhaust LEV and clean air island (CAI)	LEV	4,000	$53,350	$14,796	$21,050	4	$5,263	2	$10,525	Assumes clean air island plus 1500 cfm.
Material Handler (Post-Production										
Misters on conveyor line	Water spray to suppress dust	NA	$10,609	$1,061	$2,305	4	$576	4	$576	Assumes 100 ft. length of conveyor in this area
Improved dust suppression	hose spraying 0.25/hr/day 250 days/yr	NA	$212	$1,536	$1,647	1	$1,647	1	$1,647	Per facility; 2 year life. .25 hour of labor time per day per worker
Improve housekeeping -	HEPA vacuum cost	NA	$3,633	$511	$1,304	4	$326	2	$652	Nilfisk, 15 gallon capacity
Improve housekeeping - labor	Additional cleaning time	NA	NA	$961	$961	1	$961	1	$961	10 min/wrker/day
Grinding Operators										
Ventilated control room and HEPA filter	LEV	200	$20,328	$740	$3,123	4	$781	2	$1,561	ERG estimates based on Means and ACGIH
Control room improvements and repairs	In-house repairs	NA	$2,240	NA	$263	4	$66	2	$131	ERG estimate
Enclosures with LEV for grinding equipment	LEV	17,000	$226,737	$62,884	$89,464	4	$22,366	2	$44,732	One half of the total 34,000 cfm estimated by Knutson for a medium sized brick facility
Purchase additional HEPA vacuums	HEPA vacuum	NA	$3,633	$511	$1,304	4	$326	2	$652	Nilfisk, 15 gallon capacity

Table V-A-2: Unit and Annualized Costs and Model Specifications for Silica Engineering Controls Applied in OSHA's Cost Analysis for General Industry and Maritime (continued)

Sector/Job Category - Control Requirements	Control Description	LEV CFM	Unit Cost	Operating Cost	Annualized Cost (a)	Workers per	Cost per worker	Workers per Control	Cost per worker	Estimate Source
Enhanced housekeeping with HEPA vacuums	Labor costs	NA	NA	$961	$961	1	$961	1	$961	10 min/wrker/day
Cover conveyors in grinding area	Conveyor covers	NA	$4,147	$415	$901	4	$225	4	$225	ERG estimates based on discussions with industrial ventilation
Dust suppression for raw materials	Dust suppression activity	NA	NA	$676	$676	1	$676	1	$676	Use of oil-based sawdust dust suppressant
Tightly sealed storage units	Option not costed	NA	NA	NA	NA	NA	NA	NA	NA	No incremental costs estimated
Initial thorough cleaning	Cost per square foot, per facility	NA	$0	$0	$0	NA	NA	NA	NA	ERG estimate of costs per square foot of floorspace
Half mask respirator	Respirator	NA	NA	NA	$520	1	$520	1	$520	Annual cost of respirator use
Forming Line operators (Pug mill operators)										
Enclosed and ventilated pug mill equipment	LEV	6,000	$80,025	$22,194	$31,576	4	$7,894	2	$15,788	Estimated by Knutson.
Initial thorough cleaning	See grinding operator	NA	NA	NA	NA	NA	NA	NA	NA	No cost estimated
Misters on conveyor line	Misting	NA	$10,609	$1,061	$2,305	4	$576	4	$576	National Environmental Services Company (Kestner, 2003). [a]
Improve housekeeping -	HEPA vacuum cost	NA	$3,633	$511	$1,304	4	$326	2	$652	Nilfisk, 15 gallon capacity
Improve housekeeping - labor	Additional cleaning time	NA	NA	$961	$961	1	$961	1	$961	10 min/wrker/day
Half mask respirator	Respirator	NA	NA	NA	$520	1	$520	1	$520	Annual cost of respirator use
Forming Line Operators (Coatings Blenders)										
Initial thorough cleaning	See grinding operator	NA	NA	NA	NA	NA	NA	NA	NA	No cost estimated

Table V-A-3: Total Control Costs by Sector, Job Category, and Control for General Industry and Maritime Employers Affected by the Final Silica PEL and an Alternative Silica PEL of 100 μg/m³ (continued)

Sector/Job Category - Control Requirements	At-Risk Workers 50 μg/m³	100 μg/m³	Cost per Worker Estabs w/ >19	Estabs w/ <20	Percent Applicability	Total Cost 50 μg/m³
Eliminate compressed air (switch to vacuum)			$368	$737	100.0%	$658,192
Substitution with non-silica materials			NA	NA	NA	$0
Process automation			NA	NA	NA	$0
Wet methods			NA	NA	NA	$0
Pre-cleaning with automated equipment			NA	NA	NA	$0
Material Handler	734	286				
Enclosed, ventilated cab			$1,841	$3,682	100.0%	$1,388,980
Maintenance Operator	290	156				
Use low silica refractory			NA	NA	NA	$0
LEV for chipping tools			$247	$494	100.0%	$73,621
Pre-wetting lining to be removed			$423	$1,691	100.0%	$132,717
Maintaining moisture level in the refractory applied			$211	$845	100.0%	$66,358
Also, use of precast refractories and automated equipment for powdered refractory materials			NA	NA	NA	$0
Housekeeping Worker	134	19				
Initial thorough cleaning			NA	NA	100.0%	$181,413
Initial thorough cleaning			NA	NA	100.0%	$181,413
Nonferrous Sand Casting Foundries						
Sand Systems Operator	38	0				
LEV, mixer & muller hood			$1,991	$3,981	100.0%	$83,771
Conveyor enclosures			$6,568	$6,568	100.0%	$246,545
Bin and hopper ventilation			$1,381	$2,763	100.0%	$58,136
Bucket elevator ventilation			$2,105	$4,210	100.0%	$88,588
Screen ventilation			$1,579	$3,158	100.0%	$66,441
Substitute silica-free materials			NA	NA	NA	$0
Molder	277	62				
Upgraded sand handling equipment - covered elsewhere			NA	NA	NA	$0
Upgrade or install LEV			$1,381	$2,763	100.0%	$428,793
Rigorous housekeeping- capital			$261	$652	100.0%	$85,351
Rigorous housekeeping- labor			$1,041	$1,041	100.0%	$288,151
Eliminate compressed air			NA	NA	NA	$0
Coremaker	71	0				
Eliminated compressed air			$1,041	$1,041	100.0%	$73,699

Table V-A-3: Total Control Costs by Sector, Job Category, and Control for General Industry and Maritime Employers Affected by the Final Silica PEL and an Alternative Silica PEL of 100 μg/m³ (continued)

Sector/Job Category - Control Requirements	At-Risk Workers 50 μg/m³	At-Risk Workers 100 μg/m³	Cost per Worker Estabs w/ >19	Cost per Worker Estabs w/ <20	Percent Applicability	Total Cost 50 μg/m³
Enclosed conveyors, covered elsewhere			NA	NA	NA	$0
Non-silica cores and core			NA	NA	NA	$0
Initial thorough cleaning			NA	NA	100.0%	$37,233
Furnace operator	0	0				
No overexposures, controls not needed			NA	NA	NA	$0
Pouring operator	80	80				
No overexposures, controls not needed			NA	NA	NA	$0
Shakeout Operator	67	24				
Improve existing ventilation system efficiency (very large castings)			$37,891	$75,782	100.0%	$2,829,097
Improve existing ventilation system efficiency			$9,262	$18,524	100.0%	$691,557
Partially enclose process			$13,157	$26,313	100.0%	$982,325
Control emissions from associated operations - covered			NA	NA	100.0%	$0
Knockout Operator	29	0				
Installing and improving LEV			$1,776	$3,552	100.0%	$57,497
Installing and improving LEV			$1,776	$3,552	100.0%	$57,497
Installing and improving LEV			$1,776	$3,552	100.0%	$57,497
Reduce residual sand on castings			NA	NA	NA	$0
Automate knockout process			NA	NA	NA	$0
Abrasive Blasting Operator	77	0				
Improved maintenance for blasting cabinet			$644	$644	100.0%	$49,405
Cleaning/Finishing Operator	422	38				
LEV for workstations			$4,934	$9,867	100.0%	$2,335,436
LEV on hand tools			$397	$397	100.0%	$167,666
Eliminate compressed air (switch to vacuum)			$368	$737	100.0%	$15,853
Substitution with non-silica materials			NA	NA	NA	$0
Process automation			NA	NA	NA	$0
Wet methods			NA	NA	NA	$0
Pre-cleaning with automated equipment			NA	NA	NA	$0

Table V-C-2: Annualized Costs, by Industry, for All General Industry and Maritime Entities Affected by the Alternative Silica PEL of 100 μg/m³ (2012 dollars)

NAICS	Industry	All Establishments	Small Firms (SBA-Defined)	Very Small Entities (<20 Employees)
213112	Support Activities for Oil and Gas Operations	$7,115,229	$2,316,063	$992,599
324121	Asphalt Paving Mixture and Block Manufacturing	$308,446	$275,522	$196,586
324122	Asphalt Shingle and Coating Materials Manufacturing	$927,975	$822,141	$143,453
325510	Paint and Coating Manufacturing	$389,059	$353,220	$94,115
327110	Pottery, Ceramics, and Plumbing Fixture Manufacturing	$1,748,967	$1,500,221	$504,087
327120	Clay Building Material and Refractories Manufacturing	$2,211,135	$2,066,156	$395,702
327211	Flat Glass Manufacturing	$82,182	$64,683	$2,396
327212	Other Pressed and Blown Glass and Glassware Manufacturing	$260,593	$202,287	$52,211
327213	Glass Container Manufacturing	$238,965	$178,922	$4,361
327320	Ready-Mix Concrete Manufacturing	$16,065,211	$15,548,329	$9,531,702
327331	Concrete Block and Brick Manufacturing	$1,680,456	$1,586,809	$715,883
327332	Concrete Pipe Manufacturing	$883,824	$821,312	$300,830
327390	Other Concrete Product Manufacturing	$4,804,670	$4,645,492	$1,589,442
327991	Cut Stone and Stone Product Manufacturing	$4,162,866	$4,020,530	$2,209,362
327992	Ground or Treated Mineral and Earth Manufacturing	$908,227	$724,697	$256,292
327993	Mineral Wool Manufacturing	$301,470	$256,997	$42,505
327999	All Other Miscellaneous Nonmetallic Mineral Product Manufacturing	$1,390,804	$1,266,575	$429,486
331110	Iron and Steel Mills and Ferroalloy Manufacturing	$123,810	$52,223	$0
331210	Iron and Steel Pipe and Tube Manufacturing from Purchased Steel	$35,038	$22,416	$0
331221	Rolled Steel Shape Manufacturing	$11,253	$9,263	$0
331222	Steel Wire Drawing	$20,489	$17,904	$0
331314	Secondary Smelting and Alloying of Aluminum	$7,741	$6,456	$0
331420	Copper Rolling, Drawing, Extruding, and Alloying	$29,668	$23,315	$0
331492	Secondary Smelting, Refining, and Alloying of Nonferrous Metal (except Copper and Aluminum)	$15,580	$13,002	$0
331511	Iron Foundries	$4,103,330	$2,990,484	$224,762
331512	Steel Investment Foundries	$677,546	$445,277	$25,625
331513	Steel Foundries (except Investment)	$1,948,642	$1,313,620	$126,313
331524	Aluminum Foundries (except Die-Casting)	$595,955	$573,547	$112,065
331529	Other Nonferrous Metal Foundries (except Die-Casting)	$382,654	$346,329	$101,225
332111	Iron and Steel Forging	$34,149	$27,618	$0
332112	Nonferrous Forging	$8,774	$4,862	$0
332117	Powder Metallurgy Part Manufacturing	$11,691	$10,012	$0

Table V-C-2: Annualized Costs, by Industry, for All General Industry and Maritime Entities Affected by the Alternative Silica PEL of 100 μg/m³ (2012 dollars) (continued)

NAICS	Industry	All Establishments	Small Firms (SBA-Defined)	Very Small Entities (<20 Employees)
332119	Metal Crown, Closure, and Other Metal Stamping (except Automotive)	$76,083	$69,528	$0
332215	Metal Kitchen Cookware, Utensil, Cutlery, and Flatware (except Precious) Manufacturing	$10,693	$8,214	$0
332216	Saw Blade and Handtool Manufacturing	$40,186	$35,327	$0
332323	Ornamental and Architectural Metal Work Manufacturing	$18,063	$15,467	$6,207
332439	Other Metal Container Manufacturing	$17,063	$14,273	$0
332510	Hardware Manufacturing	$38,726	$30,652	$0
332613	Spring Manufacturing	$21,437	$19,622	$0
332618	Other Fabricated Wire Product Manufacturing	$35,424	$33,236	$0
332710	Machine Shops	$352,424	$348,006	$0
332812	Metal Coating, Engraving (except Jewelry and Silverware), and Allied Services to Manufacturers	$1,334,397	$1,293,761	$453,039
332911	Industrial Valve Manufacturing	$51,028	$38,618	$0
332912	Fluid Power Valve and Hose Fitting Manufacturing	$46,818	$29,163	$0
332913	Plumbing Fixture Fitting and Trim Manufacturing	$11,132	$7,769	$0
332919	Other Metal Valve and Pipe Fitting Manufacturing	$20,871	$15,694	$0
332991	Ball and Roller Bearing Manufacturing	$32,861	$18,490	$0
332996	Fabricated Pipe and Pipe Fitting Manufacturing	$42,869	$37,366	$0
332999	All Other Miscellaneous Fabricated Metal Product Manufacturing	$105,494	$99,947	$952
333318	Other Commercial and Service Industry Machinery Manufacturing	$76,852	$59,774	$0
333413	Industrial and Commercial Fan and Blower and Air Purification Equipment Manufacturing	$35,090	$29,802	$0
333414	Heating Equipment (except Warm Air Furnaces) Manufacturing	$25,810	$24,376	$0
333511	Industrial Mold Manufacturing	$50,722	$47,702	$0
333514	Special Die and Tool, Die Set, Jig, and Fixture	$61,855	$58,138	$0
333515	Cutting Tool and Machine Tool Accessory Manufacturing	$40,807	$40,052	$0

CHAPTER VI: ECONOMIC FEASIBILITY ANALYSIS AND REGULATORY FLEXIBILITY DETERMINATION

INTRODUCTION

In this chapter, OSHA investigates the economic impacts of its silica rule on affected employers in general industry, maritime, and construction. This impact investigation has two overriding objectives: (1) to establish whether the rule is economically feasible for all affected industries, and (2) to determine if the Agency can certify that the rule will not have a significant economic impact on a substantial number of small entities.

First, OSHA presents its approach for establishing economic feasibility and making the determination of whether the rule will have a significant economic impact on a substantial number of small entities. OSHA next applies this approach to industries with affected employers in general industry and maritime and then to industries with affected employers in construction. Finally, OSHA examines the employment effects of the silica rule. This will include a review of estimates of employment effects that commenters provided and a summary of a report prepared for the Agency by Inforum—a not-for-profit corporation (based at the University of Maryland) specializing in the design and application of macroeconomic models of the United States (and other countries)—to estimate the industry and aggregate employment effects of the silica rule.

Many commenters questioned OSHA's preliminary conclusions concerning economic feasibility, but did so for reasons that OSHA has responded to in previous chapters.

A variety of commenters raised issues concerning industries with possible silica exposure that were not covered in the Preliminary Economic and Initial Regulatory Feasibility Analysis (PEA). A full discussion of these comments and of industries added for this Final Economic and Regulatory Feasibility Analysis (FEA) appears in Chapters III (Profile of Affected Industries) and IV (Technological Feasibility Analysis) of this FEA.

Many commenters questioned why OSHA used no data after 2006 (see comments by the Brick Industry Association (BIA) (Document ID 2300, p. 5), the American Fuel & Petrochemical Manufacturers (AFPM) (Document ID 2350, p. 6), The Belden Brick Company (Document ID 3260, p. 3), Basalite Concrete Products, LLC (Document ID 2083, p. 1), SBG Consulting (Document ID 2222, p. 1), Acme Brick (Document ID 2182, p. 4), Erie Bronze & Aluminum (Document ID 1780, p. 1), Calstone (Document ID 3391, p. 2), the Chamber of Commerce (Document ID 1782, p. 1), the Mason Contractors Association of America (MCAA) (Document ID 1767, p. 2), Scango Consulting LLC d.b.a. Capitol Hardscapes (Document ID 2241, p. 3), the National Concrete Masonry Association (NCMA) (Document ID 3585, p. 2944), the American Road and Transportation Builders Association (ARTBA) (Document ID 2245, p. 4), and the Construction Industry Safety Coalition (CISC) (Document ID 4217, Attachment 1, pp. 4 and 49-52)). As discussed in Chapter III of this FEA, OSHA is using revenue data from 2012 and profit data averaged across the years 2000 through 2012. The revenue data from 2012 represent a reasonable choice because this year was neither a peak growth year nor a recession year and was the most up-to-date data available at the time this analysis was developed. The range of years for profits assures the use of profit rates from throughout the business cycle—including two recessions and two sustained growth periods.

One commenter questioned OSHA's sources and methodology for estimating revenues (Document ID 2308, Attachment 9, pp. 7-8 and 14-16). This commenter questioned the methodology used to update revenue estimates between Economic Census years. This is no longer an issue as OSHA is using 2012 Economic Census data and using 2012 as the base year for the analysis. Therefore, there is no need for a methodology to update Economic Census revenues.

OSHA also received criticism on the choice of the data source and the methodology for estimating profits of the construction industry. These include comments from the National Association of Home Builders (NAHB) and the CISC (Document ID 2296, Attachment 1, pp. 20–22; 2308, Attachment 9, pp. 7-12).

Stuart Sessions, submitting on behalf of the CISC, criticized OSHA for using the Internal Revenue Service's (IRS) *Corporation Source Book* (CSB) as the source for industry profits since those data are only presented at the four-digit NAICS level instead of the five- or six-digit NAICS level. Mr. Sessions recommended that OSHA use an alternative data source for profit data and recommended Bizminer or RMA (Document ID 4231, Attachment 1, pp.12-13). OSHA investigated these sources and determined that these data were private data sources and that their publishers would not allow the data to be made publicly available. These other sources of profit data also suffered from the disadvantage of not representing adequate and random samples of the affected industries. A further discussion on this issue appears in Chapter III of this FEA.

In the PEA, OSHA used IRS data to calculate profit rates as the ratio of net income to total receipts (with the numerator including only firms with positive net income and the denominator including firms with and without net income) by NAICS industry. In response to comments criticizing this ratio as an inappropriate method to calculate industry profitability (Document ID 2308, Attachment 9, pp. 11-12; 4209, pp. 115-116), OSHA has revised the way that estimated profits are calculated. In this FEA, OSHA calculates profit rates using the method recommended by Mr. Sessions, which is discussed more fully in Chapter III. This method includes unprofitable firms and divides the “net income” from all firms (profitable and unprofitable) by total receipts from all firms (profitable and unprofitable), resulting in somewhat lower profit rates.

Similarly, Mr. Sessions criticized OSHA for using data that he believed were at a level that was too aggregated to show economic impacts of the costs of the rule accurately (Document ID 2319, Attachment 1, p. 71). The Portland Cement Association likewise disagreed with OSHA’s presentation of costs as averages across industries. It said that “a more focused explanation of individual plant and facility costs is relevant to those industries with significant compliance responsibilities” (Document ID 2284, p. 6). OSHA’s data sources for profile data are presented in Chapter III of this FEA. In general, OSHA has disaggregated industries to the extent that the source data will allow.

The most common criticism of OSHA’s preliminary conclusions on economic feasibility was that the conclusions were based on costs that were underestimated or inaccurate (see, e.g., Document ID 2023, p. 1; 2299, p. 15; 2379, Attachment 3, pp. 2 and 10; 2388, pp. 2 and 10; 2296, Attachment 1, p. 17; 2116, Attachment 1, p. 22; and 3378, Attachment 2). For example, Wayne D’Angelo of the American Petroleum Institute (API) and the Independent Petroleum Association of America (IPAA) (API/IPAA or “the Associations”) critiqued OSHA’s feasibility analysis for the hydraulic fracturing industry, stating that OSHA had not met its obligations due to inaccurate cost data and an industry profile that, they asserted, did not “reasonably represent the typical firms in the various segments of the industry, given varying operations, exposure levels, and processes” (Document ID 2301, Attachment 1, pp. 62-63).

OSHA responded to comments on its preliminary cost estimates in Chapter V. In the aggregate, OSHA increased its cost estimate by approximately 46 percent, in part as a result of changes in cost estimates made in response to comments and in part as a result of changes in the rule.

Some commenters argued that OSHA had not adequately considered the possibility that smaller establishments might have higher costs or that the costs have a greater impact on small businesses (Document ID 4231, Attachment 1, p. 11; 2379, Attachment 2, p. 7; 3582, Tr. 2107 – 2109; 2203, p. 1; 2351, p. 8; 3433, p. 9; 3580, Tr. 1398). As discussed in Chapter V, OSHA has made a number of changes to the costs analysis to reflect higher costs for small establishments.

LEGAL INTERPETATIONS AND ANALYTIC APPROACH

Economic Feasibility

Section 6(b)(5) of the OSH Act states:

> The Secretary . . . shall set the standard which most adequately assures, *to the extent feasible*, on the basis of the best available evidence, that no employee will suffer material impairment of health or functional capacity . . . .[1] [Emphasis added.]

OSHA has interpreted the phrase "to the extent feasible" to encompass economic feasibility and was supported in this view by the U.S. Court of Appeals for the D.C. Circuit in its 1974 asbestos decision.[2] The court noted that "Congress does not appear to have intended to protect employees by putting their employers out of business,"[3] and then proceeded to define the concept of economic feasibility and to indicate its boundaries:

> Standards may be economically feasible even though, from the standpoint of employers, they are financially burdensome and affect profit margins adversely. Nor does the concept of economic feasibility necessarily guarantee the continued existence of individual employers. It would appear to be consistent with the purposes of the Act to envisage the economic demise of an employer who has lagged behind the rest of the industry in protecting the health and safety of employees and is consequently financially unable to comply with new standards as quickly as other employers. As the effect becomes more widespread within an industry, the problem of economic feasibility becomes more pressing.[4]

Thus, according to the court, OSHA standards would satisfy the economic feasibility criterion even if they imposed significant costs on regulated industries and forced some marginal firms out of business, so long as they did not cause massive economic dislocations within a particular industry or imperil the existence of the industry.[5]

The implication, for analysis of economic impacts, is that OSHA is required to determine whether its standards will eliminate or alter the competitive structure of an industry, not to determine whether any individual plants will close, or whether some marginal plants may close earlier than they otherwise might have. OSHA thus has an obligation to examine industries, and to consider industry definitions carefully. However, OSHA does not have an obligation to conduct a facility-by-facility analysis of the thousands of facilities in the dozens of industries covered by a major standard.

In practice, the economic burden of an OSHA standard on an industry—and whether the standard is economically feasible for that industry—depends on the magnitude of compliance costs incurred by establishments in that industry and the extent to which they are able to pass those costs on to their customers. That, in turn, depends, to a significant degree, on the price elasticity of demand for the products sold by establishments in that industry.

The price elasticity of demand refers to the relationship between the price charged for a product and the demand for that product: the more elastic the relationship, the less an establishment's compliance costs can be passed through to customers in the form of a price increase and the more it has to absorb compliance costs in the form of reduced profits. When demand is inelastic, establishments can recover most of the variable costs of compliance (i.e., costs that are highly correlated with the amount of output) by raising the prices they charge; under this scenario, if costs are variable rather than fixed, profit rates are largely unchanged and the industry remains largely unaffected. Any impacts are primarily on those customers using the relevant product. On the other hand, when demand is elastic, establishments cannot recover all compliance costs simply by passing the cost increase through in the form of a price increase; instead, they must absorb some of the increase from their profits. Commonly, this will mean reductions both in the quantity of goods and services produced and in total profits, though the profit rate may remain unchanged. Other things being equal, higher fixed costs mean that the optimal scale of the typical establishment will be larger than it would be if fixed costs were lower. This in turn means that, where there are higher fixed costs, there will be fewer plants for the same level of production. Whether an increase in fixed costs results in closures of existing plants depends on several factors. If demand regularly increases (such as due to economic growth) or the industry regularly experiences plant closures, the optimal scale may be arrived at by reduced entry rather than premature closures. If plants are not part of a simple homogeneous market, it may not be possible to shift the scale of production. For example, if a plant provides foundry products to others in the same city, it may not be able to readily expand its scale of production.

In general, "[w]hen an industry is subjected to a higher cost, it does not simply swallow it; it raises its price and reduces its output, and in this way shifts a part of the cost to its consumers and a part to its suppliers." *Am. Dental Ass'n v. Sec'y of Labor*, 984 F.2d 823, 829 (7th Cir. 1993). This summary by the court is in accord with microeconomic theory. In the long run, an industry can remain viable only if its profits are adequate to provide a return on investment that ensures that investment in the industry will continue. As technology and costs change, the long-run demand for some products naturally increases and the long-run demand for other products naturally decreases. In the face of additional compliance costs (or other external costs), firms that otherwise have a profitable line of business may have to increase prices to stay viable. Increases in prices typically result in reduced quantity demanded, but rarely eliminate all demand for the product. Whether this decrease in the total production of goods and services results in smaller output for each establishment within the industry; the closure of some plants within the industry; a reduced number of new establishments entering the industry; or a combination of the three, is dependent on the cost and profit structure of individual firms within the industry.

If demand is perfectly inelastic (i.e., the price elasticity of demand is zero), then the impact of compliance costs that are one percent of revenues for each firm in the industry would result in a one percent increase in the price of the product, with the quantity demanded constant. (This outcome would hold in the long run, regardless of type of costs, but in the short run would only hold with certainty if compliance costs are strictly variable.) Such a scenario represents an extreme case, but might be observed in situations in which there were few if any substitutes for the product in question, or if the products of the affected sector account for only a very small portion of the revenue or income of its customers. Under this scenario, both profits and output of the industry would be unaffected, but customers would be worse off.

If the demand is perfectly elastic (i.e., the price elasticity of demand is infinitely large), then no increase in price is possible and before-tax profits would be reduced by an amount equal to the costs of compliance (net of any cost savings—such as reduced workers' compensation insurance premiums—resulting from the standard) if the industry attempted to maintain production at the same level. Under this scenario, if the costs of compliance are such a large percentage of profits that some or all plants in the industry could no longer operate with hope of an adequate return on investment, then some or all of the firms would close. Similarly, if compliance costs are fixed, such costs may result in premature closures or reduced entry into the market in some circumstances.

A commonly discussed intermediate case would be a price elasticity of demand of one.[6] In this scenario, if the costs of compliance amount to one percent of revenues, then

[6] Here and throughout this chapter, the price elasticity of demand is reported as an absolute value.

production would decline by one percent and prices would rise by one percent. (As before, this outcome would hold in the long run, regardless of type of costs, but in the short run would hold with certainty only if compliance costs are variable.) Under this scenario, and if marginal costs of the regulation fall proportionally with output, then industry revenues would remain the same, with somewhat lower production, but with similar profit rates. Customers would, however, receive less of the product for their (same) expenditures, and firms would have lower total profits; this, as the court described in *Am. Dental Ass'n v. Sec'y of Labor*, is the more typical case.

A decline in output as a result of an increase in price may occur in a variety of ways: individual establishments could each reduce their levels of production; some marginal plants could close; or, in the case of an industry with high turnover of establishments, new entry may be delayed until demand equals supply. In many cases a decrease in overall output for an industry will be a combination of all three kinds of reductions. Which possibility is most likely depends on the rate of turnover in the industry and on the form that the costs of the regulation take.

When turnover in an industry is high, or an industry is expanding rapidly, then the key issue is the long run costs as determined by the cost of entry into the industry. For example, if there is annual turnover in an industry of ten percent per year, and a price elasticity of one, then a single year without new entry would result in a price rise of ten percent. Such a rise would be more than enough to compensate existing employers for a cost increase of one percent of revenues.

If the costs are variable costs (i.e., costs that vary with the level of production at a facility), then economic theory suggests that any reductions in output will take the form of reductions in output at each affected facility, with few, if any, plant closures. If the costs of a regulation primarily take the form of fixed costs (i.e., costs that do not vary with the level of production at a facility), and assuming perfect competition, then reductions in overall output can only take the form of plant closures or delays in new entry. Most of the costs of this regulation, as estimated in Chapter V of this FEA, are variable costs. Almost all of the major costs of program elements, such as medical surveillance and training, will vary in proportion to the number of employees (which is a rough proxy for the amount of production). Exposure monitoring costs will vary with the number of employees, but do have some economies of scale to the extent that a larger firm need only conduct representative sampling rather than sample every employee. The costs of engineering controls in construction also vary by level of production because almost all necessary equipment can readily be rented and the productivity costs of using some of these controls vary proportionally to the level of production. Finally, the costs of operating engineering controls in general industry (the majority of the annualized costs of engineering controls are in general industry) vary by the number of hours the establishment works, and thus vary by the level of production and are not fixed costs in the strictest sense.

This leaves two kinds of costs that are, in some sense, fixed costs—capital costs of engineering controls in general industry and certain initial costs that new entrants to the industry will not have to bear.

Fixed costs in the form of capital costs of engineering controls in general industry and maritime due to this standard are relatively small as compared to the total costs, representing less than 21 percent of total annualized costs and approximately $1,019 per year per affected establishment in general industry.

There are some initial fixed costs in the sense that they might only be borne by firms in the industry today. For example, costs for general training not currently required and initial costs of medical surveillance may not be borne by establishments new to the industry to the extent they can hire from a workforce that may have already had this training and/or initial medical surveillance. An initial thorough facility cleaning is not a cost a new establishment would need to bear. These costs will disappear after the initial year of the standard and thus would be difficult to pass on. These costs, however, represent less than two percent of total costs and less than $58 per affected establishment. These initial fixed costs that may be borne by firms in the affected industries today, together with capital costs, gives a total fixed cost of approximately 22 percent of total annual costs.

Because the remaining three-fourths of the total annual costs are variable, OSHA expects it is somewhat more likely that reductions in industry output resulting from the increase in costs associated with this rule will be met by reductions in output at each affected facility rather than as a result of plant closures or reduced new entry. However, closures of some marginal plants or poorly performing facilities are always possible.

To determine whether a rule is economically feasible, OSHA begins with two screening tests to consider minimum threshold effects of the rule under two extreme cases: (1) all costs are passed through to customers in the form of higher prices (consistent with a price elasticity of demand of zero), and (2) all costs are absorbed by the firm in the form of reduced profits (consistent with an infinite price elasticity of demand).

In the former case, the immediate impact of the rule would be observed in increased industry revenues. While there is no hard and fast rule, in the absence of evidence to the contrary, OSHA generally considers a standard to be economically feasible for an industry when the annualized costs of compliance are less than a threshold level of one percent of annual revenues. Retrospective studies of previous OSHA regulations have shown that potential impacts of such a small magnitude are unlikely to eliminate an industry or significantly alter its competitive structure,[7] particularly since most industries have at least some ability to raise prices to reflect increased costs and, as shown in the FEA, normal price variations for products typically exceed three percent a year.[8] Of course, OSHA recognizes that even when costs are within this range, there could be unusual circumstances requiring further analysis.

In the latter case, the immediate impact of the rule would be observed in reduced industry profits. OSHA uses the ratio of annualized costs to annual profits as a second check on economic feasibility. Again, while there is no hard and fast rule, in the absence of evidence to the contrary, OSHA generally considers a standard to be economically feasible for an industry when the annualized costs of compliance are less than a threshold level of ten percent of annual profits. In the context of economic feasibility, the Agency believes this threshold level to be fairly modest, given that normal year-to-year variations in profit rates in an industry can exceed 40 percent or more.[9] OSHA's choice of a threshold level of ten percent of annual profits is low enough that even if, in a hypothetical worst case, all compliance costs were upfront costs, then upfront costs would still equal 88.5 percent of profits using a three percent discount rate (See section Normal Year-to-Year Variations in Prices and Profit Rates below) and thus would be affordable from profits alone without the need for an employer to resort to credit markets. If the threshold level were *first-year* costs of ten percent of annual profits, firms could even more easily expect to cover first-year costs at the threshold level out of current profits without having to access capital (including credit markets) markets and otherwise being threatened with short-term insolvency.

In general, it is usually the case that firms would be able to pass on some or all of the costs of the rule to their customers in the form of higher prices. OSHA therefore will tend to give much more weight to the ratio of industry costs to industry revenues than to the ratio of industry costs to industry profits. However, if costs exceed either the threshold percentage of revenue or the threshold percentage of profits for an industry, or if there is other evidence of a threat to the viability of an industry because of the standard, OSHA will examine the effect of the rule on that industry more closely. Such an examination

---

[7] See OSHA's web page, http://www.osha.gov/dea/lookback.html#Completed, for a link to all completed OSHA lookback reviews.

[8] See, for example, Table VI-3 and the accompanying text presented later in this chapter.

[9] See, for example, Table VI-5 and the accompanying text presented later in this chapter.

would include market factors specific to the industry, such as normal variations in prices and profits, international trade and foreign competition, and any special circumstances, such as close domestic substitutes of equal cost, which might make the industry particularly vulnerable to a regulatory cost increase.

The preceding discussion focused on the economic viability of the affected industries in their entirety. However, even if OSHA found that a standard did not threaten the survival of affected industries, there is still the question of whether the industries' competitive structure would be significantly altered. For example, if the annualized costs of an OSHA standard were equal to ten percent of an industry's annual profits, and the price elasticity of demand for the products in that industry were equal to one, then OSHA would not expect the industry to go out of business. However, if the increase in costs were such that most or all small firms in that industry would have to close, it could reasonably be concluded that the competitive structure of the industry had been altered. For this reason, OSHA also examines the differential costs by size of establishment.

Public Comments on OSHA Approach to Economic Feasibility

Some commenters were concerned that reductions of profits of less than ten percent could still represent major losses to an employer. For example, one commenter said:

> The proposed rule states that in no cases will the amount of revenue or profits exceed 8.8% noting that this number is easily passed to consumers in the form of increased product and service costs. For a rule as specific and slight as one affecting only silica dust inhalation, a reduction in profits by 8.8% should give the government pause (Document ID 2189, p. 1).

Another commenter expressed similar concerns about a reduction in profits of 4.8 percent (Document ID 1882, Attachment 1, p. 2). OSHA is not dismissive of losses in profits of less than ten percent. However, such losses need to be weighed against the OSH Act's objectives of occupational safety and health. For purposes of assessing economic feasibility, OSHA needs to be concerned with major dislocating effects on entire industries, which will not be the result of relatively small changes in profits. Further, as will be discussed below, these costs can likely be passed on to consumers.

API/IPAA, while disagreeing with OSHA's cost estimates, acknowledged that OSHA's use of the rules of thumb of ten percent of profits or one percent of revenues has been upheld in court (Document ID 2301, Attachment 1, pp. 62-63).

Some commenters were also concerned that OSHA's screening analysis methodology did not give adequate consideration to upfront costs (Document ID 2379, Attachment 3, p.

39; 2119, Attachment 3, p. 22). As will be discussed below, OSHA's choice of a threshold level of ten percent of annual profits is low enough that even if, in a hypothetical worst case, all compliance costs were upfront costs, then upfront costs would still equal 88.5 percent of profits and thus would be affordable from profits alone without needing to resort to credit markets. (If the cost exceeds 100 percent of profits then the company would have to borrow to pay the balance. Otherwise the firm will not have to borrow but could finance the cost internally.)

While not specifically addressed to the issue of the screening analysis, Mr. Sessions provided some estimates of how various percentage cost increases might interact with demand and supply elasticities to produce estimates of declines in total industry output. His estimates show that the decline in total revenues (and, in this situation, total production) associated with increased costs of one percent of revenues ranges from zero to 0.83 percent of total production (the range depending on the elasticities of supply and demand, with the highest impact on total revenues associated with a very unlikely price elasticity of ten) (Document ID 4231, Attachment 1, p. 31). Even the largest decline in revenues would result in only a 0.83 percent decline in revenues, which would not represent a major dislocation of any affected industry.[10] While OSHA does not necessarily endorse this particular approach to calculating changes in total revenue for given percentage change in costs, the calculation confirms OSHA's general view that increases of less than one percent of costs do not render a standard economically infeasible.

After reviewing these comments, OSHA has decided to retain its screening test of ten percent of profits and one percent of revenues as levels below which significant dislocation of an industry is extremely unlikely.

Regulatory Flexibility Screening Analysis

The Regulatory Flexibility Act (RFA), Pub. L. No. 96-354, 94 Stat. 1164 (codified at 5 U.S.C. 601), requires Federal agencies to consider the economic impact that a rulemaking will have on small entities. The RFA states that whenever an agency promulgates a final rule under section 553 of this title, after being required by that section or any other law to publish a general notice of proposed rulemaking the agency shall prepare a final regulatory flexibility analysis (FRFA). 5 U.S.C. 604(a). Pursuant to section 605(b), in lieu of an FRFA, the head of an agency may certify that the final rule will not have a significant economic impact on a substantial number of small entities. A certification

[10] Mr. Sessions's analysis assumes that profits will remain sufficient to assure the viability of the remaining firms in the industry. This is a common assumption in analyzing long run economic effects of a cost change.

must be supported by a factual basis. If the head of an agency makes a certification, the agency shall publish such certification in the Federal Register at the time of publication of the final rule. 5 U.S.C. 605(b). Thus, if OSHA cannot issue the required certification, it must prepare a FRFA.

OSHA makes its determination about whether it can issue the required certification by applying screening tests to consider minimum threshold effects of the rule on small entities. These screening tests are similar in concept to those OSHA described above to identify minimum threshold effects for the purposes of demonstrating economic feasibility and are discussed below.

There are, however, two differences. First, for each affected industry, the screening tests are applied, not to all establishments, but to small entities (defined as "small business concerns" by the Small Business Administration (SBA)) and also to very small entities (as defined by OSHA as small businesses with fewer than 20 employees). Second, although OSHA's regulatory flexibility screening test for revenues also uses a minimum threshold level of annualized costs equal to one percent of annual revenues, OSHA has established a minimum threshold level of annualized costs equal to five percent of annual profits for the average small entity or very small entity (rather than the ten percent threshold applicable for general economic feasibility screening). The Agency has chosen a lower minimum threshold level for the profitability screening analysis and has applied its screening tests to both small entities and very small entities in order to ensure that certification will be made, and an FRFA will not be prepared, only if OSHA can be highly confident that a final rule will not have a significant economic impact on a substantial number of small entities or very small entities in any affected industry.

OSHA has prepared separate regulatory flexibility screening tests for general industry, maritime, and construction.

IMPACTS IN GENERAL INDUSTRY AND MARITIME

In this section, OSHA will determine whether (1) the rule is economically feasible for all affected industries in general industry and maritime, and (2) the Agency can certify that the rule will not have a significant economic impact on a substantial number of small entities in general industry and maritime. OSHA concludes that the rule is economically feasible, but the Agency is unable to certify that it will not have a significant economic impact on a substantial number of small entities.

Economic Feasibility Screening Analysis: All Establishments

Earlier chapters of this FEA identified the general industry and maritime sectors potentially affected by the final rule; presented summary profile data for affected industries, including the number of affected entities and establishments, the number of at-risk workers, and the average revenue for affected entities and establishments; and developed estimates, by affected industry, of the costs of the rule. The economic impacts of the final rule on general industry and maritime are driven, in part, by the costs of additional dust control measures, respirators, and silica program activities needed to comply with the rule.

To determine whether the final rule's projected costs of compliance would threaten the economic viability of affected industries; OSHA first compared, for each affected industry, annualized compliance costs to annual revenues and profits per (average) affected establishment. The results for all affected establishments in all affected industries in general industry and maritime are presented in Table VI-1, using annualized costs per establishment for the PEL of 50 $\mu g/m^3$. Shown in the table for each affected industry are total annualized costs, the total number of affected establishments, annualized costs per affected establishment, annual revenues per establishment, the profit rate, annual profits per establishment, annualized compliance costs as a percentage of annual revenues, and annualized compliance costs as a percentage of annual profits.

The annualized costs per affected establishment for each affected industry were calculated by distributing the industry-level (incremental) annualized compliance costs among all affected establishments in the industry, where annualized compliance costs reflect a three percent discount rate.[11] Dividing the total compliance cost from Table VI-1 by the total number of affected establishments gives the annualized cost for the average establishment, $4,939 (370,810,530 / 75,074) in 2012 dollars.[12] It is clear from Table VI-1 that the estimates of the annualized costs per affected establishment in general industry and maritime vary widely from industry to industry. These estimates range from $220,558 for NAICS 213112 (Support Activities for Oil and Gas Operations) and $57,403 for NAICS 331511 (Iron Foundries) to $377 for NAICS 324121 (Asphalt Paving Mixture and Block Manufacturing) and $304 for NAICS 621210 (Offices of Dentists).

[11] Tables VI-A-1 and VI-A-2 in Appendix VI-A show per-establishment annualized costs and ratios of annualized cost to annual revenue and annualized costs to annual profit using discount rates of seven percent and zero percent, respectively, to annualize costs.

[12] This estimate excludes NAICS 482110 (Railroad transportation) because the number of railroad establishments was not provided in the Census data.

Additionally, OSHA estimated before-tax profit rates using corporate balance sheet data from the IRS's *Corporation Source Book* (IRS, 2012). For each of the years 2000 through 2012, OSHA calculated profit rates as the ratio of total receipts for all firms (profitable and unprofitable) to net income of all firms (profitable and unprofitable) by NAICS group and averaged profit rates across the 13-year (2000 through 2012) period.[13] Since some data provided by the IRS were not available at disaggregated levels for all industries and profit rates, data at more highly aggregated levels were used as proxy for such industries, that is, where data were not available for each six-digit NAICS code, corresponding four- and five-digit NAICS codes were used as appropriate.

As previously discussed, OSHA has established a minimum threshold level of annualized costs equal to one percent of annual revenues—and, secondarily, annualized costs equal to ten percent of annual profits—below which the Agency has concluded that costs are unlikely to threaten the economic viability of an affected industry. Table VI-1 shows that there are eight industries in which the annualized costs of the rule exceed ten percent of annual profits and none where annualized costs exceed one percent of annual revenues. NAICS 213112 (Support Activities for Oil and Gas Operations), has the highest cost impact as a percentage of revenues, of 0.56 percent. NAICS 327110 (Clay Building Materials and Refractories Manufacturing) has the highest cost impact as a percentage of profits, of 31.08 percent. For all affected establishments in general industry and maritime, the estimated annualized cost of the rule is, on average, equal to 0.06 percent of annual revenue and 2.43 percent of annual profits.

The industries with costs that exceed ten percent of profits are: NAICS 327120 - Clay Building Material and Refractories Manufacturing, 31 percent; NAICS 327110 - Pottery, Ceramics, and Plumbing Fixture Manufacturing, 31 percent; NAICS 327991 - Cut Stone and Stone Product Manufacturing, 24 percent; NAICS 327390 - Other Concrete Product Manufacturing, 17 percent; NAICS 327999 - All Other Miscellaneous Nonmetallic Mineral Product Manufacturing, 16 percent; NAICS 327332 – Concrete Pipe Manufacturing, 13 percent; NAICS 327331 Concrete Block and Brick Manufacturing, 13 percent; and NAICS 327320 Ready-Mix Concrete Manufacturing, 10 percent.

Based on the analysis that follows in the discussions of year-to-year variations and of international trade, OSHA finds that the final rule is economically feasible in these industries.

---

[13] During the recession some industries had a negative "net income." The NAICS code 3361, Motor Vehicle Manufacturing, had a large negative "net income" for 2008 and 2009, pulling the average profit rate down to -0.05 percent, resulting in a negative cost to profit ratio.

Table VI-1 Screening Analysis for Establishments in General Industry and Maritime Affected by OSHA's Silica Standard

NAICS	Industry	Total Compliance Costs	Total Affected Establishments	Annual Cost per Affected Establishment	Annual Revenues per Establishment ($1000)	Percent Profit	Annual Profit per Establishment	Cost to Revenue	Cost to Profit

Normal Year-to-Year Variations in Prices and Profit Rates

The United States has a dynamic and constantly changing economy in which an annual percentage changes in industry revenues or prices of one percent or more is common. Examples of year-to-year changes in an industry that could cause such variations in revenues or prices include increases in fuel, material, real estate, or other costs; tax increases; and shifts in demand.

Methodology

To demonstrate the normal year-to-year variation in prices for all the manufacturers in general industry and maritime affected by the rule, OSHA developed Table VI-2 and Table VI-3, which show, respectively, year-to-year producer price indices and year-to-year percentage changes in producer prices, by industry, for the years 2004 through 2014. For the combined affected manufacturing industries in general industry and maritime over the 11-year period, Table VI-3 shows an average change in producer prices of 2.7 percent a year. For the industries in general industry and maritime with the largest estimated potential annual cost impact as a percentage of revenue—NAICS 213112 – Support Activities for Oil and Gas Operations, 0.56 percent; and NAICS 327991 - Cut Stone and Stone Product Manufacturing, 0.42 percent—the average annual changes in producer prices in these industries over the 12-year period were, respectively, 3.8 percent, and 0.5 percent.

Based on these data, it is clear that the potential cost impacts of the rule in general industry and maritime are all well within normal year-to-year variations in prices in those industries. The maximum cost impact of the rule as a percentage of revenue in any affected industry is 0.56 percent, while the average annual change in producer prices for affected industries was 2.7 percent for the period 2004 through 2014 (changed from 1998 to 2009 in the PEA). Furthermore, even a casual examination of Table VI-3 reveals that annual changes in producer prices in excess of five or even ten percent are possible without threatening an industry's economic viability. Thus, OSHA concludes that the potential price impacts of the rule would not threaten the economic viability of any industries in general industry and maritime.

Changes in profit rates are also subject to the dynamics of the U.S. economy. A recession, a downturn in a particular industry, foreign competition, or the increased competitiveness of producers of close domestic substitutes are all easily capable of causing a decline in profit rates in an industry of well in excess of ten percent in one year or for several years in succession.

To demonstrate the normal year-to-year variation in profit rates for all the manufacturers in general industry and maritime affected by the rule, OSHA developed Table VI-4 and Table VI-5, which show, respectively, year-to-year profit rates and year-to-year percentage changes in profit rates, by industry, for the years 2000 through 2012. For the combined affected manufacturing industries in general industry and maritime over the thirteen-year period, OSHA calculated an average change in profit rates of 138.5 percent a year (average for all industries calculated from the per-NAICS averages shown in Table VI-5). For the industries in general industry and maritime with the largest estimated potential annual cost impacts as a percentage of profit— NAICS 327120 - Clay Building Material and Refractories Manufacturing, 31 percent; NAICS 327110 - Pottery, Ceramics, and Plumbing Fixture Manufacturing, 31 percent; NAICS 327991 - Cut Stone and Stone Product Manufacturing, 24 percent—the average annual percentage changes in profit rates in these industries over the 13-year period were, respectively, 951 percent, 951 percent, and 113 percent.

One complicating factor is that the annualized costs of the rule, if absorbed in lost profits, would involve not just a temporary loss of profits but a longer term negative effect on profits relative to the baseline. To address this issue, the Agency compared the effect of a longer term reduction in profits to much larger reductions in profits but over shorter periods. Assuming a three-percent discount rate, the Agency determined a ten percent decline in profit rates relative to the original baseline, which remains constant at that lower level over a ten-year period, would be equivalent to:[14]

- an 88.5 percent decline in profit rates for one year;
- a 44.5 percent decline in profit rates that remains constant at the lower level for two years; or
- a 30 percent decline in profit rates that remains constant at the lower level for three years.[15]

[14] Note that the reduction in profits rates over time, as a result of the rule, is being measured here relative to the baseline. If the reduction in profit rates were made relative to the previous year, as is done in Table VI-5 below, then there would be only a one-time reduction in the profit rate in year one as a result of the rule, after which the profit rate would reach a new (lower) level but would not change from year to year.

[15] Assuming a seven-percent discount rate, a ten-percent decline in profit rates over the ten-year annualization period would be equivalent to: a 75-percent decline in profit rates for one year; a 39-percent decline in profit rates that remains constant at the lower level for two years; or a 27-percent decline in profit rates that remains constant at the lower level for three years.

An examination of Table VI-5, for the thirteen year period from 2000 to 2012, clearly shows that short-run changes in average industry profit rates of the above magnitudes have occurred on numerous occasions in general industry and maritime, without threatening the economic viability of the affected industries. For this reason, OSHA is confident that potential profit rate impacts of ten percent or less as a result of the rule would not threaten the economic viability of the affected industries in general industry and maritime.

A longer-term loss of profits in excess of ten percent a year could be more problematic for some affected industries and might conceivably, under sufficiently adverse circumstances, threaten an industry's economic viability. In OSHA's view, however, affected industries would generally be able to pass on most or all of the costs of the rule in the form of higher prices rather than bear the costs of the rule in reduced profits. In other words, the demand for the goods and services produced by affected industries in general industry and maritime do not appear to be perfectly elastic or close to it. While there are substitutes for these products, there are no perfect substitutes that would lead the price elasticity to be extremely high. As a result, the demand for quantities of brick and structural clay, vitreous china, ceramic wall and floor tile, other structural clay products (such as clay sewer pipe), and the various other products manufactured by affected industries would not significantly contract in response to a 0.48 percent (or lower) price increase for these products. It is of course possible that such price changes will result in some reduction in output, and the reduction in output might be met through the closure of a small percentage of the plants in the industry. However, the only realistic circumstance under which an entire industry would be significantly affected by small price increases would be the availability in the market of a very close or perfect substitute product not subject to OSHA regulation. The classic example, in theory, would be foreign competition. In the following discussion, OSHA examines the threat of foreign competition for affected U.S. establishments in general industry and maritime, and concludes that it is unlikely to threaten the viability of any affected industry.

Public Comments on Year-to-Year Variations in Prices and Profit Rates

The American Chemistry Council (ACC) stated, with respect to a similar analysis in the PEA, that short-term volatility within an industry sector is of little value in projecting what will happen when a new regulation resets the baseline for profits and revenue because OSHA is comparing short-term changes to long-term changes (Document ID 2307, Attachment 2, p. 196). Another commenter made the similar point that year-to-year fluctuations cannot be compared to long-term changes (Document ID 2308, Attachment 9, p. 7).

OSHA first examines the issue of changes in prices over time. Such changes, on the whole, represent pass through of changes in costs, since profits are not continually rising. These changes in costs are not "fluctuations" with upward and downward shifts in prices.

For almost all industries these changes in costs are continuing upward shifts that average each year much larger changes than the maximum price change any industry will need to incur in order to comply with the silica rule.

For variations in profits, these are indeed fluctuations and profits do indeed both rise and fall. However, if, as the commenters argue only long-term average profits matter, then we could reach the very counterintuitive result that there should be no excess plant closures during recessions. This is not the case because long-term profits are, in fact, nothing more than a prediction and the present value of long term profits will be different at the beginning than at the end of a recession. Recognizing these timing effects is why OSHA examined the annualized value of losses in profits associated with the recession beginning 2008 and compared it to the annualized value of the loss in profits as result of costs of this standard. While temporary and permanent losses are different, the use of discounting enables us to compare short- and long-term losses.

International Trade Effects

The magnitude and strength of foreign competition is an important factor in determining the ability of firms in the U.S. to pass on (part or all of) the costs of the rule in the form of higher prices for their products. If firms are unable to do so, they must absorb the costs of the rule out of profits, possibly resulting in the business failure of individual firms or even, if the cost impacts are sufficiently large and pervasive, causing significant dislocations within an affected industry.

Below, OSHA examines the likelihood of significant dislocations. The discussion will begin with some theoretical background and then proceed with empirical evidence and estimated impacts. Throughout, the Agency draws on ERG (2007c) (Document ID 1710), which was prepared specifically to help analyze the international trade impacts of OSHA's silica rule. OSHA concludes, based on the following analysis, that the rule will not result in significant dislocations due to foreign competition within any affected industry.

Theoretical Background

Despite the long history of international economics, there are relatively few tools that are directly applicable to analyzing the projected impacts of a domestic regulation on the international trade of affected industries. Ideally, such impacts would be evaluated using trade elasticities: econometric estimates of the percentage change in a country's imports and exports in response to a given percentage change in price caused by the regulation. Academic international trade economists tend to focus their attention on patterns of trade and factor flows, trade policy, and the implications of exchange rate regimes.[16] The vast amount of theoretical and econometric work performed on these topics tends to be at too high a level of aggregation to be of use in the narrow context of projecting the potential trade impacts on a specific industry.

A second reason trade elasticity estimates tend to be relatively rare in the literature might be attributable to the difficulty of estimating them. Data—including prices and quantities of imports, exports, domestic and foreign consumption and supply, and the myriad of other factors that affect consumption of these products—are often not available at a useful level of detail. For example, data tend to be either too aggregated to be informative or so granular that generating consistent indices of products of interest over several years is costly and difficult. In addition, because trade is rarely bilateral, the elasticity of the change in Japanese demand for U.S. products, for example, will not only depend on the

[16] See, for example, Deardorff (1984), Document ID 0617, and Goldstein and Kahn (1985), Document ID 0709.

U.S. price change, but also on the supply of the same product from Japan's other trading partners.

Because of the difficulty in obtaining useful, reliable trade elasticities, economists sometimes use "synthetic" elasticities to analyze trade impacts. These elasticities are not econometrically estimated, but instead are calculated from available data using relationships derived from the theoretical literature. Thus, a synthetic trade elasticity might be calculated as a function of the domestic price elasticity, transportation costs, and trade shares (Goldstein and Kahn, 1985, Document ID 0709). ERG examined two approaches to estimating trade elasticities using a synthetic approach: (1) one country's traded product is a *perfect* substitute (a good that can be used in the exact same way as the good it replaces) for its trade partner's product, and (2) one country's traded product is an *imperfect* substitute (a product someone can use as a substitute but it is not considered identical) for its trade partner's product.

When traded products are perfect substitutes, there are no models with distinct import demand or export supply relationships. Conceptually, trade is a residual in the perfect substitutes case; that is, a country's imports result from the excess demand for the domestic product. Similarly, exports are a residual resulting from excess supply remaining from domestic consumption. Thus, in the perfect substitutes model, trade can be estimated as the difference between domestic demand and domestic supply.

To simplify the model, the world can be divided into trade between the U.S. and the rest of the world (ROW). The relationship between the ROW price and the U.S. price is a function of the monetary exchange rate and transportation costs. The elasticity of U.S. imports with respect to a change in the U.S. domestic price is subject to key parameters such as transportation costs and relies on the assumption that what the U.S. imports is equal to what the ROW exports.

While this "perfect substitutes" approach to modeling trade elasticities makes intuitive sense, there is a significant methodological inconsistency in applying it to countries that both import and export a specific product because this combination creates opposing conditions. In the perfect substitutes framework, trade is a residual: the difference between domestic demand and supply. And U.S. exports for the same product are also determined as a residual: the difference between domestic supply and demand. Clearly both conditions cannot be true at the same time. Either domestic production exceeds demand and the country exports, or domestic demand exceeds domestic production and the country imports, but not both. This inconsistency suggests that the perfect substitutes framework is unsatisfactory for developing estimates of trade elasticities when a country both imports and exports the same product.

The second model involves imperfect substitutes. If consumers perceive foreign and domestically produced goods to be close, but not perfect, substitutes—that is, if consumers differentiate foreign from domestically produced goods—then a country may both import and export that general class of products simultaneously. This description better matches U.S. trade patterns for many products, including those produced by industries projected to be highly impacted by OSHA's silica rule.

One of the earliest and most frequently used methods for dealing with international trade in differentiated products is the synthetic elasticity model developed by Armington (1969a, Document ID 0533 and 1969b, Document ID 0534).[17] Armington models make two basic assumptions in order to differentiate internationally traded products. First, traded goods can be thought of as "weakly separable." Second, there exists a constant elasticity of substitution between all products in each broad category of goods the country imports.

The first assumption implies that consumption may be modeled using a two-stage decision-making process. In the first stage, consumers allocate their income across the spectrum of broad goods categories that they purchase; in the second stage, consumers allocate that share of income earmarked for a particular goods category among the differentiated products that comprise the category (Armington, 1969a, Document ID 0533). Thus, in the first stage, the Armington specification models consumers as choosing how to allocate their income across broad categories of goods—such as food, clothing, transportation, housing, etc.—given their income and the relative prices of each good. Assuming a consumer chooses fine earthenware in the first stage, in the second stage, the consumer needs to decide how to allocate that share of income among china and pottery products from the U.S., China, Great Britain, and other countries. This second division of income among the differentiated products depends only on the relative price of those products and the consumer's perceived elasticity of substitutability between those products. The second decision is "separable" from the first decision.

The second assumption—identical and constant elasticities of substitution between pairs of different countries' products—allows the Armington model to be estimated with less data and fewer computing requirements than if the demand for each country's product

[17] The Armington framework has become ubiquitous for incorporating trade flows in computable general equilibrium models (CGE). Significant CGE models such as those used by the U.S. International Trade Commission, the World Trade Organization, Australia's Productivity Commission, Trade Canada, and the Global Trade Analysis Project based at Purdue University all use Armington-type specifications to model trade flows. In addition, ERG developed a synthetic model for EPA to estimate trade elasticities for iron and steel products based on the Armington framework (EPA, 2002, Document ID 0656). This approach was revised and further developed to model the potential effects of EPA effluent guideline on trade in the meat and poultry product industries (EPA, 2004, Document ID 0659).

needed to be individually estimated. Although this second assumption is not literally true for all quantities of imports consumed in each country, it is a reasonable assumption for a country at its market equilibrium and for small changes from that equilibrium.

Armington (1969a, Document ID 0533) showed that trade in differentiated products—whether imports or exports—can be expressed as a function of (1) total demand for that product class regardless of source, (2) foreign and domestic market shares, and (3) the willingness of consumers to substitute foreign made for domestically made products (the elasticity of substitution, often referred to as the Armington elasticity). Armington (1969a, Document ID 0533, 1969b, Document ID 0534) derived relationships between certain important elasticities implied by his model, including the partial elasticity of demand in the i^{th} country for the j^{th} country's product; that is, the import price elasticity of demand for the i^{th} country with respect to a change in the j^{th} country's price. These relationships can be further simplified by looking at only two "countries," the U.S. and the rest of the world (ROW).

Empirical Evidence and Estimated Impacts

ERG (2007c) (Document ID 1710) reviewed Gallaway, McDaniel, and Rivera (2000) (Document ID 0694) for estimates of the elasticity of substitution for products from eight of the industries likely to be most affected by the silica rule and for which import and export data are available. These eight industries are listed with their NAICS code in Table VI-6, as well as with their estimated short-run Armington elasticity. These elasticity estimates range from 0.359 (iron foundries, NAICS 331511) to 1.073 (ground or treated mineral and earth manufacturing, NAICS 327992).

Relying on a variant of the imperfect substitutes model developed by Armington as a function of the elasticity of substitution, ERG combined econometric estimates of the elasticity of substitution between foreign and domestic products, Annual Survey of Manufactures data, and assumptions concerning the values for key parameters, such as the ROW consumption, to estimate the effect of a range of hypothetical price increases on total domestic production of a product. In particular, ERG estimated the domestic production that would be replaced by imported products and the decrease in exported products that would result from a one percent increase in prices—under the assumption that firms would attempt to pass on all of a one percent increase in costs arising from the final rule. The sum of the increase in imports and decrease in exports represents the total loss to industry attributable to the rule. These projected losses are presented as a percentage of baseline domestic production to provide some context for evaluating the relative size of these impacts.

The effect of a one percent increase in the price of a domestic product is derived from the baseline level of U.S. domestic production and the baseline level of imports. Table VI-6 shows the baseline ratio of import value to total U.S. consumption for the 8 affected industries. The ratios range from 0.04 for iron foundries to 0.547 for ceramic wall and floor tile manufacturing—that is, baseline imports range from 4 percent to more than 50 percent of domestic production in these 8 industries. Table VI-6 also shows ERG's estimates of the percentage reduction in U.S. production for the 8 affected industries due to increased domestic imports.[18] The estimated percentage reductions in U.S. production due to increased domestic imports (arising from a 1 percent increase in the price of domestic products) range from 0.013 percent for iron foundries to 0.237 percent for cut stone and stone product manufacturing.

The method to project impacts on U.S. exports closely parallels the method used to project the increase in U.S. imports. Under the simplified construction of bilateral trade between the U.S. and the ROW, U.S. exports are identical to ROW imports. Thus, ERG could estimate the change in ROW imports in a manner identical to that used to estimate the change in U.S. imports. However, there is one important difference between projecting the change in U.S. imports and projecting the change in U.S. exports. Projecting the change in U.S. exports (i.e., ROW imports) requires estimating the U.S. export share of ROW consumption. ERG was unable to find any data on ROW consumption for industries affected by the silica rule and instead made the very conservative assumption that ROW consumption of these products was ten times larger than U.S. domestic consumption of these products.[19]

Table VI-6 shows the estimated baseline ratio of ROW imports to ROW consumption for the 8 affected industries. The ratios range from 0.001 for other concrete manufacturing to 0.035 percent for nonclay refractory manufacturing. Table VI-6 also shows ERG's estimates of the percentage decrease in U.S. exports relative to total U.S. production for the 8 affected industries.[20] The estimated percentage reductions in U.S. production due to reduced U.S. exports (arising from a one percent increase in the price of domestic products) range from 0.014 percent for ceramic wall and floor tile manufacturing to 0.201 percent for nonclay refractory manufacturing.

---

[18] For more details about the derivation of these estimates, see ERG (2007c) (Document ID 1710).

[19] ERG (2007c) performed a sensitivity analysis on the assumption concerning the size of ROW domestic consumption relative to U.S. domestic consumption. Varying the ROW domestic consumption from 2 to 20 times the size of U.S. domestic consumption had only a small effect on the projected changes in U.S. exports. This is because the U.S. export share of ROW consumption is relatively minor even when, for example, ROW consumption is assumed to be only twice as large as U.S. consumption rather than 10 times larger (Document ID 1710).

[20] For more details about the derivation of these estimates, see ERG (2007c) (Document ID 1710).

Table VI-6: Projected Total Trade Impacts for Selected Industries from a One Percent Price Increase in Response to Silica Rule

NAICS	Industry	Armington Elasticity[a]	Estimated Ratio of Imports to Total U.S. Consumption[b]	Estimated Ratio of ROW Imports to ROW Consumption[c]	Percentage Change in U.S. Production Due to Increased Domestic Imports[d]	Change in U.S. Exports Relative to Total U.S. Production[e]	Total Percentage Change in U.S. Production[f]

[f] Source: ERG (2007c), Table 4-3. Calculated from sum of change in U.S. imports plus the change in U.S. exports to ROW.

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis, based on ERG (2007c).

The last column of Table VI-6 shows ERG's estimates of the total percentage change in U.S. production for the 8 affected industries. Total impacts are calculated as the sum of the 2 previous columns, resulting from increased imports and from a loss of exports. The total percentage reduction in U.S. production arising from a 1 percent increase in the price of domestic products ranges from a low of 0.085 percent for other concrete product manufacturing to a high of 0.299 percent for porcelain electrical supply manufacturing.

These estimates suggest that the silica rule will have modest international trade effects. It was previously hypothesized that if price increases resulted in a substantial loss of revenue to foreign competition, then the increased costs of the rule would have to come out of profits. That possibility has been contradicted by the results reported in this section. The maximum loss to foreign competition in any affected industry due to a one percent price increase has been estimated at approximately 0.3 percent of industry revenue. Because, as reported earlier in this chapter, the maximum cost impact of the final rule for any affected industry would be 0.56 percent of revenue, this means that the maximum loss to foreign competition in any affected industry as a result of the rule would be 0.2 percent of industry revenue—which would hardly qualify as a substantial loss to foreign competition. This analysis cannot tell us whether the resulting change in revenues will lead to a small decline in the number of establishments in the industry or slightly less revenue for each establishment. However it can reasonably be concluded that revenue changes of this magnitude will not lead to the elimination of industries or significantly alter their competitive structure.

Based on the Agency's preceding analysis of economic impacts on revenues, profits, and international trade, along with the discussion of industry concerns below, OSHA concluded that the annualized costs of the final rule are below the threshold level that could threaten the economic viability of any industry in general industry or maritime. OSHA further noted that while there would be additional costs (not attributable to the final rule) for some employers in general industry and maritime to come into compliance with the new silica standard, these costs would not affect the Agency's determination of the economic feasibility of the final rule.

Public Comment on International Trade Effects

Foundries

The following comments discuss the loss of business to foreign competition in the foundry industry. The comments have been grouped together by issue and are followed by OSHA's response. The first group of commenters used impact numbers from an alternative cost model to discuss the loss of business to foreign competition.

The United States Chamber of Commerce ("the Chamber") stated that additional costs of the rule's ancillary provisions along with engineering controls will result in reduced competitiveness relative to foreign foundries (Document ID 2288, pp. 27-28). The Chamber also critiqued OSHA's inability to determine feasibility because of a lack of data to analyze economic impacts across facilities by age, design, operations, condition and region (Document ID 2288, pp. 29-30).

In the comments above, the negative economic effect of losing business to foreign competition is based on an alternative cost model report prepared for the American Foundry Society (AFS) by Environomics. This report is addressed in the Engineering Control Costs section in Chapter V of this FEA, where OSHA concluded that the costs in that report were inflated. Because these inflated costs also underpin the Chamber's claim that the rule will reduce competitiveness with foreign foundries, OSHA does not accept that claim. In response to the Chamber's criticism of OSHA's data sources, the Agency notes that Chapter III, the section on Survey Data and OSHA Economic Analyses, discusses why it was infeasible to collect and compile a full-scale national survey of the kinds of baseline conditions and practices that the Chamber of Commerce urged OSHA to consider.

The following comments from foundry firms and associations address foreign competition in metalcasting from China and India along with the inability to pass the cost on to their customers.

AFS submitted comments that the metalcasting industry would lose business to foreign competition as follows:

> Many foundries have closed in recent years with foreign competition assuming much of that business. Five of the eleven identifiable foundries used in the PEA to support OSHA's assertion of feasibility have closed. Because castings are the starting point of many manufacturing processes, loss of foundry jobs also means loss of other manufacturing jobs.
>
> The U.S. metalcasting industry is made up of 1,978 facilities, down from 2,170 five years ago. This reduction can be attributed to the recession, technological advancements, foreign competition and tightening regulations (Document ID 2379, Attachment 3, p. 42; 4035, p. 5).

The Indiana Cast Metals Association concurred with these comments and also suggested that other industries would also be negatively impacted if U.S. foundries shut down (Document ID 2049, p. 1). The Ohio Cast Metals Association submitted two comments stating that the rule will increase costs and undermine the Ohio-based metalcasting industry's ability to compete in the global marketplace:

> [The silica rule] will significantly increase costs, slow down or eliminate hiring, reduce the number of foundry jobs and undermine our industry's ability to compete in the global marketplace. For some foundries, the rulemaking could be the final straw that destroys their business.
>
> * * * Over the past two decades Ohio foundries along with other manufacturers throughout the United States have faced tremendous international competition from China, Brazil, and India and many foundries have closed and thousands of employees have lost their jobs during this period. To suggest that Ohio foundries can just pass on the tremendous costs associated with compliance with the proposed silica rule with "minimal loss of business to foreign competition" indicates that the individuals performing this analysis were driven by other agendas or misinformed (Document ID 2119, Attachment 3, pp. 1- 2).

Grede Holdings L.L.C. submitted a comment expressing its view that it would be difficult for foundries to pass the cost of compliance to the customer because of international competition, and that the number of foundries in the U.S. has dropped by more than half since 1980, going from 4,200 foundries to 2,050 foundries (Document ID 2298, p. 3).

Sawbrook Steel submitted two comments voicing concern that the implementation of the regulation will cause jobs to move overseas, resulting in a shrinking of the domestic casting manufacturing (Document ID 2227, p. 2; 1995, p. 1).

In the comments above, businesses and associations state that the costs of the rule will be too high and they will lose business to foreign competition. The chief advantage of foreign imports to downstream users, as reported to the U.S. International Trade Commission (ITC) during an investigation they conducted into the competitive conditions in the U.S. foundry market, is their low pricing. Respondents to the investigations said the cost of foreign produced products ranged from ten percent to forty percent less than the cost of U.S. products (Document ID 0753, table 5-60, p. 5-53 as referenced in Document ID 1710, pp. 5-4). U.S. producers have responded to competition with a broad array of initiatives, such as implementing lean manufacturing, improving customer service, and increasing automation (Document ID 0753, pp. 10-14 and 10-15). According to the ITC study:

> The use of technology may also be influenced by the type of castings produced and relative wage rates. Low-value, low-quality castings, for example, generally require a lower level of technology and relatively more semi-skilled labor than foundries producing more complex castings. To lower labor costs, foundries in developed countries with higher wage rates may install more automation and technological improvements, whereas foundries in developing countries with relatively lower wage rates may

> substitute labor for relatively high-cost capital investments (Document ID 0753, p. 2-11).

Before addressing issues on international competition for metalcasters, it should be noted that all foundry industries affected by this rule are below the ten percent cost to profit threshold and one percent cost to revenue threshold. This means that even if the argument that costs cannot be passed on were to be correct, the loss in profits would be less than ten percent and unlikely to effect the feasibility of the industry. Further the costs to be passed on would require less than one percent price increases. In general, metalcasters in the U.S. have shortened lead times, improved productivity through computer design and logistics management, provided expanded design and development services to customers, and provided a higher quality product than foundries in China and other nations where labor costs are low (Document ID 0753, p. 3-12). All of these measures, particularly the higher quality of many U.S. metalcasting products and the ability of domestic foundries to fulfill orders quickly, are substantial advantages for U.S. metalcasters that may outweigh the very modest price increases projected above in Tables VI-3 and VI-4 (Document ID 1710, p. 5-4). According to the ITC study, quality was the number one purchasing decision factor for the majority of purchasers, with price and lead times ranking lower, and U.S. metalcasters are able to deliver that quality (Document ID 0753, p. 4-5). The ITC report noted:

> Certain purchasers noted that when inventory management and complex manufacturing skills are required, U.S. foundries excel. U.S. foundries were also cited by responding U.S. purchasers as manufacturing with a low defect (rejection) rate. (Id.)

Purchaser responses to the ITC’s survey stated that some U.S. foundries are also completely inoculated against foreign competition, even if the prices of U.S. foundry products rise:

> As noted in questionnaire responses, certain purchasers are committed to buying solely U.S.-made castings. One U.S. foundry official noted that if downstream customers require castings to be made in the United States, then U.S. foundries are guaranteed that business. This situation often occurs when foundries supply castings for federally funded operations, such as construction projects (Document ID 0753, p. 4-5).

Foundries in China and India, while expanding their capacities, are also faced with rising domestic demand due to their own rapidly expanding domestic industrial economies, which affect their ability to fulfill export demand (Document ID 0753, p. 5-16). ERG’s research noted a growth in U.S. foundry exports, which could help to offset some of the foreign imports entering the U.S. market. According to one report cited by ERG, U.S.

foundry exports were roughly equivalent to 53 percent of the imports (Document ID 1710, p. 5-5).

ERG's research also provided some evidence that the combination of U.S. and foreign demand for metalcasting may outstrip the supply to such a degree that, even if the U.S. foundries operated at full capacity, their maximum output would fail to meet the demand from the U.S. and foreign markets (Document ID 1710, p. 5-5). The U.S. foundry industry is unlikely to face any significant economic impacts if there is ample demand and a limited supply because such a condition makes it easier to pass along any costs of the rule.

Tile Production

The following comments discuss the difficulties of competing with foreign tile producers followed by OSHA's response.

Tile Council of North America (TCNA) noted the import price sensitivity between domestic tile and imported tile as follows:

> The low cost of imported tile places an enormous burden on U.S. tile manufacturers to maintain current pricing to remain competitive.
>
> According to the latest data collected by TCNA, the average price per square foot of U.S. tile shipments is $1.43. The average price per square foot of Chinese imports is $0.86. With Chinese imports 60% less expensive than U.S. tile in what is an extremely price-competitive market, OSHA's claim that "any price increases would result in minimum loss of business to foreign competition" strains credulity.
>
> To illustrate the tremendous import/price sensitivity between domestic tile and imports, we note the increase in imports from Peru as a result of a bilateral free trade agreement between Peru and the United States eliminating duty on tile from Peru. Although only amounting to a price change of 4 – 5 cents per square foot, from 2008, the year before the bilateral agreement to the end of 2011, tile imports from Peru into the United States grew by 59%. This illustrates how even a small change in price due to modest increases in operating costs and raw material costs pose an existential threat to the tile manufacturing industry.
>
> The import sensitivity of domestic tile manufacturing operations is well known by the United States International Trade Commission (USITC) and the office of the United States Trade Representative (USTR). The assertion made by OSHA that cost increases will not result in lost market share to foreign competition is in direct conflict with information known

> by USITC and the USTR and contrary to established public policy (as reflected in existing Free Trade Agreements) and industry testimony.
>
> Contrary to the assertion made by OSHA, the marginal price increases anticipated by required conformance to the rule as proposed would make the domestic tile manufacturing industry highly uncompetitive threatening the very viability of this import-sensitive industry (Document ID 2363, p. 9).

The National Tile Contractors Association also questioned OSHA’s preliminary determination that the tile industry could pass on most or all costs through higher prices, calling the claim “wildly erroneous”:

> Implementation of the proposed rule's requirements would increase both production and installation costs, and would put pressure on consumer prices. At a time when U.S. consumption of ceramic tile is more than 25% below its peak level (2006), this is a serious concern. The U.S. market is already flooded with lower quality, lower priced imports from many countries that likely do not respect the health, safety, and rights of workers. The low cost of imported tile places an enormous burden on U.S. tile manufacturers to maintain current pricing to remain competitive (Document ID 2267, p. 8).

Dal-Tile echoed the TCNA comments regarding the inability to pass costs onto the customer (Document ID 2147, p. 3).

OSHA does not dispute the commenters’ information indicating that Chinese and Peruvian tile are significantly cheaper than U.S. tile, but that point actually undercuts their claim that a small change in the price of U.S. tile would place an “enormous burden” on U.S. tile manufacturers. The commenters note that Chinese tile is already available in the U.S. at just over half the price of U.S. tile. If the market was actually as sensitive as the commenters suggest, and the Chinese tile was competing for the same market share as U.S. tile, under the commenter’s logic the U.S. tile industry would have already gone out of business. But that has not happened, suggesting that U.S. tile manufacturers have been able to identify customers for whom the tile price is not the predominant factor. Likewise, the example of Peruvian tile demonstrates only that the lower-priced imported tile is sensitive to small price changes. The commenter provides no evidence that the Peruvian tile is competing for the same customers as the U.S. tile industry.

In summary, the TCNA’s argument that cost increases will result in lost market share to foreign competition is unconvincing because it is not clear that there is a strong relationship between the price of the foreign tile and the price of the U.S. tile. One likely cause for this disconnect is that, as TCNA notes, the market is "already flooded with lower quality, lower priced" imports (Document ID 2363, p. 8), suggesting that tile from China, Peru, and the other lower-priced foreign importers are of a lower quality that may be targeted at a different customer base than the higher-quality U.S. tile. This perception that tile from China and other low-cost tile producing countries may be of lower quality produces an imperfect substitution scenario and adds to the inelasticity of demand for domestic tiles, enabling producers to pass some of the costs on to the consumer.

On the other end of the tile price range are the Italian tiles. Italy and China are the top countries of origin for tiles imported into the U.S., but tiles from these countries command very different prices. In terms of general tile products, one source indicates that the average prices of tiles imported by the U.S. in 2012 were $20.20 to $20.90 per square meter for Italian tiles and between $8.30 and $8.70 per square meter for Chinese tiles imported by the U.S, a significant price difference that could be explained by a difference in quality.[21] TCNA stated above that the average price of tile from China is $0.86 per square foot or $9.25 (10.76 X 0.86) per square meter. TCNA's average price of American tile is $1.43 per square foot or $15.39 (10.76 X 1.43) per square meter (Document ID 2363, p. 9), which shows the U.S. producers to be supplying a mid-priced product. Although Italy is also a major source of tile imports in the U.S. despite their higher price, the commenters did not suggest that an increase in U.S. tile prices would cause the U.S. to lose market share to the Italian tile; nor did the commenters suggest that lower-priced U.S. tile could be exported to dominate the Italian market. The implication is, again, that different customers are willing to pay different prices for different quality tile.

Using price as an indicator of quality, the tile market can be segmented into three categories: low quality, mid-grade, and high quality. The U.S. tile industry has located a niche between the lowest quality/lowest priced tile and the highest quality/highest priced tile. While it is possible that a few tile firms that produce very low-quality or very high-quality tile may be negatively impacted by an increase in the price of their tile, OSHA concludes that the majority of firms would not experience a significant negative economic impact. This is along with the fact that the increase in price from this rule is expected to be minimal. TCNA commented that the average price per square foot of U.S. tile shipments is $1.43. The cost to revenue ratio for NAICS 327122 Ceramic Wall and Floor Tiles is 0.35 percent, meaning this final rule will increase the average cost of U.S. tile by five hundredths of a cent (or $0.0005 per square foot). It is therefore fair to say this extremely modest increase in the average price of U.S. tile would not have a significant economic impact on the U.S. tile industry as a whole.

Brick Industry

[21] http://www.scirp.org/journal/PaperInformation.aspx?PaperID=43515

During the public hearing Belden Tri-State Building Materials stated that the brick industry has foreign competition, mostly from Canada, and some from Mexico (particularly in Texas, Oklahoma or Arkansas), and Germany (Document ID 3586, Tr. 3457). They indicated that their competition includes not only imported brick but also “other cladding materials like vinyl siding and HardiePlank,” but the competition from imported brick is typically “more expensive brick” because of “innovations in Europe that we just haven't caught up to, different sizes, different colors, different processes” (Id.).

ACME Brick Company representatives indicated in testimony that oversees competition was virtually nonexistent because it is “hard to get that across the ocean economically” and noted that they generally locate their production facilities strategically to be near their markets because “[p]roduction costs really are about a third of the cost of the brick when we have them close. . .[The] farther away [the bricks come from] -- there are some distinctions in the quality or the makeup of a brick” (Document ID 3577, Tr. 736).

This testimony indicates to OSHA that international competitors will not be able to take advantage of any potential price increases made by U.S. producers in the U.S. domestic brick market. The brick making industry will therefore be able to pass on most, if not all, of the costs of complying with the rule.

Hydraulic Fracturing

To determine the economic impacts for most industries, OSHA used the Census Bureau’s Statistics of U.S. Businesses to estimate revenues on a six-digit NAICS basis but these revenue data were not sufficiently precise to isolate the hydraulic fracturing component from the larger industry (NAICS 213112). As a result, instead of using data from the Economic Census, revenues for hydraulic fracturing firms were based on estimated utilization rates and per stage revenues. As discussed in Chapter III, Profile of Affected Industries, the data on this industry have been updated to reflect the comments in the record and the best data available in 2012. The cost to profit percentage for the hydraulic fracturing industry estimated in this FEA is 7.67 percent (below OSHA’s ten percent threshold) for fleets of all sizes. The ratio of costs to revenues for hydraulic fracturing firms in this FEA is estimated to be 0.54 percent for all establishments in the industry, 0.17 percent for small entities and 0.24 percent for very small entities. Although the costs as a percent of revenue increased for all establishments, the impacts still remain well below the one percent threshold.

However, these estimates are based on the state of the industry in the base year of 2012 supplemented with data provided in comments to the proposed rule in 2013 and early

2014. When the PEA was published in 2006, the price of oil fluctuated between $70 and $80 a barrel. During the years following the publication of the PEA the price of oil has had some large fluctuations. Before the recession of 2008 the price of oil peaked at $146 per barrel but dropped to $44 dollars per barrel during the economic downturn in 2008.[22] As the price of oil steadily increased during 2009, there was an influx of money invested in the hydraulic fracturing industry. This FEA uses revenue data from 2012 when the price per barrel fluctuated between $90 and $100. However, in the fourth quarter of 2014, the price of oil dropped to $49 per barrel. The price of oil in 2015 has oscillated between approximately $45 and $60 per barrel.[23] Because of this major change in the industry since the record closed in 2012, OSHA has supplemented its feasibility analysis with more current data.

The Structure of the Hydraulic Fracturing Industry

Hydraulic fracturing nearly doubled U.S. oil production from 5.6 million barrels a day in 2010 to a rate of 9.3 million barrels a day in 2015. Up until the drop in oil prices during the fourth quarter of 2014, the expected annual increase in production was one million barrels. The economics of hydraulic fracturing wells is much different than conventional wells.[24] The marginal cost of producing a barrel of oil from a conventional well for large oil producing countries is around $15 to $30.[25] Therefore, the owners of conventional wells continue to produce even as the price per barrel decreased from $100 to $40, and would remain in business at costs down to $30. The traditional oil drilling business is driven by marginal costs, not costs spent to drill the well. This means that supply is inelastic relative to demand. This has not been true for the hydraulic fracturing industry.

Hydraulic fracturing wells have a very short life compared to conventional wells. For example, a well in the Bakken region straddling Montana and North Dakota may start out producing 1,000 barrels a day then decline to 280 barrels at the beginning of year two. By year three, more than half of the reserves will be depleted. Therefore, to generate revenue, producers need to constantly drill new wells. In this sense, hydraulic fracturing wells are more like gold or silver mines than conventional oil production.[26] The recent drop in oil prices has caused a series of bankruptcies and closures across the oil

industries. Although there was a reduction in the number of rigs from about 1,600 to 800,[27] hydraulic fracturing still accounted for 4.6 million barrels a day out of a total of 9.4 million barrels or 49 percent of total oil produced in February 2015. Hydraulic fracturing also accounted for 54 percent of natural gas output.

The Energy Information Administration (EIA) projects the Brent crude oil price will average $40 a barrel in 2016 and $50 a barrel in 2017. However, EIA expects crude oil prices to rise in future years, rising to over $70 per barrel by 2020 and to $100 per barrel by 2028. EIA's crude oil price forecast remains subject to significant uncertainties as the oil market moves toward balance and could continue to experience periods of heightened volatility.[28] Thus, industry implementation of OSHA's engineering control requirements, which are not required until five years after the effective date of the rule, may come during a period of much higher and rising energy prices. In any case, the price increase required by this rule is a very small fraction of the fluctuation in energy prices during the past several years.

However, the possibility that oil prices are not going to increase in the near future has spurred a new wave of innovation in energy exploration. Now that prices have dropped to around $50 a barrel, companies are focusing on efficiency and getting the most petroleum for the least amount of money. With the effective date of this rule on the horizon, it is possible that some of this innovation will lead to technologies that not only increase efficiency but reduce worker exposures to silica at the same time.

Through the application of new technology OSHA believes that, even in a lower price environment, hydraulic fracturing entrepreneurs will be able to implement the controls required by this final rule without imposing significant costs, causing massive economic dislocations to the hydraulic fracturing industry, or imperiling the industry's existence. Big oil-field-services like Haliburton Co. and Schlumberger Ltd. report that they have witnessed customers concentrating on using technology such as lasers and other high-tech equipment and data analytics before they drill to make sure new wells deliver the most crude for the investment cost. The application of this new technology as well as fiber-optic tools that help monitor a well during hydraulic fracturing to make sure that it's working as well as possible and new techniques to stimulate microbes already present that attach themselves to bits of oil, essentially breaking it up and making it easier for the crude to flow through rock[29] have had positive quantitative results. Productivity at some

[29] http://www.wsj.com/articles/oil-companies-tap-new-technologies-to-lower-production-costs-

"super-fracking" wells has increased 400-600 barrels a day per rig from just a few years ago. Drilling efficiency in some areas has increased as much as 26 percent in a single year[30] while the time to drill and fracture a well has come down from an average of 32 days in 2008 to now only about half that time: 14-16 days from start to finish and in some cases even less. These increased efficiencies result in significant cost savings.[31] Also, the lower demand by hydraulic fracturing companies for equipment rental, trucking, and labor has caused a decrease in their prices, reducing the overall cost of hydraulic fracturing.[32]

Although the drop in the price of oil has caused an initial reduction in hydraulic fracturing operations, the application of recently developed technology to new wells has increased per well production. One expert was quoted in Fortune magazine as saying "[t]here tailing off in U.S. drilling activity, but I expect continued development drilling in major new areas, particularly the Bakken, even at $50 (a barrel)."[33] In the Bakken region in 2015 the decrease in oil production resulting from the reduction of rigs was substantially offset by increases in new well oil production per rig. There are reasons to believe in the continuance of tight oil growth. An analysis by IHS shows that most of the potential U.S. tight oil capacity additions in 2015 have a break-even price in the range of $50 to $69 per barrel. Continued productivity gains, such as improvements in well completion and downspacing, also support the continuation of U.S. production growth at lower prices.[34] Based on these advances, it is plausible that hydraulic fracturing shale operations may achieve break-even costs of $5-$20 per barrel.[35]

A sign of the ongoing effectiveness of upgrades in efficiency in the hydraulic fracturing business is evident in the projections for U.S. crude production. The EIA's Annual

Energy Outlook for 2015 has projected that the U.S. is on track to hit reach a record for crude output at 10.6 million barrels a day in 2020.[36]
While the economic conditions faced by the hydraulic fracturing industry have changed significantly since the publication of the proposed rule, this discussion shows that there is significant reason to believe that this rule will not have a significant impact on the hydraulic fracturing industry. Advancements in technology and the application of new efficient drilling methods continue to increase the per-rig production capacity of new-well oil drilling rigs while lowering the costs of operating these rigs. These technological changes increase the energy recovered through hydraulic fracturing, and thus the value of fracturing services, without increasing the costs per well associated with controlling silica exposures. Further, the demand for fracturing services will depend, in part, on energy prices. The costs associated with complying with the silica rule are a minor issue by comparison. Thus, OSHA's conclusion that this rule is economically feasible for the hydraulic fracturing industry has not changed.

Railroads

In the PEA, OSHA did not include any estimates of costs as percentage of revenues or as a percentage of profits for railroads. This was due to the fact that the standard sources of economic statistics that were used for data on revenues and employment for all other affected industries do not include railroads. The Association of American Railroads (AAR) expressed concern about the impact of the rule on small railroads (although not on larger railroads), but did not provide any estimates or analysis, or suggest that OSHA use any specific sources to conduct such an analysis. For this FEA, OSHA did examine costs as percentage of revenues and profits for the railroad industry as a whole using supplemental information from sources typically relied on by the industry.

For this FEA, OSHA estimated that 16,895 workers in the rail transportation industry (NAICS 4821; "railroads") will be covered by the final standard, including 7,239 workers employed as Ballast Dumpers and 9,656 workers employed as Machine Operators (for the purposes of this analysis, OSHA assumed that the machine operators would be conducting at least some work outside of the cab of the equipment). The Agency estimated that compliance costs for railroads will total $16.6 million, or $980 per affected worker.

Based on these estimates, OSHA judged that the final rule is feasible for railroads because combining supplemental data from BLS37 and the Association of American

[37] Bureau of Labor Statistics, Quarterly Census of Employment and Wages, Series ID

Railroads38 for the estimated 105 rail transportation establishments in NAICS 4821 with a reported revenue of $72.9 billion, the cost-to-revenue impacts are an estimated 0.02 percent and cost-to-profit impacts are an estimated 0.4 percent. In addition, the per-worker cost for railroads ($980) is lower than the average per-worker cost ($1,231) across all affected NAICS industries in general industry and for 2000-2012, the average profit rate for rail transportation, 6.2 percent, was significantly higher than the average profit rate for all affected NAICS industries throughout general industry (3.4 percent).

The AAR noted that small railroads had not been covered in the Initial Regulatory Flexibility Analysis (Document ID 2366, p. 4). The commenter is correct that OSHA did not examine small entities in this sector but has done so for this FEA using supplemental information on railroads.

In 2012, 574 U.S. freight rail establishments, employing 181,264 workers, operated on roughly 169,000 miles of track.39 The Surface Transportation Board in the U.S. Department of Transportation classifies railroads into three groups based on annual revenues:

- Class I for freight railroads defined as railroads with annual operating revenues above $467.1 million ($2013)
- Class II, includes some regional railroads, defined as railroads each with operating revenues between $37.4 million and $467.1 million ($2013)
- Class III for all other freight rail operations (including smaller regional, short-line, switching, and terminal).40

In 2013**,** in addition to the seven Class I freight railroad systems, there were 21 regional railroads (line-haul railroads operating at least 350 miles of road and/or earning revenue between roughly $40 million and the Class I threshold), and over 500 local railroads (line-haul or short-line railroads smaller than regional railroads).41 Among the 567

[41] Freight Railroads Background. (FRA, 2015) Stephanie Lawrence, Office of Policy, Office of Rail

railroads that fell below the Class I revenue threshold, 11 qualified as Class II and the remainder (556, including 10 regional railroads) qualified as Class III (FRA, 2015). Class III railroads are typically local short-line railroads serving a small number of towns and industries or hauling cars for one or more larger railroads. Many Class III railroads were once branch lines of larger railroads or abandoned portions of main lines.

In 2012, employment within 546 local railroad companies totaled 12,293 workers and employment within 21 regional railroads totaled 5,507 workers. Line Haul Railroads are classified in NAICS 482111 and entities within this industry with 1,500 or fewer workers are classified as small by SBA size standards. Local/Short Line Railroads are classified in NAICS 482112 and entities within this industry with 500 or fewer workers are classified as small by the SBA size standard. For 2012, OSHA estimated that all 567 Class II and Class III railroads (combined total of 17,800 workers) qualified as small entities according to the SBA definitions.

In a recent study prepared for Congress42, the Federal Railroad Administration reported that in 2013, 546 Local/Short Line Railroads employed 12,293 workers and earned $2.6 billion in revenue. OSHA estimates that of the 16,895 affected employees throughout rail transportation, 1,146 employees of Short-Line railroads are affected by the final rule.43 According to the BLS Quarterly Census of Employment and Wages, on average 32 establishments were identified within NAICS 482112, Short-Line Railroads (an establishment can operate more than one railroad). Therefore, if all 546 Class III railroads are controlled by 32 establishments, OSHA estimates that revenue per establishment is approximately $81.3 million.

OSHA estimated that compliance costs for rail transportation will total $16,562,059. Therefore, if costs per affected worker ($980 per worker) are apportioned to the establishments operating Short-Line Railroads, OSHA estimates that costs for these local railroads will total $1.1 million, or roughly $35,100 per establishment. As noted above, annual revenues among Short-Line rail operations total approximately $2.6 billion, or $81.3 million per establishment. Applying the industry-wide profit rate of 6.23 percent for NAICS 4821, OSHA estimated that profits per establishment in NAICS 482112 are $5.1 million. Therefore, OSHA estimates that impacts measured as costs as a percent of

---

Policy and Development, Federal Railroad Administration April 2015. https://www.fra.dot.gov/eLib/Details/L03011. These regional railroads are almost evenly divided between Class II (11 railroads) and Class III (10 railroads).

[42] Summary of Class II and Class III Railroad Capital Needs and Funding Sources, Federal Railroad Administration, Report to Congress, October 2014. https://www.fra.dot.gov/Elib/Document/14131.

[43] (16,895 affected workers / 181,264 total employees in NAICS 4821) * 12,293 total Short-Line employees = 1,146 affected Short-Line employees.

revenues will not exceed 0.04 percent, and that impacts measured as costs as a percent of profits will not exceed 0.69 percent. Thus, OSHA concludes that the silica standard will not impose a significant impact on a substantial number of small entities in rail transportation and therefore will not threaten the competitive structure or viability of small entities in NAICS 482110.

Economic Feasibility Screening Analysis: Small and Very Small Businesses

The preceding discussion focused on the economic viability of the affected industries in their entirety. Even though OSHA found that the final standard did not threaten the survival of these industries, there is still the possibility that the competitive structure of these industries could be significantly altered.

To address this possibility, OSHA followed its normal rulemaking procedure for examining the annualized costs per affected small entity and very small entity for each affected industry in general industry and maritime. Again, OSHA used its typical minimum threshold level of annualized costs equal to one percent of annual revenues—and, secondarily, annualized costs equal to ten percent of annual profits—below which the Agency has concluded that the costs are unlikely to threaten the survival of small entities or very small entities or, consequently, to alter the competitive structure of the affected industries.

Compliance costs for entities with fewer than 20 employees were estimated, in many cases, using a derived compliance cost per employee. Assuming costs to be equally distributed among all employees, OSHA estimated the compliance cost per employee by dividing total costs for each NAICS by the number of employees. OSHA then multiplied the compliance cost per employee with the ratio of the average number of employees per entity with fewer than 20 employees. Similarly, compliance costs per small entity were estimated from the product of compliance costs per employee and the average number of employees in entities within the SBA classification for the given NAICS. However, some compliance costs, such as some engineering control costs, were modified to reflect diseconomies of scale for very small establishments.

Table VI-7 shows that the annualized cost of the final rule for the average small entity in general industry and maritime is estimated to be $2,967 in 2012 dollars. Table VI-8 shows that the annualized cost of the final rule for the average very small entity in general industry and maritime is estimated to be $1,532 in 2012 dollars. The only industry in which the annualized costs of the final rule for small entities exceed one percent of annual revenues is NAICS 213112 (Support Activities for Oil and Gas Operations), which is estimated to be 1.29 percent. There are two industries for very small entities exceeding one percent of annual revenues - NAICS 213112 (Support Activities for Oil and Gas Operations), 2.09 percent and NAICS 327110 (Pottery, Ceramics, and Plumbing Fixture Manufacturing), 1.21 percent.

Small entities in nine industries in general industry and maritime are estimated to have annualized costs in excess of ten percent of annual profits; NAICS 327110: Pottery, Ceramics, and Plumbing Fixture Manufacturing (38.57 percent); NAICS 327120: Clay Building Material and Refractories Manufacturing (33.59 percent); NAICS 327991: Cut Stone and Stone Product Manufacturing (24.70 percent); NAICS 327999 All Other Miscellaneous Nonmetallic Mineral Product Manufacturing (20.90 percent); NAICS 327390: Other Concrete Product Manufacturing (18.59 percent); NAICS 213112: Support Activities for Oil and Gas Operations (18.15 percent); NAICS 327332: Concrete Pipe Manufacturing (14.53 percent); NAICS 327331: Concrete Block and Brick Manufacturing (13.11 percent); and NAICS 327320: Ready-Mix Concrete Manufacturing (11.51 percent).

Very small entities in sixteen industries are estimated to have annualized costs in excess of ten percent of annual profit: NAICS 327110: Pottery, Ceramics, and Plumbing Fixture Manufacturing (90.64 percent); NAICS 327120 Clay Building Material and Refractories Manufacturing (58.51 percent); NAICS 327999: All Other Miscellaneous Nonmetallic Mineral Product Manufacturing (51.05 percent); NAICS 327991: Cut Stone and Stone Product Manufacturing (30.81 percent); NAICS 327390: Other Concrete Product Manufacturing (29.24 percent); NAICS 213112: Support Activities for Oil and Gas Operations (29.46 percent); NAICS 327212: Other Pressed and Blown Glass and Glassware Manufacturing (22.66 percent); NAICS 327332: Concrete Pipe Manufacturing (22.11 percent); NAICS 327211: Flat Glass Manufacturing (20.44 percent); NAICS 327331: Concrete Block and Brick Manufacturing (19.52 percent); NAICS 327993: Mineral Wool Manufacturing (17.42 percent); NAICS 327992: Ground or Treated Mineral and Earth Manufacturing (16.33 percent); NAICS 327320: Ready-mix Concrete Manufacturing (15.91 percent); NAICS 331513: Steel Foundries (except investment) (12.27 percent); NAICS 331524: Aluminum Foundries (except die-casting) (11.29 percent); NAICS 331511: Iron Foundries (10.03 percent).

In general, cost impacts for affected small entities or very small entities will tend to be somewhat higher, on average, than the cost impacts for the average business in those affected industries. That is to be expected. After all, smaller businesses typically suffer from diseconomies of scale in many aspects of their business, leading to lower revenue per dollar of cost and higher unit costs. Small businesses are able to overcome these obstacles by providing specialized products and services, offering local service and better service, or otherwise creating a market niche for themselves. The higher cost impacts for smaller businesses estimated for this rule generally fall within the range observed in other OSHA regulations for which there is no record of major industry failures.

In allocating the share of costs to very small entities, OSHA did not have direct information about how many very small entities were engaged in silica-related activities. Instead, OSHA assumed that the affected employees would be distributed among entities of different size according to each entity size class's share of total employment. In other words, if 15 percent of employees in an industry worked in very small entities (those with fewer than 20 employees), then OSHA assumed that 15 percent of affected employees in the industry would work in very small entities. However, in reality, OSHA anticipates that in industries with foundries, none of the entities with fewer than 20 employees have foundries or, if they do, that the impacts are much smaller than estimated here.

Table VI-7 Screening Analysis for SBA Establishments in General Industry and Maritime Affected by OSHA's Silica Standard

NAICS	Industry	Compliance Costs	Total Affected SBA Entities	Annual Cost per Affected Entity	Annual Revenue per SBA Entity ($1000)	Percent Profit	Annual Profit per Entity	Cost to Revenue	Cost to Profit
213112	Support Activities for Oil and Gas Operations	$24,247,594	150	$161,651	$12,562	7.09%	$890,424	1.29%	18.15%

[a] Costs and impact to rail transportation were estimated separately. See the previous discussion in this chapter for more information.

* In the PEA, OSHA identified a number of industries as having captive foundries and estimated that some very small entities in those industries would have captive foundries. For this FEA, the Agency determined that this assumption was incorrect and that entities with fewer than 20 employees would not have enough workers to perform foundry operations as well as their primary business operations. For the sake of comparability between the PEA and FEA, OSHA has left those industries in this table but shown that very small entities will have no costs associated with this final rule.

SBREFA Comments on Impacts on the General Industry and Maritime

In this section, OSHA reviews comments addressing economic impacts in general industry and maritime that were submitted during the SBREFA process prior to the PEA. OSHA addressed these comments in the PEA that was made available for public comment, but OSHA did not receive comments specifically addressing its responses to the SBREFA recommendations. OSHA is reprinting its responses here for the convenience of the reader.

SERs from foundries stated that there had been a long-run decline in the number of foundries in the United States, with the industry under continued pressure from foreign competitors and the need to meet new domestic regulations. The total expense of the draft standard and inability to meet lower PELs would pressure more U.S. foundries out of business, continuing an historical trend in this industry, SERs said. The variability in the foundry products and small open-area production plants would make meeting lower PELs difficult and costly. Many smaller foundries would be put out of business, the SERs said, and many jobs lost in the industry. “Twenty percent of profits is a great deal to spend on engineering controls with questionable results.… The economics of the foundry industry today are not pretty,” one SER said. And another: “The cost of meeting the standard will be very difficult …. A PEL of 50 would put us out of business.” OSHA found in this FEA that costs as percentage of profits for even very small foundries would not rise to a level of 20 percent.

SERs from the brick industry stated that meeting the provisions of the draft proposed standard, particularly with a lower PEL, would be very tough for their competitive, low margin industry. Similarly, a SER from the pre-cast concrete industry said, “The problem is not putting the company out of business, but that the price of products will increase.” OSHA found that because bricks face limited foreign competition, a very small change in the price of bricks would not affect the viability of the industry.

Other SERs (industrial sand, molding powders, refractory concrete) noted that the impact of the standard on them, particularly if the PEL is lowered, would entail substantial costs, but indirect effects could be significant as well since their major customers (foundries) could be negatively impacted, too. “Refractory companies are going out of business with the foundries,” one SER said. OSHA has concluded that foundries will not, in general go out of business.

Regulatory Flexibility Screening Analysis

To determine if the Assistant Secretary of Labor for OSHA can certify that the final silica standard for general industry and maritime will not have a significant economic impact on a substantial number of small entities, the Agency has developed screening tests to consider minimum threshold effects of the final standard on small entities. The minimum threshold effects for this purpose are annualized costs equal to one percent of annual revenues and annualized costs equal to five percent of annual profits applied to each affected industry. (OSHA uses five percent as a threshold for significant impacts on small entities rather than the ten percent used for potentially serious impacts on industries in order to assure that small entity impacts will always receive special attention.) OSHA has applied these screening tests both to small entities and to very small entities. For purposes of certification, the threshold level cannot be exceeded for affected small entities or very small entities in any affected industry.

Tables VI-7 shows that the only industry for small entities in which the annualized costs of the final rule exceed one percent of annual revenues is NAICS 213112 (Support Activities for Oil and Gas Operations), 1.29 percent. Table VI-8 shows two industries for very small entities exceeding one percent of annual revenues - NAICS 213112 (Support Activities for Oil and Gas Operations), 2.09 percent and NAICS 327110 (Pottery, Ceramics, and Plumbing Fixture Manufacturing), 1.21 percent. These tables also show that the annualized costs of the final standard exceed 5 percent of annual profits for small entities in 15 industries and for very small entities in 25 industries. OSHA is therefore unable to certify that the final standard will not have a significant economic impact on a substantial number of small entities in general industry and maritime and must prepare a Final Regulatory Flexibility Analysis (FRFA). The FRFA is presented in Chapter IX of this FEA

IMPACTS IN CONSTRUCTION

In this section, OSHA will determine whether (1) the final rule is economically feasible for all affected industries in construction, and (2) the Agency can certify that the final rule will not have a significant economic impact on a substantial number of small entities in construction.

Economic Feasibility Screening Analysis: All Establishments

To determine whether the rule's estimated costs of compliance would threaten the economic viability of affected construction industries, OSHA used the same data sources and methodological approach that were used earlier in this chapter for general industry and maritime. OSHA first compared, for each affected industry, annualized compliance costs to annual revenues and profits per (average) affected establishment. The results for all affected establishments in all affected construction industries are presented in Table VI-9, using annualized costs per establishment for the PEL of 50 $\mu g/m^3$. Shown in the table for each affected industry are total annualized costs, annualized costs per affected establishment, annual revenues per establishment, profit rate, annual profits per establishment, annualized compliance costs as a percentage of annual revenues, and annualized compliance costs as a percentage of annual profits.

The annualized costs per affected establishment for each affected construction industry were calculated by distributing the industry-level (incremental) annualized compliance costs among all affected establishments in the industry, where annualized compliance costs reflect a three percent discount rate.[44] The annualized cost of the rule for the average establishment in construction, encompassing all construction industries, is estimated at $1,097 in 2012 dollars. It is clear from Table VI-9 that the estimates of the annualized costs per affected establishment in the ten construction industries vary widely. These estimates range from $4,811 for NAICS 237300 (Highway, Street, and Bridge Construction) and $4,463 for NAICS 237100 (Utility System Construction) to $364 for NAICS 236100 (Residential Building Construction) and $360 for NAICS 221100 (Electric Utilities).

As previously discussed, OSHA has established a minimum threshold level of annualized costs equal to one percent of annual revenues—and, secondarily, annualized costs equal to ten percent of annual profits—below which the Agency has concluded that costs are unlikely to threaten the economic viability of an affected industry. Table VI-9 shows that the annualized costs of the rule do not exceed one percent of annual revenues or ten percent of annual profits for any affected construction industry. NAICS 238100 (Foundation, Structure, and Building Exterior Contractors) has both the highest cost impact as a percentage of revenues, of 0.12 percent, and the highest cost impact as a percentage of profits, of 3.66 percent. For all affected establishments in construction, the estimated annualized cost of the final rule is, on average, equal to 0.05 percent of annual revenue and 1.52 percent of annual profit. These are well below the minimum threshold levels of 1 percent and 10 percent, respectively.

Therefore, even though the annualized costs of the rule incurred by the construction industries as a whole are roughly twice the combined annualized costs incurred by general industry and maritime, OSHA concludes, based on its screening analysis, that the annualized costs as a percentage of annual revenues and as a percentage of annual profits are below the threshold levels that could threaten the economic viability of any of the construction industries. OSHA therefore finds that the final rule is economically feasible for each of the industries engaged in construction activities. OSHA further notes that while there may be additional costs (not attributable to the final rule) for some employers in construction industries to come into compliance with the preceding silica standard, these costs do not affect the Agency's determination of the economic feasibility of the final rule. Below, OSHA provides additional information to further support the Agency's conclusion.

[44] Tables VI-A-3 and VI-A-4 in Appendix VI-A show per-establishment annualized costs and ratios of annualized cost to annual revenue and annualized costs to annual profit using discount rates of seven percent and zero percent, respectively, to annualize costs. As can be seen, the effects of the lower discount rates on these ratios are quite modest in absolute terms.

Table VI-9: Screening Analysis for Establishments in Construction Affected by OSHA's Final Silica Standard

NAICS	Industry	Total Annualized Costs	Affected Establishments	Annual Cost Per Affected Establishment	Annual Revenues per Establishment ($1000)	Percent Profit	Annual Profit Per Establishment	Cost to Revenue	Cost to Profits

Normal Year-to-Year Variations in Profit Rates

As previously noted, the United States has a dynamic and constantly changing economy in which large year-to-year changes in industry profit rates are commonplace.[45] A recession, a downturn in a particular industry, foreign competition, or the increased competitiveness of producers of close domestic substitutes are all easily capable of causing a decline in industry profit rates of well in excess of ten percent in one year or for several years in succession.

To demonstrate the normal year-to-year variation in profit rates for all the establishments in construction affected by the rule, OSHA developed Table VI-10 and Table VI-11, which show, respectively, year-to-year profit rates and year-to-year percentage changes in profit rates, by industry, for the years 2000–20012.[46] For the combined affected industries in construction over the 13-year period, Table VI-11 shows an average change in profit rates of 63.09 percent a year. If the three worst years are excluded, there is still substantial variation in profits, far larger than the change in profits that would be necessary if the costs of this rule cannot be passed on.

These data indicate that even if the annualized costs of the rule for the most significantly affected construction industries were completely absorbed in reduced annual profits, the magnitude of reduced annual profit rates is well within normal year-to-year variations in profit rates in those industries and does not threaten their economic viability. Of course, a permanent loss of profits would present a greater problem than a temporary loss, but it is unlikely that all costs of the rule would be absorbed in lost profits. Given that the overall price elasticity of demand for the outputs of the construction industry is fairly low[47] and that almost all of the costs estimated in Chapter V are variable costs, the data and economic theory suggest that most firms will see small declines in output; none but the most extremely marginal firms would face any real risk of closure. Many parts of the construction industry have already absorbed much more drastic changes in profit without evidence of industry collapse or major change.

---

[45] OSHA expects that large year-to-year variations in revenues and prices in construction industries are also commonplace. However, OSHA does not have price data for construction industries comparable to the producer price indices available for manufacturing industries.

[46] The IRS profit data for construction industries were available only at the 3-digit NAICS level in 2000 and 2001. Therefore, the reported profit data were the same for each construction industry in those years.

[47] See, for example, Durlauf and Blume (2008), p. 547, which concludes that recent estimates of the after-tax price elasticity of housing demand cluster around -0.5. The article by Hanushek and Quigley (1980) reaches similar findings. For office and hotel construction, see Wheaton, Torto, and Evans (1997) and Wheaton and Rosoff (1998), whose empirical results suggest a price elasticity of demand for office and hotel construction of -0.4.

Market Structure and Market Impacts in the Construction Industry

At a conceptual level, the market-determined output of the construction industry depends on the intersection of demand and supply curves. Incremental compliance costs of the rule (which are almost entirely variable costs) shift the construction supply curve upward. The net effect is an increase in the price for construction activities and a reduction in the level of activity (with the magnitude of this effect depending on the price elasticity of demand). Lower levels of activity mean less construction work, a reduction in the number of construction establishments, and a concomitant reduction in construction employment. The greater the price elasticity of demand and the greater the increase in marginal costs, the larger will be the reduction in equilibrium output. In terms of prices, the greater the price elasticity of demand, the smaller the increase in prices will be for a given increment to marginal costs, and the larger the reduction in output.

Increasing the cost of construction project activities that generate silica exposures has two effects on the demand for these activities. First, increasing the cost of silica-related jobs relative to the costs of other construction inputs might result in substitution away from this type of work. Architects, building designers, and contractors might be more likely to choose building methods and materials that eliminate or reduce the need to perform silica-related jobs. For example, pre-cast concrete structures that require a relatively high level of concrete finishing work would become more expensive relative to other building technologies. Contractors and others could reduce the cost impact of the standard by switching to other building methods unaffected by the silica rule when the alternative would result in lower cost than would compliance with the rule. The magnitude of these impacts will depend on the feasibility, characteristics, and relative expense of alternative technologies.

Second, some of the increase in the cost of silica-generating activities will increase the marginal cost of construction output and cause the construction supply curve to shift upward, resulting in a higher price for each quantity produced. The magnitude of the impact of the cost increases due to the silica rule on the supply relationship will depend on the size of the cost increases and the importance of silica-generating activities in the overall cost of construction projects. If the silica-generating activities are a small portion of the overall cost of construction then the supply curve shift will be smaller when compared to a shift in the supply curve from silica-generating activity that is a large portion of the overall cost of construction. If, for example, there is a one percent increase in the costs of a silica generating activity and the silica generating activity constitutes only one percent of the costs of a building, then the total increase in the cost of the building will be an almost unobservable 0.01 percent. Magnitude of shifts in derived demand for a service used in making another product are determined by the price change for the final product, not the price change for the service itself.

In practice, if one considers the costs of the final rule relative to the size of construction activity in the United States, it is clear that the price and profit impacts of the final rule on construction industries must be quite limited. The annualized cost of the final rule would be equal to approximately 0.1 percent of the value of annual construction activity in the U.S. Moreover, construction activity in the U.S. is not subject to any disadvantage from foreign competition-- any foreign firms performing construction activities in the United States would be subject to OSHA regulations.

Impacts by Type of Construction Demand

The demand for construction services originates in three independent sub-sectors: residential building construction, nonresidential building construction, and nonbuilding construction.

Residential Building Construction

Residential building demand is derived from the household demand for housing services. These services are provided by the stock of single and multi-unit residential housing units. Residential housing construction represents changes to the housing stock and includes construction of new units and modifications, renovations, and repairs to existing units. A number of studies have examined the price sensitivity of the demand for housing services. Depending on the data source and estimation methodologies, these studies have estimated the demand for housing services at price elasticity values ranging from -0.40 to -1.0, with the smaller (in absolute value) less elastic values estimated for short-run periods (Glennon, 1989, Document No. 0707; Mayo, 1981, Document No. 0794). In the long run, it is reasonable to expect the demand for the stock of housing to reflect similar levels of price sensitivity.

Many of the silica-generating construction activities affected by the rule are not widely used in single-family construction or renovation (See Profile of Affected Industries, Chapter III). This assessment is consistent with the cost estimates that show relatively low impacts for residential building contractors (See Table VI-9 – the costs as a percent of revenues for Residential Building Construction are estimated to be 0.03 percent and the costs as a percent of profits are estimated to be 1.29 percent). Multi-family residential construction might have more substantial impacts, but, based on Census data, this type of construction represents a relatively small share of net investment in residential buildings.

In 2012 approximately 9,000 multifamily buildings were completed versus 483,000 single family buildings completed.[48]

Nonresidential Building Construction

Nonresidential building construction is defined by the NAICS codes as consisting of industrial, commercial, and other nonresidential structures. As such, construction demand is derived from the demand for the output of the industries that use these types of buildings. For example, the demand for commercial office space is derived from the demand for the output produced by the users of the office space. The price elasticity of demand for this construction category will depend, among other things, on the price elasticity of demand for the final products produced, the importance of the costs of construction in the total cost of the final product, and the elasticity of substitution of other inputs that could substitute for nonresidential building construction. ERG found no studies that attempted to quantify these relationships. But given the costs of the silica rule relative to the size of construction spending in the United States, the resultant price or revenue effects are likely to be quite small as well.

Nonbuilding Construction

Nonbuilding construction includes roads, bridges, and other infrastructure projects. Utility construction (power lines, sewers, water mains, etc.) and a variety of other construction types are also included. A large share of this construction (63.8 percent) is publicly financed (ERG, 2007a, Document ID 1709). For this reason, a large percentage of the decisions regarding the appropriate level of such investments are not made in a private market setting. The relationship between the costs and price of such investments and the level of demand might depend more on political considerations than the factors that determine the demand for privately produced goods and services.

While a number of studies have examined the factors that determine the demand for publicly financed construction projects, these studies have focused on the ability to finance such projects (e.g., tax receipts) and socio-demographic factors (e.g., population growth) to the exclusion of cost or price factors. In the absence of budgetary constraints, the price elasticity of demand for public investment is therefore probably quite low. On the other hand, budget-imposed limits might constrain public construction spending. If the dollar value of public investments were fixed, a price elasticity of demand of one would be implied and any percentage increase in construction costs would be offset with

---

[48] http://www.census.gov/construction/chars/pdf/c25ann2012.pdf

an equal percentage reduction in investment (measured in physical units), keeping public construction expenditures constant.

Public utility construction comprises the remainder of nonbuilding construction. This type of construction is subject to the same derived-demand considerations discussed for nonresidential building construction, and for the same reasons, OSHA expects the price and profit impacts to be quite small.

SBREFA Comments on Impacts on the Construction Industry

In this section OSHA reviews comments addressing economic impacts in construction that were submitted during the SBREFA process prior to the PEA. OSHA addressed these comments in the PEA that was made available for public comment, but did not receive comments specifically addressing its responses to the SBREFA recommendations. OSHA is reprinting its responses here for the convenience of the reader.

One commenter believed that OSHA had ignored the range of profitability among businesses, and thus did not adequately recognize that the average percentage reduction in profits could mean bankruptcy for those firms struggling to stay afloat (Document ID 0968, p. 7). The Agency's approach to economic feasibility is designed to address the overall health of industries in compliance with legal precedent, which permits OSHA to find a regulation economically feasible even though it may close some marginal firms.[49] In most years, ten percent or more of construction firms exit the industry (See U.S. Census Bureau Business Dynamics Statistics, available at http://www.census.gov/ces/dataproducts/bds/data_firm.html). The slight acceleration of the closure of such firms is not the kind of economic impact that would make a regulation economically infeasible.[50]

The commenter also asserted that OSHA ignored the cost of credit and that this also varies across businesses (Document ID 0968, p. 7). OSHA believes that the cost of credit is not an important issue in this case because OSHA's analysis demonstrates that, in most cases, upfront costs can usually be met from cash flow. Earlier in this chapter, OSHA noted that its choice of a threshold level of ten percent of annual profits for economic feasibility determinations is low enough that even if, in a hypothetical worst case, all compliance costs were upfront costs, then upfront costs would still equal 88.5 percent of

[49] See, e.g., Am. Iron and Steel Inst. v. OSHA, 939 F.2d 975, 980 (D.C. Cir. 1991); United Steelworkers of Am., AFL-CIO-CLC v. Marshall, 647 F.2d 1189, 1265 (D.C. Cir. 1980).

[50] *Indus Union Dep't v. Hodgson*, 499 F.2d 467 (D.C. Cir. 1974).

profits and thus would be affordable from profits alone without needing to resort to credit markets. As shown in Table VI-12, all industries' costs are a very small percentage of profits, assuring that even upfront costs can be met from profits without resorting to credit markets. Further, a firm that is having trouble meeting upfront costs can rent the appropriate tools without incurring any upfront capital investment costs.

A SER asserted that the impact of the rule would be "catastrophic" for the concrete cutting industry. One SER maintained that the rule would be both economically and technologically infeasible for the specialty trade concrete cutting industry (Document ID 0937, p. 69). The Small Business Advocacy Review (SBAR) Panel recommended that OSHA thoroughly review the economic impacts, and develop a more detailed economic feasibility analysis for certain industries (OSHA, 2003, Document ID 0937, p. 69). OSHA believes that the analyses in this chapter and in Chapter IX of this FEA address the SER's comments and the SBAR Panel recommendations.

Concrete cutting is undertaken for such purposes as grooving for projects such as highways, bridges, and sidewalks along with repairing these structures when they become operationally unsound. These contracts are bid on by firms who will all fall under the final silica rule, so there is no economic disadvantage between firms caused by the silica rule. Because the silica rule only applies in areas subject to OSHA jurisdiction, there is no foreign competition that would not also be subject to the silica standard. The cutting industry also works on runways and parking lots along with homebuilders for smaller projects. The demand for these products are relatively inelastic and not subject to foreign competition, enabling these companies to pass most of the costs of this final rule onto their consumers. Based on these analyses, OSHA disagrees that the rule would be "catastrophic" or economically infeasible for the concrete cutting industry.

Economic Feasibility Screening Analysis: Small and Very Small Businesses

The preceding discussion focused on the economic viability of the affected construction industries in their entirety. However, even though OSHA found that the silica standard did not threaten the survival of these construction industries, there is still the possibility that the industries' competitive structures could be significantly altered.

To address this possibility, OSHA examined the annualized costs per affected small entity and very small entity for each affected construction industry. Again, OSHA used a minimum threshold level of annualized costs equal to one percent of annual revenues—and, secondarily, annualized costs equal to ten percent of annual profits—below which the Agency has concluded that the costs are unlikely to threaten the survival of small entities or very small entities or, consequently, to alter the competitive structure of the affected construction industries.

Compliance costs were distributed across entities using the method described in the general industry screening analysis, above, that is largely in terms of costs per employee, with some exceptions. Table VI-12 and Table VI-13 show that in no construction industries do the annualized costs of the rule exceed one percent of annual revenues or ten percent of annual profits either for small entities or for very small entities. Therefore, OSHA concludes, based on its screening analysis, that the annualized costs as a percentage of annual revenues and as a percentage of annual profits are below the threshold level that could threaten the competitive structure of any of the construction industries.

Table VI-12: Screening Analysis for Small Entities in Construction Affected by OSHA's Final Silica Standard

NAICS	Industry	Total Annualized Costs	Affected Small Entities	Annual Cost Per Affected Establishment	Annual Revenues per Establishment ($1000)	Profit Rate	Annual Profit Per Entity	Costs as a Percentage of Revenue	Costs as a Percentage of Profits

Differential Impacts on Small Entities and Very Small Entities

Below, OSHA provides some additional information about differential compliance costs for small entities and very small entities that might influence the magnitude of differential impacts for these smaller businesses.

The distribution of impacts by size of business is affected by the characteristics of the compliance measures. For silica controls in construction, the dust control measures consist primarily of equipment modifications and additions made to individual tools, rather than large, discrete investments, such as might be applied in a manufacturing setting. As a result, compliance advantages for large firms through economies of scale are limited. It is possible that some large construction firms might derive purchasing power by buying dust control measures in bulk. However, given the simplicity of many control measures, such as the use of wet methods on machines already manufactured to accommodate controls, such differential purchasing power appears to be of limited consequence.

The greater capital resources of large firms will give them some advantage in making the relatively large investments needed for some control measures. For example, cab enclosures on heavy construction equipment or foam-based dust control systems on rock crushers might be particularly expensive for some small entities with an unusual number of heavy equipment pieces. Nevertheless, where differential investment capabilities exist, small construction firms may also have the capability to achieve compliance with lower-cost measures, such as by modifying work practices. In the case of rock crushing, for example, simple water spray systems can be arranged without large-scale investments in the best commercially available systems.

In the program area, large firms might have a slight advantage in the delivery of training or in arranging for health screenings. This phenomenon has been accounted for in the analysis that OSHA provides.

Regulatory Flexibility Screening Analysis

To determine if the Assistant Secretary of Labor for OSHA can certify that the final silica standard for construction will not have a significant economic impact on a substantial number of small entities, OSHA applies the same screening analysis to construction as it does for general industry, as discussed earlier in that section and for the same reasons: annualized costs equal to one percent of annual revenues and annualized costs equal to five percent of annual profits applied to each affected industry. OSHA has applied these screening tests both to small entities and to very small entities. For purposes of certification, the threshold levels cannot be exceeded for affected small entities or very small entities in any affected industry.

Table VI-12 and Table VI-13 show that in no construction industries do the annualized costs of the rule exceed one percent of annual revenues or five percent of annual profits either for small entities or for very small entities. However, as previously noted in this chapter, OSHA is unable to certify that the final standard will not have a significant economic impact on a substantial number of small entities in general industry and maritime and must prepare a Final Regulatory Flexibility Analysis (FRFA). The FRFA is presented in Chapter IX of this FEA.

EMPLOYMENT IMPACTS ON THE U.S. ECONOMY

The discussion below on employment impacts of the silica rule on the U.S. economy is divided into three parts: (1) a brief summary of the employment impacts of the proposed silica rule (based on an analysis performed for OSHA by its subcontractor, Inforum, in 2011) that the Agency included in the PEA in support of the silica proposal; (2) a review of estimates provided by commenters on the employment effects of the silica proposal; and (3) a summary of a recent analysis of the employment effects of the final silica rule that Inforum performed for OSHA, followed by a critique of the commenters' analysis of employment effects relative to Inforum's analysis.

Inforum Analysis of Employment Effects Prepared for Silica Proposal

In October 2011, OSHA directed Inforum[51] to run its macroeconomic model to estimate the employment impacts of the costs[52] of the proposed silica rule. Inforum ran the model for the ten-year period 2014-2023 and reported its annual and cumulative employment and other macroeconomic results. While employment effects varied from year to year and from industry to industry, a key Inforum result was that the proposed silica rule cumulatively would generate an additional 8,625 job-years over the period 2014 - 2023, or an additional 862.5 job-years annually, on average, over the period.[53] A fuller discussion of Inforum's macroeconomic model and the results of its analysis can be found in Chapter VI of the PEA in support of OSHA's silica proposal and in the Inforum report itself (Inforum, 2011).

Estimates by Commenters on Employment Effects of the Silica Proposal

Three commenters on the silica proposal—the National Federation of Independent Business (NFIB) with the NFIB Research Foundation; the American Chemistry Council (ACC) with Stuart Sessions of Environomics, Inc.; and the Construction Industry Safety Coalition (CISC)

---

[51] Inforum, which stands for the INterindustry FORecasting at the University of Maryland, is a non-for-profit Maryland corporation. Inforum has over 45 years of experience designing and using macroeconomic models of the United States (and other countries). Details of Inforum's macroeconomic model are presented later in this section.

[52] The estimated cost at the time was approximately $650 million in 2009 dollars using a 3 percent discount rate.

[53] A "job-year" is the term of art used to reflect the fact that an additional person is employed for a year, not that a new job has necessarily been permanently created.

with Environomics, Inc.—provided or reported estimates of the employment effects of the proposed silica rule. These commenter estimates are summarized below.

1. The NFIB Research Foundation performed a study (Document ID 2210, Attachment 2) to estimate the employment and other macroeconomic effects of OSHA's proposed rule, using the Agency's own estimates of the annualized compliance costs of the proposed rule for affected employers of approximately $637 million in 2009 dollars. The study modeled (a) anticipated employer costs due to the proposed rule, (b) changes to private sector demand, and (c) changes to state and local government spending associated with the proposed rule, and then forecast their effects using NFIB's Business Size Impact Module (BSIM) to run a simulation. The BSIM is a dynamic, multi-region model based on the Regional Economic Models, Inc. (REMI) structural economic forecasting and policy analysis model, which integrates input-output, computable general equilibrium, econometric, and economic geography methodologies. Costs were estimated by 5 size classes of firms. It was noted that the annualized compliance costs of the proposed rule

> …also represent new demand for private sector goods and services for firms who assist businesses affected by the new PEL in complying with the proposed rule. In the BSIM, this new demand for goods and services provided by the private sector acts as a countervailing force to any negative impact on employers the new annualized compliance costs may have (Document ID 2210, Attachment 2, p. 8).

The summary findings of the NFIB Research Foundation study included an overall loss of 27,000 jobs and lost output of over $72 billion in the long run, with at least half the loss expected to occur in the small business sector.

2. The American Chemistry Council (ACC) (Document ID 4209-A1) reported on Mr. Sessions's post-hearing brief (Document ID 4231), which provided estimates of the economic and employment impacts of the general industry costs to comply with the proposed silica rule and, in addition, criticized Inforum's estimates of the employment effects of the proposed silica rule (Inforum, 2011).

Mr. Sessions estimated economic impacts based on the URS Corporation estimates of $6.131 billion as the cost of the proposed silica rule on 19 general industry sectors (Document ID 4209-1, pp. 102-103). (Note that the analysis does not include the construction sector and is more than 50 times higher than OSHA's general industry cost estimate in the proposal). The economic impacts were estimated in two analytical steps: (1) estimate the impact of the proposed regulation's compliance costs on the value of output of the affected industries; and (2) estimate how the expected changes in output will reverberate throughout the economy, using IMPLAN—a well-known input-output model of the U.S. economy.

The first step was achieved by estimating the amount of cost pass-through of the compliance costs, using a supply elasticity of 1.0, and then estimating the demand response to this price increase assuming a demand elasticity of -1.5. This results in a decline in industry revenue equal to about 20 percent of annualized compliance costs, which—given URS's estimates of compliance costs—is equal to $1.23 billion per year. Again using the IMPLAN model, the corresponding estimated employment effect is 18,000 lost jobs annually (5,400 direct effect;

5,000 indirect effect; and 7,500 induced effect) and a loss in economic output/GDP of more than $1.6 billion per year.

Additionally, Mr. Sessions reviewed Inforum's analysis of the employment impacts of the proposed rule. He asserted that OSHA had supplied Inforum with year-by-year compliance costs that were only 53 percent of the annualized costs that OSHA had estimated in the PEA so that Inforum's projections of employment effects would be seriously underestimated:

> OSHA estimates the cost of the Proposed Standard to be $658 million per year in 2009 dollars on an annualized basis, excluding the hydraulic fracturing industry. Assuming a 7%/year discount rate, this annual cost, *continuing forever* as OSHA estimates it will, is equivalent to a present value cost of $9.4 billion dollars in the initial year of compliance. For comparison with this figure, I calculate (also assuming a 7% discount rate) that the present value in the first year for the ten-year schedule of compliance costs shown in Inforum's Table 1 is only $5.0 billion [italics added] (Document ID 4231).

In reviewing the above procedures, OSHA concludes that Mr. Sessions has misinterpreted his own calculations. The annualized value of an infinite series of costs (i.e., continuing forever) discounted at 7 percent is equal to 0.07 (the annualization factor) x the present value (PV). Hence, the annualized cost of Mr. Session's present value of $9.4 billion should equal $658 million. Now, OSHA provided a stream of costs for 10 years, not forever. The annualization factor for annualized costs incurred over ten years using a 7 percent discount rate is equal to 0.1424. Therefore, the PV of OSHA's costs given to Inforum should be $658 million/0.1424, or about $4.6 billion. Mr. Sessions only confused issues by using first-year costs (which is irrelevant to his exercise) rather than annualized costs. So, there is nothing in Mr. Sessions's calculations that would suggest that OSHA had provided Inforum with seriously incomplete costs. However, just to make sure, OSHA and ERG also reviewed the year-by-year proposal cost data given to Inforum (for Inforum, 2011) and found nothing amiss.

3. The Construction Industry Safety Coalition, submitted a late comment on the silica proposal (CISC, 2015), which contains estimates prepared by Environomics, Inc. (Environomics, 2015) of the employment impacts of the proposed silica rule on the construction sector. This late comment, including the contained Environomics study, has been excluded from OSHA decision-making consideration, but is presented here for informational purposes only.

The employment effects estimated by Environomics (2015) reflect annual costs to construction industries of $4.9 billion, which includes almost $3.9 billion of direct compliance costs to construction employers and another $1.05 billion of costs passed through from general industry (as a result of the silica rule for general industry) to the construction industry. Environomics used the IMPLAN model to translate the estimated $4.9 billion annual cost of the silica rule into more than 52,700 lost jobs related to the construction industry. These job losses would consist of about 20,800 in construction; 12,180 additional jobs lost in industries that supply materials, products, and services to the construction industry; and nearly 20,000 further jobs lost when those who lose their jobs in construction and supplier industries no longer have earnings to spend (i.e. "induced" jobs). Furthermore, Environomics argued that "(t)hese job figures are expressed on a full-time equivalent basis. Given the number of part-time and seasonal jobs in construction, the number of actual workers and actual jobs affected will be much more than 52,700" (Environomics, 2015, p. 2).

Inforum Analysis of Employment Effects of the Final Silica Rule

In December 2015, OSHA directed Inforum to run its macroeconomic model to estimate the industry and aggregate employment impacts on the U.S. economy of the cost of OSHA's final silica rule.[54] The Agency believes that the specific model of the U.S. economy that Inforum uses—called the LIFT (Long-term Interindustry Forecasting Tool) model—is particularly suitable for this work because it combines the industry detail of a pure input-output model (which shows, in matrix form, how the output of each industry serves as inputs in other industries) with macroeconomic modeling of demand, investment, and other macroeconomic parameters.[55] The Inforum model can thus both trace changes in particular industries through their effect on other industries and also examine the effects of these changes on aggregate demand, imports, exports, and investment, and in turn determine net changes to Gross Domestic Product (GDP), employment, prices, etc.

Using industry-by-industry compliance cost estimates provided by OSHA,[56] Inforum employed the LIFT model of the U.S. economy to compute the industry-level and macroeconomic impacts expected to follow implementation of the silica standard. The general methodology was to embed the compliance costs into the industry price functions of the LIFT model, solve the equations of the model with the additional costs included in the calculations, and then compare the simulation to a baseline scenario which did not include the additional costs. Enforcement of the rule was

[54] The estimated cost of the final rule that OSHA provided Inforum was about $962 in annualized terms in December 2015. The final cost presented in this FEA is about $1,030 million in annualized terms, or about 7 percent ($68 million) higher than the costs used by Inforum to estimate the employment effects of the final rule. OSHA believes that if the most recent cost estimates had been used, they would have had a minor effect on Inforum's estimate of the employment impact of the final rule.

[55] The LIFT model combines a dynamic input-output (I-O) core for 110 productive sectors with a full macroeconomic model with more than 1,200 macroeconomic variables that are consistent with the National Income and Product Accounts (NIPA) and other published data. LIFT employs a "bottom-up" regression approach to macroeconomic modeling (so that aggregate investment, employment, and exports, for example, are the sum of investment and employment by industry and exports by commodity). Unlike some simpler forecasting models, price effects are embedded in the model and the results are time-dependent (that is, they are not static or steady-state, but present year-by-year estimates of impacts consistent with economic conditions at the time).

[56] OSHA contractor ERG provided silica-rule compliance cost data for 13 segments of the construction sector plus construction activity by state and local governments, and for 102 industrial sectors. The costs were specified in 2012 dollars and covered a 10 year horizon, beginning with the implementation of the rule. The data covered eight cost types and were classified as intermediate, capital, and direct labor costs. In order to integrate the compliance costs within the LIFT model framework, Inforum established a mapping between the OSHA NAICS-based industries and the LIFT production sectors. See Inforum (2016) for a discussion of these and other transformations of OSHA's cost estimates to conform to the specifications of the LIFT model.

assumed to start in 2017 in construction and in 2018 in general industry and maritime (with enforcement of engineering control requirements for hydraulic fracturing activities beginning in 2021). The timing of the compliance costs reflected the phased-in enforcement of the rule, and the LIFT model results were calculated over a ten-year horizon, that is, through 2026.

The most significant Inforum result is that the final silica rule cumulatively generates an additional 9,500 job-years over the period 2017-2026, or an additional 950 job-years annually, on average, over the period (Inforum, 2016). It should be noted, however, that these results vary significantly from year to year. For example, in 2017, the first year in which the silica final rule would be in effect and when most capital costs for control equipment would be incurred, an additional 21,100 job-years would be generated as a result of the silica rule. Then, through 2026, the change in job-years relative to the baseline ranges from a high of 19,600 (in 2019) to a low of -17,300 (in 2020).[57] Inforum emphasized that all of these estimated job-year impacts of the silica rule, both positive and negative, should be viewed as negligible—relative to total U.S. employment of between 157 and 168 million workers during the time period under consideration and not statistically different from an estimate of 0 job-years (that is, that the silica rule would have no job impact).

The employment impacts of the silica rule would also vary significantly from industry to industry and from sector to sector. For example, for the period 2017 - 2026, the construction industry would, on average, gain 4,260 job-years annually while the rest of the U.S. economy would, on average, lose 3,310 job-years annually. Again, relative to total employment in the construction sector of about 10 million workers and employment in the rest of the U.S. economy of about 150 million workers over the 10-year period, these employment impacts should be considered negligible. For a fuller discussion of OSHA's estimate of the employment and other macroeconomic impacts of the silica rule, see Inforum (2016).

One obvious question is why the employment impacts of the silica rule would be positive in construction and negative elsewhere. There seem to be two major reasons. One is that, as reflected in the Inforum model, there is little foreign competition in U.S. construction and the price elasticity of demand in construction is extremely low relative to demand for products in most other industries. Hence, output and employment would be expected to decline minimally in response to any price increase if employers in construction pass on the costs of the silica rule. Second, and probably more important in OSHA's view, compliance with many of the provisions in the silica rule is relatively labor-intensive, often requiring the application of additional labor in the regulated firms themselves. Examples would include time spent for training, medical surveillance, and activities to meet the PEL (such as setting up and using control equipment and performing housekeeping tasks). The increased labor required to produce a unit of output in regulated firms would tend to increase employment in those industries (holding output constant). This is particularly true in construction, where compliance with the PEL would be much more

[57] The fluctuations in employment from year to year as a result of the proposed rule reflect how the Inforum model works The model has large short-term multipliers (from the initial increase in compliance expenditures) but long-term stabilizers to return to an equilibrium output and employment level. Hence, the short-term multipliers may cause output and employment to overshoot in one year and adjust in the other direction in the next year or two as the model (and the real-world economy) equilibrates

labor-intensive—both because engineering controls in construction are typically mobile and require more worker activity and because housekeeping and other worker actions are expected to play a larger role in achieving compliance with the PEL. By comparison, engineering control equipment in general industry/maritime is usually in a fixed location (eliminating the need for workers to move the equipment) and worker actions would play a smaller role in achieving compliance with the PEL.

Finally, OSHA turns to a critique of the commenters' analysis of employment effects of the proposed silica rule relative to Inforum's analysis of employment effects of the final silica rule. This critique reflects comments provided in the Inforum report (Inforum, 2016).

The NFIB Research Foundation Analysis: Although the NFIB Research Foundation study (Document ID 2210, Attachment 2) reported that careful attention was given to the analysis of costs and their attribution by firm size, it doesn't offer much information on how the BSIM model works or how the results were obtained. "From what is generally known about the REMI model upon which it is based, the general mechanism is probably the sequence of (1) increased costs leading to (2) increased output price leading to (3) reduced demand and therefore jobs" (Inforum, 2016, p. 8). The study does acknowledge that the costs also represent new private sector demand for firms that assist affected employers in complying with the new PEL, but the purported positive impacts of this private sector demand are not visible in the study. Presumably the reported impacts are net effects that combine the negative effects from the increased prices and reduced demand of the affected sectors with the stimulus from spending on the supplying sectors; however, that is not clear, and the stimulus is not quantified. In Inforum's analysis (Inforum, 2016), these effects are explicitly considered, both for intermediate goods and services as well as investment.

Another important difference from Inforum's analysis is that the NFIB study did not attempt to quantify the additional jobs created in the affected industries. In Inforum's LIFT model, these were captured as changes in labor productivity. For several industries, especially construction, although the industry does experience increased costs, it must also hire more workers to comply with the silica rule. The additional jobs required in the affected industries are not discussed or apparently modeled in the NFIB study. In summary, it seems that the counteracting influences due to intermediate and investment related purchases from other industries, and the job-creating expenditures in the affected industries were not, in fact, captured in the study.

The CISC and ACC Studies: These two studies are being critiqued together because they both rely on costs many times higher than OSHA's estimates and because they both made projections using the IMPLAN model.

What accounts for the difference between LIFT simulations and the CISC and ACC estimates? There are several factors at play:

Probably most importantly, CISC's estimate starts with annual compliance costs for the construction industry that are nearly 7 times larger than OSHA's estimates for the construction industry (only) ($4.1 billion vs. an average of over $600 million, both in 2012 dollars). Meanwhile, the ACC study estimates costs for general industry that are more than 16 times larger than OSHA's estimates for the final rule ($6.1 billion in 2009 dollars versus $359 million in 2012 dollars. Moreover, the CISC and ACC studies assumes that the same annualized cost estimates are imposed each year, whereas the OSHA cost estimates vary over the 10 year time period, with peak costs occurring in the first year.

Neither the CISC nor the ACC application of the IMPLAN model accounted for the increase in demand for capital equipment and intermediate goods and services needed to comply with the proposed silica rule. Thus, the employment and income boosting impacts of these expenditures are not captured in their analysis. In contrast, Inforum's methodology uses an explicit price function where annual compliance costs by industry change commodity prices in proportion to their share of total annual gross costs. In turn, price changes affect production and employment through a dynamic general equilibrium framework. Demand and supply price elasticities in the LIFT model are composites of several sets of empirically estimated functions for final demand, exports, imports, and price mark-ups. Furthermore, the parameters of these functions vary by type of product according to the econometric estimation.

At OSHA's request, Inforum made a separate run using the LIFT model in the absence of the final silica rule for the construction industry but with the final silica rule for general industry and maritime. The purpose of this run was to calculate the indirect effects (only) of the final silica rule for general industry and maritime on prices and employment in the construction industry (Inforum, 2016). This LIFT simulation estimated that the final silica rule for general industry and maritime indirectly increased prices in the construction industry by an average of .005 percent. The direction, if not the magnitude of this effect, is consistent with the CISC/Environomics results (Environomics, 2015). This led to a modest decline in construction output and construction jobs. As shown in Table 9, the decline in jobs varied from +290 to -940 a year over the period 2017 to 2026, with a cumulative job impact of -4.8 thousand jobs over the 10-year period. Again, it should be emphasized that this separate run was made in the absence of the final silica rule for the construction industry.[58]

The IMPLAN model is static and cannot compute employment and output impacts over time, and it cannot show how the economy evolves to cope with changes in costs. In order to extrapolate over ten years, the authors simply multiply the first year effects by 10. The results are implausible for a dynamic economy as the full static one-year impact is unlikely to be the average impact over the course of several years. At least theoretically, the economy contains powerful forces pushing it towards full employment equilibrium. Therefore, most changes to output and employment due to cost or demand shocks tend to be neutralized through time. That is, most impacts, negative or positive, will approach zero over the long term. Indeed, Inforum's LIFT model produces dynamic results that vary from year to year, which is consistent with fluctuations in the state of the economy and with short and long term expenditure effects. It

[58] As shown in Table 6, the cumulative effect of the final rule for general industry, maritime, and construction is to increase construction employment by 42,600 job years over the 10-year time period (from Table 6), or about 4,260 jobs a year, on average. Hence, the cumulative effect of the final rule for construction alone is to increase construction employment by about 47,400 (42,600+4,800) jobs, or about 4,740 jobs a year, to the extent that the two components are additive.

shows how the employment is reallocated among industries and how the economy eventually will return to the baseline, or potential, level of employment.

While the IMPLAN study places the regulatory analysis within the context of the overall economy, it does not take full advantage of the framework. For instance, given data for gross output in the base year it is possible to compute the industry price effect so that the revenue shocks can be judged relative to a price elasticity of demand. Instead, the study employs an unrealistically large construct of a 5 to 1 compliance cost to revenue loss. Finally, the IMPLAN model's inability to model the long-term properties of the economy severely undermines the study's conclusion of long term cost to the economy.

CHAPTER VII: BENEFITS AND NET BENEFITS

INTRODUCTION

In this chapter, OSHA discusses the benefits and net benefits of the final silica rule. To set out an approach to estimate the benefits, the Agency will, in the following sections, estimate the number of silica-related diseases prevented as a result of the rule, estimate the timing of the potentially avoided diseases, monetize their economic value, and discount them. Taking into account the estimated costs of the final rule, presented in Chapter V of this FEA, OSHA will then estimate the net benefits and incremental benefits of the rule. Finally, the Agency will assess the sensitivity of the estimates to changes in various cost and benefit parameters.

This chapter presents OSHA's quantitative estimates of what rule-induced benefits would be under certain assumptions. OSHA acknowledges that these estimates are heavily influenced by the underlying assumptions, and also that the long time frame of this analysis (60 years) is a source of uncertainty. The assumptions underlying these estimates of deaths and morbidity avoided will be discussed in detail as they appear in the remainder of this chapter, but the major ones are as follows:

- The exposure profile and other industrial profile data presented in Chapter III of this FEA reflect both current conditions and future conditions (extending over the next sixty years);
- To separate the effects of this new rule from the effects of compliance with existing standards, it is assumed that any workers currently exposed above the preceding PEL are exposed to levels of silica that exactly meet the preceding PEL;
- The rule will result in workers being exposed at the new PEL but will never reduce exposures below the new PEL;
- Workers have identical exposure tenures (45 years, except where otherwise noted);
- The effects of baseline respirator use on risk are ignored; and
- The assumptions inherent in developing the exposure-response functions discussed in Section VI, presented in Table VI-1 of the preamble are reasonable throughout the exposure ranges relevant to this benefits analysis. (The reasonableness of these assumptions is discussed in Section VI.)

The first two assumptions are also the basis for the cost analysis in Chapter V of this FEA. The basis for the last assumption is discussed in greater detail in Section VI of the preamble and will be briefly reviewed in this section. It bears emphasis, however, that the sources of data for OSHA's benefits analysis are the same as those used in the Quantitative Risk Assessment (Section VI of the preamble) and the technological feasibility analysis in Chapter IV of this FEA.

While OSHA did not quantify the benefits of the ancillary provisions, consistent with the statute (29 U.S.C. 655(b)(7), section 6(b)(7)), the Agency finds that these provisions are beneficial and necessary in order for the standard to be fully and correctly implemented and for the full benefits of the rule to be realized. On the whole, OSHA intends the requirements for training on control measures, housekeeping, and other ancillary provisions of the rule to apply where those measures are used to limit exposures. Without effective training on use of engineering controls, for example, it is unreasonable to expect that such controls will be used properly and consistently. The ancillary provisions found in the rule are generally standard and common throughout OSHA regulations.

The provision requiring exposure assessment in general industry is integral to determining the engineering controls and work practices needed to control employee exposure to the new PEL, to evaluate the effectiveness of the required engineering and work practice controls, and to determine whether additional controls must be instituted. In addition, monitoring is necessary to determine which respirator, if any, must be used by the employee, and it is also necessary for compliance purposes.

The requirement for regulated areas in general industry and maritime serves several important purposes including alerting employees to the presence of respirable crystalline silica at levels above the PEL, restricting the number of people potentially exposed to respirable crystalline silica at levels above the PEL, and ensuring that those who must be exposed are properly protected. Similarly, the competent person requirement in the construction standard will protect bystanders by restricting access to work areas only when necessary, benefiting those bystanders through reduced exposures.

Written exposure control plans provide a systematic approach for ensuring proper function of engineering controls and effective work practices that can prevent overexposures from occurring. OSHA expects a written exposure control plan will be instrumental in ensuring that employers comprehensively and consistently protect their employees.

The medical surveillance provisions have the potential to protect workers through the early detection of silica-related illnesses and will enable employees to take actions in response to information about their health status gleaned from medical surveillance. Additionally, by requiring medical surveillance to general industry and maritime workers exposed at or above the action level, OSHA provides an incentive for employers to further reduce exposures, where possible, to avoid incurring the costs of medical surveillance.

ESTIMATES OF THE NUMBER OF AVOIDED CASES OF SILICA-RELATED DISEASE

For reasons described in detail in the preamble, OSHA has adopted a PEL of 50 μg/m^3 in its silica standards covering general industry, maritime, and construction, along with an alternative method of compliance (Table 1) in construction. Analogous to the estimates in the PEA, OSHA has calculated estimates of the benefits associated with the PEL of 50 μg/m^3 for respirable crystalline silica, and corresponding Table 1 in construction, by applying the dose-response relationships developed in OSHA's quantitative risk assessment (QRA) to exposures at or below the preceding PELs.

Exposure profiles

OSHA determined exposure levels at or below the preceding PELs by first developing an exposure profile of current exposures for industries with workers exposed to respirable crystalline silica, using OSHA inspection and site-visit data, and then applying this exposure profile to the total current worker population. The industry-by-industry exposure profile is presented in Chapter III of this FEA.

Because OSHA relied solely on measurement of airborne exposures, respirator use may result in lower baseline exposures inside the respirator than would be indicated by the airborne exposures measurements. The extent to which this affects OSHA's benefits calculations depends on the extent to which there was baseline respirator use in the risk assessment studies OSHA relied on and how these studies accounted for respirator use, if they did so at all. OSHA reviewed the risk assessment studies it is relying on as well as earlier studies that described the source of exposure data for each cohort and how exposures were estimated for cohort members to determine whether respirator use was accounted for. OSHA found that the overwhelming majority of studies did not mention either respirator use or how they accounted for respirator use, even though many took place in time periods and at exposures levels where some respirator use could have been expected. Some studies accounted for use of "dust controls" but did not state whether these "dust controls" included respirator use. Two studies (Rando et al. (2001, Document ID 0415), whose exposure estimates for North American industrial sand workers were used by Hughes et al. (2001, Document ID 1060), and Dosemeci et al. (1993), whose exposure estimates for Chinese mine and pottery workers were modified and used by Chen et al. (2001, Document ID 0332; 2005, Document ID 0985), mention adjusting exposure estimates to account for respirator use, but did not discuss in detail how these adjustments were calculated. Most studies OSHA relied on, directly or indirectly, cover long periods of time, over which respirator use varied. Most cover some time after OSHA set a general industry PEL of approximately 100 μg/m^3 and required the use of a respirator if that exposure level was exceeded. In summary, OSHA does not know the extent of respirator use in the risk assessment studies relied on for the benefits analysis, nor how they might differ from current respirator use. As a result, OSHA is unable to accurately adjust its estimates to account for baseline respirator use.

OSHA also is not able to quantify the effectiveness of respirator use. (OSHA regulations provide for assigned protection factors, but these are based on ideal conditions rather than real world conditions.) It is thus difficult to know how to correct for possible respirator use. As will be discussed below, OSHA estimates benefits relative to a baseline characterized by compliance with the preceding PEL. The preceding PEL in construction and maritime is approximately 250 μg/m^3. If respirators have a protection factor of five, then they would be equivalent to the new PEL of 50 μg/m^3 if fully effective at 250 μg/m^3. In general industry there is a preceding PEL of approximately 100 μg/m^3. If respirators have a protection factor of two, then they would be equivalent to the new PEL of 50 μg/m^3, if fully effective Beyond this, OSHA does not have the data to quantify the effects of respirator use because it is well known that in actual practice in work settings, respirators are not always as protective as the assigned protection factors would indicate. For the purpose of estimating the health benefits of the final rule, exposures above the relevant preceding PELs were set at the relevant preceding PEL; for purposes of comparing the effects of the preceding and the new standards, the analysis thus assumes full compliance with both, without taking baseline respirator use into account.

By applying the dose-response relationships from the literature to estimates of exposures at or below the preceding PELs across industries, it is possible to estimate the number of cases of the following diseases expected to occur in the worker population given exposures at or below the preceding PELs (the "baseline"):

- fatal cases of lung cancer,
- fatal cases of non-malignant respiratory disease (NMRD) (including silicosis),
- fatal cases of end-stage renal disease, and
- cases of silicosis morbidity.

Non-fatal cases of lung cancer, NMRD and end-stage renal disease were not estimated. In that respect, the estimates of benefits are understated. However, OSHA's benefits calculations do not, for example, factor in any impact on the rule's implementation of the following aspect of the Agency's enforcement approach: as a general matter, where compliance with a standard's requirement clearly creates a new hazard, employers can raise a defense that compliance with the requirement is not feasible, and OSHA would work with the employer to implement an alternative means of protection that does not create a serious hazard.[1]

In a comment suggesting that some reductions in exposures (and thus some benefits) were not included in OSHA's analysis, Dr. Ruth Ruttenberg noted that "OSHA/ERG did not consider stomach cancer, autoimmune disease, and other cancer and non-cancer health effects of silica exposure" (Document ID 2256, Attachment 4, p. 11). These potential benefits were not quantified, for the PEA or FEA because the Agency does not, at this time, have sufficient exposure-response data to perform a quantitative risk assessment for these illnesses. The Health Effects and Significance of Risk sections of the preamble contain a more detailed discussion of these potential silica-related health effects that were not quantified.

OSHA's Method for Using Risk Models and Exposure Profile to Estimate Cases Avoided as a Result of the Rule

The core of OSHA's methodology for benefits analysis is to calculate the number of estimated premature deaths and illness cases avoided as a result of the new rule. To do this, OSHA will first estimate the expected number of mortality and morbidity cases expected to occur under the assumption that the preceding PEL is being met (i.e. those workplaces where the preceding PEL is currently exceeded are set equal to the preceding PEL), and then subtract the expected number of mortality and morbidity cases estimated to occur with the new rule in place. To estimate benefits, the Agency first estimates the numbers of disease cases (silicosis morbidities) and deaths (mortalities) that result given the current numbers of workers exposed to silica, assuming full compliance with the preceding PEL (baseline exposure levels). OSHA then estimates the numbers of disease cases and deaths that would result after the new standard goes into effect (i.e., assuming full compliance in that no worker will be exposed in excess of the new PEL). For this purpose, OSHA assumes all exposures above the new PEL are reduced to the new PEL of 50 $\mu g/m^3$. The difference between these estimates represents the numbers of disease cases and deaths that the Agency estimates would be avoided as a result of issuing the

1 In FEA Chapter 4, OSHA responds to commenters who have stated that safety hazards would increase in the presence of the rule (due to, for instance, use of wet methods on roofs) by suggesting technologically feasible alternatives, including using wet methods or exhaust ventilation on the ground or on platforms or scaffolds. Other commenters also described how fall protection on roofs was already being used where wet methods are employed.

new standard. That is, this approach focuses on calculating estimates derived from eliminating those exposures between the preceding PEL and the new PEL. As explained later, these estimated mortality and morbidity cases avoided are then monetized to comprise the benefits (in dollar terms) of the rule.

By focusing on exposures between the preceding PEL (even for workers exposed above the preceding PEL) and the new PEL exclusively, and ignoring the possibility that workers' exposures are reduced below the new PEL, OSHA's calculations will have a tendency toward underestimation. Some exposures may be reduced to below the new PEL of 50 $\mu g/m^3$ as a result of engineering controls that do more than needed. Also, some exposures below the new PEL of 50 $\mu g/m^3$ may be reduced further due to "bystander effects," by which those already exposed below the new PEL but working near other exposed workers would have their exposures reduced further.

In order to estimate the number of deaths prevented, OSHA uses a lifetime risk model, which is a mathematical framework that explicitly follows workers from the beginning of their work lives until retirement. Workers are assumed to start work at age 20 and work continuously until age 65, resulting in a 45-year work life, and then assumed to live another 15 years post-retirement, or until age 80. This estimate is useful because the OSH Act requires OSHA to examine exposures for an entire working life. Shorter job tenures will be discussed further below.

Using this model, OSHA calculates the workers' cumulative workplace exposures to silica, and estimates the probability of their dying each year from silica-related diseases. The model also establishes the background probability of the workers' dying from non-silica-related causes. The increase in the workers' probability of dying due to cumulative silica exposure in the workplace is added to this background probability. As will be explained in more detail later, the difference in these probabilities is used to form the basis for estimating the number of illnesses and deaths due to silica exposures as they currently exist and the estimated number of illnesses and deaths that would be avoided when the standard is fully in effect, assuming full compliance.

The background, age-specific survival probabilities are based on the current (2011) U.S. (male) population, the latest year for which age-specific all-cause mortality statistics are available.[2] The exposure-response functions for different diseases, which relate

[2] Overall, approximately 3 percent of all construction workers are women. (BLS, 2014--Labor Force Statistics from the Current Population Survey, available at http://www.bls.gov/cps/cpsaat11.pdf). There is no comparable breakdown for manufacturing occupations as a whole but, for selected occupations for which data are available, women are always fewer than 15 percent of the relevant manufacturing workforce. OSHA used background mortality rates for the U.S. male population because the cohorts in the

cumulative silica exposure and increased probabilities of respective disease endpoints, are drawn from specific studies discussed in the preamble, Section VI – Final Quantitative Risk Assessment and Significance of Risk.[3] Estimates of the number of cases of silicosis prevented by the new standard were also based on cumulative risk models taken from several morbidity studies, but were not used in life table analyses as was done for mortality (see Section VI of the preamble, Final Quantitative Risk Assessment and Significance of Risk). The exposure levels used in the model cover the U.S. exposure profile as presented in Table III-9 in Chapter III Industry Profile of this FEA. OSHA's exposure profiles for general industry and maritime and for construction contain the estimated numbers of employees exposed within specific bands of exposure levels, assuming full compliance with the preceding PEL: below 25 $\mu g/m^3$, 25 to 50 $\mu g/m^3$, and above 50 $\mu g/m^3$ (in bands of 50 $\mu g/m^3$ to 100 $\mu g/m^3$, 100 $\mu g/m^3$ to 250 $\mu g/m^3$, and above 250 $\mu g/m^3$, whenever any of these bands are above the preceding PEL, OSHA lowered the estimate for the band to the preceding PEL).

The results in Table III-9 represent average daily exposures in the risk model for general industry and maritime. In construction, occupational exposure is commonly intermittent (i.e., not occurring every workday), necessitating an adjustment to accurately estimate

---

key studies used in the Agency's quantitative risk assessment were composed overwhelmingly of male workers. OSHA used the exposure-response models from these studies in a life table analysis to estimate excess risk of disease mortality from exposure to respirable crystalline silica after accounting for competing causes of death due to background causes. Because, in most key studies, the exposure-response models were built using data from male workers only, it is unknown how these models would change for female workers, or for mixed-gender populations, as it is not clear that females would react to the silica exposure in the same exact way as males. There is no such model data available for these cohorts. Furthermore, OSHA believes that use of all-cause mortality data for the U.S. population as a whole is not appropriate since the working populations studied in the cohort studies, as well as the present population of workers covered by the rule, are overwhelmingly male and do not reflect the nearly equal proportion of males and females represented by the all-cause mortality data for the U.S. population as a whole. If one were to assume that the exposure-response model for female workers was the same as that for male workers, then the resulting relative risk (RR, the ratio of the risk of disease mortality occurring in the exposed to the risk of disease mortality occurring in the unexposed) for a particular cumulative exposure would be the same. Because the risk of disease mortality in the exposed population is calculated by multiplying the RR by the background risk in the unexposed population, the risk of mortality in the exposed population would be different between females and males and would depend upon the background gender-specific disease risks. Because the background cause-specific (e.g., lung cancer or NMRD) mortality for females is generally lower than that for males, the Agency would expect that the predicted risk of mortality to exposed females may be slightly lower than that for exposed males. On the other hand, this effect may be offset by female workers' greater likelihood of surviving to the advanced age groups in which silica-related diseases most typically appear in severe forms and become a cause of death. Given the absence of exposure-response models for female workers, which are required to estimate a proper RR of disease for females, it is impossible to make any sound conclusion on how the risk estimates would change for female workers.

[3] Specifically the low estimate for lung cancer uses estimates from ToxaChemica (2004), the high estimate for lung cancer uses Attfield and Costello (2004), the renal disease estimate uses Steenland, Attfield, and Mannetje (2002), the morbidity estimate for silicosis uses Buchanan, Miller, and Soutar (2003), and the mortality estimate for silicosis uses Mannetje, et al. (2002). See Section VI – Final Quantitative Risk Assessment and Significance of Risk in the preamble for more discussion.

these workers' cumulative exposure and risk. Workers in the construction sector perform a multitude of tasks, only some of which involve silica exposure. OSHA's estimated exposure levels represent the 8-hour time-weighted average of exposure on days when workers perform tasks involving silica exposures. However, to account for the fact that, in most affected construction occupations, workers do not do such tasks every day, the cumulative exposure estimate for these workers needed to be adjusted. To account for this intermittent exposure, the risk model uses an adjustment factor which estimates the percentage of days in which a worker will typically perform tasks that generate silica exposures. These adjustment factors are generally based on the proportion of time workers perform silica-generating activities along with associated work crew sizes.[4] So, for example, if, on average, 20 percent of a group of workers' time is estimated to be spent performing tasks involving silica exposure, the model multiplies the base exposure level—the exposure that the group of workers is estimated to have based on the exposure profile—by this 20 percent. In the Agency's model, this adjustment factor is calculated as the total number of full time equivalent days that affected employees spend on silica-related tasks divided by total affected employment as shown in Chapter III of this FEA. For all construction occupations other than hole drillers using hand-held drills, OSHA calculated an FTE adjustment factor of 28 percent that was derived from the exposure profile. Hole drillers using hand-held drills have a large number of employees and an extremely low adjustment factor as compared to all other occupations. Because the risk models are nonlinear, averaging such disparate groups together provides unrepresentative results and therefore, this occupation has its risk calculated separately. For hole drillers using hand-held drills, OSHA calculated an adjustment factor of 3.5 percent.

In order to calculate the number of expected and avoided cases for each health outcome, OSHA assumes that all workers whose exposures fall within a band are exposed the same and assigns the average of all individual exposure observations within the relevant band (i.e., the mean exposure) as the single point estimate within each band.[5] This point estimate of exposure is then used with the associated risk estimate for each health outcome, which is multiplied by the estimated number of workers exposed within the exposure band to calculate the number of workers who experience that health outcome in the absence of the new rule. For workers currently exposed above the new PEL, OSHA assumes that their post-rule exposures will be lowered to the new PEL of 50 μg/m^3. This reflects the fact that the Agency is estimating no benefits for reducing exposure above the

[4] Detailed methodology and estimates for each occupation are discussed in the construction engineering control cost section in Chapter V of this FEA, in the subsection entitled "Aggregate 'Key' and 'Secondary' Labor Costs for Representative Projects."

[5] Individual exposure data are presented within various sections of Chapter IV, Technological Feasibility, of this FEA. All individual observations are in OSHA (2016) included in the public docket containing the rulemaking record.

preceding PELs to the preceding PELs. The analysis starts from a baseline of the preceding PELs. A similar calculation is then performed at these new exposure levels for these currently overexposed workers: The numbers of workers exposed within each exposure band of the post-rule exposure profile is then multiplied by the associated risk estimates for each health outcome to yield estimates of the numbers of disease cases and fatalities that will occur after the standard is implemented. Finally, subtracting this post-implementation number of deaths and disease cases from those estimated under baseline (pre-rule) conditions yields an estimate of the number of deaths and illness cases averted due to the standard.

As an example, Exhibit VII-1 presents the summary calculations for a risk model that produces one estimate of the number of lung cancer deaths avoided by the revised standard for workers in general industry and maritime if they were all exposed to silica for 45 years (this uses the ToxaChemica, 2004 risk model of lung cancer deaths avoided).

Exhibit VII-1 Lung Cancer Benefits Model

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis and Office of Technological Feasibility

In Exhibit VII-1, the total General Industry population at risk for excess lung cancer is 291,019. There are 142,071 workers in the range of silica exposure of below 25 μg/m^3, 51,377 workers exposed between 25 and 50 μg/m^3, etc. The "Model Exposure Level-Baseline" row provides the mean exposure level within each range, which is the point estimate of exposure for which the associated lifetime risk estimate is used to estimate the number of lung cancer deaths that occur among workers exposed within each exposure range. For example, from the exposure profile, the mean exposure for workers in General Industry who are exposed below 25 μg/m^3 is 14 μg/m^3, and the risk of lung cancer for all workers in this exposure band is calculated from this average exposure of 14 μg/m^3. Though the exposure profile includes 28,297 workers exposed in the range of 100-250 μg/m^3 and 28,443 workers exposed above 250 μg/m^3, to estimate the number of baseline lung cancer deaths, those workers' exposure levels are set at the preceding PEL of 100 μg/m^3. In this example, estimated benefits due to the new PEL do not include any benefits to workers for their exposures being reduced to the preceding PEL; only those benefits associated with the exposure levels being reduced from the preceding PEL or lower to the new PEL are included in the estimates. The row labeled "Model Exposure Level-50 PEL" shows the expected exposures among workers that result after the standard is promulgated. Exposures of workers exposed below 50 μg/m^3 are expected to remain unchanged while the exposures of all workers who are currently exposed above 50 μg/m^3 are expected to be reduced to the new PEL of 50 μg/m^3.[6]

Exhibit VII-1 also presents the estimated excess risk of lung cancer per 1,000 workers for each exposure band and the number of lung cancer deaths that would occur among workers exposed within each exposure band for 45 years. For example, among workers exposed within the lowest exposure band, the lifetime risk model estimates an increased risk of lung cancer above the background mortality risk of 14.7 deaths per 1,000 workers at a constant exposure to 14 μg/m^3 silica for 45 years. Multiplying this risk estimate by the number of workers at risk in that exposure band, (142,071) yields an estimated 2,084 lung cancer deaths. Doing the same across the various baseline exposure level bands results in an estimated baseline total of 5,021 lung cancer deaths due to exposure to silica for the population of workers at risk. The table shows similar estimated lung cancer risks and estimated numbers of deaths in the post-standard scenario. For all workers whose baseline 45-year exposures are at or above 50 μg/m^3, the estimated risk of lung cancer associated with exposure at the new PEL of 50 μg/m^3 is 19.0 per 1,000 workers. Multiplying this risk by the number of workers exposed to silica at levels between 50 and 100 μg/m^3 (41,596), for example, yields an estimated 776 deaths occurring in this group for the post-standard scenario. Doing the same for each exposure band for the post-standard scenario and summing across all exposure bands, the number of estimated

[6] For the purposes of estimating costs and benefits, OSHA assumes full compliance with all applicable OSHA standards.

excess lung cancer deaths post-standard is 4,858. The next two rows show the difference between the baseline and the post-standard scenarios, both for lung cancer death risks ("differential lung cancer death rate") and numbers of deaths ("lung cancer deaths averted"). The final total number of lung cancer deaths averted is 163. Dividing by the analytic time horizon of 45 years results in about 4 annual deaths averted.

The preceding example assumes a constant exposure level each year for 45 years. Elsewhere in this chapter, OSHA examines what would happen if the day-to-day exposure remains the same but job tenure is shorter. In order to have a valid comparison, OSHA compares each scenario to what is estimated to happen over 45 years. All job tasks, and hence cumulative exposure, do not change with decreased job tenure; they are just spread over more workers. Thus, if OSHA were to examine a job tenure of 25 years, almost twice as many workers would be exposed for almost half as long as for the 45-year assumption. With a strictly proportional (linear) risk function the benefits of having half the exposure for twice the number of workers would exactly offset each other and final benefits would be the same. Hence the net effect of such changes is directly related to non-linearities in the various lifetime risk models.

Results for Cases Avoided

OSHA received a number of comments concerning the Agency's preliminary risk assessment and discussion of the health effects of silica in the preamble to the proposed rule. Those comments are discussed in detail in Sections V (Health Effects) and VI (Final Quantitative Risk Assessment and Significance of Risk) of the preamble to the final rule.

OSHA examined the various lung cancer risk models presented in its QRA to estimate the benefits of lowering the PEL. As can be inferred from Table VI-1 of the Final QRA, the ToxaChemica, Inc. (2004) log-linear model estimated the lowest estimate of lung cancer cases avoided from lowering the PEL to 50 or 100 $\mu g/m^3$, whereas the Attfield and Costello (2004) model estimated the highest number of lung cancer cases avoided. The remainder of the studies indicated an intermediate reduction in risk. OSHA used the ToxaChemica 2004 (log-linear model) and Attfield and Costello studies to characterize a range of estimated lung cancer reduction, acknowledging that neither of these estimates captures the full range of uncertainty associated with the models and data used.

Table VII-1 shows the range of modeled estimates for the number of avoided fatal lung cancers for PELs of 50 μg/m^3 and 100 μg/m^3 for the scenario in which workers are uniformly exposed to silica for 45 years. At the final PEL of 50 μg/m^3, the modeling approach yields estimates of 2,921 to 8,246 lung cancers prevented over the lifetime of the worker population, with a midpoint estimate of 5,584 fatal lung cancers prevented. This is the equivalent of between 65 and 183 cases avoided annually, with a midpoint estimate of 124 cases avoided annually, given a 45-year working life of exposure.

Following Park (2002), as discussed in the Agency's QRA, OSHA's estimation model suggests that the final PEL of 50 μg/m^3 would, in the scenario in which workers are uniformly exposed to silica for 45 years, prevent 14,606 fatalities over the lifetime of the worker population from non-malignant respiratory diseases arising from silica exposure.[7] This is equivalent to 325 fatal cases prevented annually. Some of these fatalities would be classified as silicosis, but most would be classified as other pneumoconiosis and chronic obstructive pulmonary disease (COPD), which includes chronic bronchitis and emphysema. That is one reason why we would expect this estimate to exceed the count based solely on death certificates (for instance, in 2013, CDC's count based on state-provided vital records is 111 deaths annually from silicosis in the United States).

Certain commenters argued that the recent CDC count of silicosis mortality from death certificates is evidence that OSHA's benefits were overestimated.

Some commenters, such as the American Chemistry Council and Faten Sabry, Ph.D., representing the Chamber of Commerce, argued—based on the numbers of silicosis-related deaths recorded in recent years reported in mortality surveillance data—that OSHA overestimated the estimated benefits of the standard (Document ID 2263, p. 57; 3729, p. 1; 2288, Appendix 6; 4209, pp. 3-4). Dr. Sabry stated that the 52 deaths reported by the CDC in 2010 where silicosis was identified as an underlying cause of death were considerably fewer than the number of silicosis-related deaths that OSHA claimed would be avoided once the proposed standard becomes fully implemented. Dr. Sabry concluded, "[s]o, by OSHA's calculation, reducing the PEL to 50 μg/m^3 will prevent more silicosis-related deaths than actually occur in the United States today – which suggests that OSHA's risk assessment is faulty" (Document ID 2288, Appendix 6). The National Utility Contractors Association (NUCA) made the same argument when it asserted: "OSHA predicts that this proposed rule will prevent approximately 600 silica related deaths per year, but the CDC is recording less than 100 deaths per year" (Document ID 3729, p. 1). The National Federation of Independent Business also argued that OSHA estimated 375 prevented cases of silicosis that would have led to deaths, but the CDC

[7] Park et al. (2002) also found that silica exposure was responsible for a significant number of deaths that had been attributed to diseases other than silicosis.

reported only about 150 deaths per year where silicosis was the underlying cause or a contributing factor, causing OSHA to overestimate lives saved due to the standard by about 150 percent (Document 2210, Attachment 1, p. 3).

OSHA disagrees that the silicosis mortality surveillance data alone provides evidence that OSHA has overstated the quantitative benefits of the rule. OSHA derived its benefits estimates from exposure data presented in the Industry Profile chapter of this FEA and from its quantitative risk assessment, which is based on epidemiological data that quantify relationships between exposure and disease risk. OSHA relied on these estimates to estimate the number of silicosis-related deaths and illnesses that would occur absent a revised standard and the number of deaths that would be avoided by promulgation of such a standard. From this analysis, OSHA estimated that 325 deaths from silicosis and other non-malignant lung disease and 918 silicosis morbidity cases are estimated to be avoided annually once the full effects of the standards are realized. The 52 deaths cited by Dr. Sabry appears to refer to only the number of deaths with silicosis coded as the “underlying” cause of death on death certificates, and does not include deaths coded with silicosis as a “contributing” cause. Combined with the deaths where silicosis is coded as a “contributing” cause, in this case 49, CDC/NIOSH reported a total of 101 deaths where silicosis was either an underlying cause of death or a contributing cause of death.

OSHA’s model does not only count fatalities related to silicosis. OSHA’s estimate of the impact of exposure to respirable crystalline silica includes deaths from other diseases (lung cancer, non-malignant respiratory disease such as chronic bronchitis and emphysema, and end-stage renal disease) that, according to scientific evidence, can be caused by exposure to respirable crystalline silica (Document ID 1711; 2175, p. 2). OSHA also estimated, based on the Park study discussed previously, that 325 cases of fatal non-malignant respiratory diseases associated with exposure to silica, including, but not limited to silicosis, that would be prevented annually due to the final standard. Thus, OSHA’s estimates of the numbers of deaths prevented that are due to non-malignant respiratory disease are not comparable to surveillance statistics that only capture silicosis as a cause of death. Furthermore, Dr. Sabry’s comments are primarily focused on the hydraulic fracturing industry, which only recently became a major source of silica exposure, where most of the effects of current exposures will likely not be seen for a number of years, underlining why this analysis of past trends is not instructive for epidemiological estimates.

In response to NUCA’s comparison of OSHA’s estimate of 679 deaths avoided to the estimate of fewer than 100 deaths from the surveillance data, the Agency again points out that the model accounts for causes of death other than those resulting from silicosis and therefore reported to CDC/NIOSH in the surveillance data. Therefore, NUCA's comparison is faulty because focusing exclusively on silicosis mortality fails to capture silicosis morbidity, as well as mortality and morbidity resulting from other diseases related to silica exposure, including lung cancer, other non-malignant respiratory disease such as chronic bronchitis and emphysema, and renal disease (see Section VI, Final Quantitative Risk Assessment and Significance of Risk, Table VI-1).

George Kennedy of the National Utilities Contractor's Association makes a similar "apples and oranges" error in his comment:

> OSHA predicts that this rule will prevent approximately 600 silica-related deaths per year. But how is this possible if the CDC is reporting less than 100? (Document ID 3583, p. 2240)

Mr. Kennedy's comment is based on comparing CDC counts of documented silicosis fatality cases, but this count is not a report on *all* silica-related deaths. The Agency's articulated need for the standard, however, is based on the finding that silica exposure results in an array of adverse, mutually independent health endpoints. In contrast, the CDC estimate deals with a small part of the overall health risk from silica exposure.

As also discussed in the Agency's QRA, OSHA finds that workers with higher cumulative exposures to silica are at elevated risk of lung cancer, end-stage renal disease, and non-malignant respiratory diseases. Based on the midpoint of the high-end estimate (Attfield and Costello, 2004) and the low-end estimate (ToxaChemica, 2004 log-linear model), OSHA's estimation model estimates that the new PEL of 50 $\mu g/m^3$ would, in the scenario in which workers are uniformly exposed to silica for 45 years prevent 5,584 cases of lung cancer, or about 124 cases annually upon reaching "steady state" (see later discussion of this concept) in 60 years. Based on Steenland, Attfield, and Mannetje (2002), OSHA's estimation model estimates that the final PEL would prevent 8,689 cases of end-stage renal disease, or about 193 cases annually in steady state. And based on Park (2002), OSHA's estimation model estimates that the new PEL would prevent 14,606 cases of non-malignant respiratory diseases (including silicosis) over the lifetime of 45 cohorts' worth of worker population, or about 325 cases annually in steady state, of which 2,970 (66 annually) are attributable to diagnosed cases of silicosis, based on Mannetje (2002).

Combining the three major fatal health endpoints—lung cancer, non-malignant respiratory diseases, and end-stage renal disease—OSHA's modeling approach yields estimates that the new PEL would prevent between 26,216 and 31,541 premature fatalities over the lifetime of the current worker population, with a midpoint estimate of 28,879 fatalities prevented. This is the equivalent of between 583 and 701 premature fatalities avoided annually, with a midpoint estimate of 642 premature fatalities avoided annually, given a 45-year working life of exposure.

In addition, the final silica rule is estimated to prevent a large number of cases of silicosis morbidity. Table VII-2 is designed to compare available estimates of actual silicosis cases to the estimates generated by OSHA exposure profile and models. The first set of rows compares present estimates of 2/1 and the second set of rows estimates of 1/0 cases of silicosis generated by various risk models using OSHA's exposure profile. Going across, the first columns are for a tenure length of 45 years, the second set for a tenure length of 13 years. Then below in the second panel, the final set of rows is based on Rosenman, et al. (2003) estimates of actual silicosis cases, generated with an alternative modeling approach. To be consistent with OSHA's jurisdiction, OSHA revised Rosenman's estimate to remove workers not in OSHA's jurisdiction, such as miners. The lower panel, based on Rosenman, et al. shows, assuming 45 years of exposure, that between 2,700 and 5,475 new cases of silicosis, at an ILO x-ray rating of 1/0 or higher, are estimated to occur annually at current exposure levels as a result of silica exposure at establishments within OSHA's jurisdiction (i.e. excluding miners).[8] The various models OSHA used yield estimates of between 836 and 8,011 cases, assuming 45 years of exposure and between 393 and 10,107 cases assuming 13 years of exposure at an ILO x-ray rating of 1/0 or higher. OSHA's risk models for morbidity using OSHA's exposure profile are thus somewhat consistent with epidemiologically based estimates of silicosis cases though some are a bit over the epidemiological estimates. When a job tenure of 13 years is assumed, the table shows that for most models, as compared to the 45 year job tenure analysis, the results are a lower numbers of cases, while other models yield estimates of cases within the range estimated by Rosenman for U.S. workers other than miners (who are outside OSHA's jurisdiction.) There are, however, exceptions. The estimated number of cases for some models falls below Rosenman's estimates. On the other hand, two models show an increased number of cases which are above the range of Rosenman's estimates. This is a result of very high rates of cases expected to occur in persons exposed at levels above the preceding PELs. Since OSHA does not estimate benefits to workers exposed at levels above the preceding PELs, any estimated increase in cases among such workers will not affect OSHA's benefits analysis.

[8] Rosenman indicated that the underlying cases of silicosis morbidity have changed little over time, testifying that data from the National Intake Survey indicated that the nationwide number of hospitalizations where silicosis was one of the discharge diagnoses has remained constant, with 2,028 hospitalizations reported in 1993 and 2,082 in 2011 (Document ID 3425, p. 2).

A number of commenters took issue with the general idea that silicosis is an occupational health problem for workers whose exposures to silica did not exceed the preceding PELs. These commenters typically pointed to the significant decline in the number of silicosis deaths reported by the CDC in the last few decades.

OSHA does not find these comments persuasive. As explained in depth in the Health Effects and Risk Assessment sections of the preamble, while the Agency welcomes any apparent decline in silicosis cases, the Agency has substantial evidence that significant risk remains at preceding PELs. The commenters do not account for the undercounting of silicosis deaths from death certificates, as demonstrated by Rosenman and others; nor do they address other health endpoints beyond fatal silicosis. Although the decline in reported cases may indicate the Agency's success up to this point in reducing the incidence of silicosis, it cannot be taken as an absolute measure of how many silica-related disease cases currently exist in the population. Most silicosis cases are not fatal—given that the total cases of silicosis have apparently remained largely constant, fewer silicosis fatalities may mean that more individuals are living with silicosis for longer periods while ultimately dying of other causes.[9]

While OSHA has estimated morbidity from silicosis, it has not attempted to estimate the number of morbidity cases from these other health endpoints. Including these other endpoints would increase estimates of the number of overall cases avoided.

As summarized in Table VII-2, OSHA expects that, in the scenario in which workers are uniformly exposed to silica for 45 years, the silica rule will eliminate the majority of 1/0, 1/1, and 1/2 silicosis cases. However, the Agency has not included the elimination of these less severe silicosis cases in its estimates of the monetized benefits and net benefits of the final rule. Instead, as shown above in Table VII-1, OSHA focused its morbidity-only benefits and related net benefits analysis exclusively on the number of silicosis cases reaching the more severe levels of 2/1 and above (moderate-to-severe silicosis, using the ILO method for assessing severity). As discussed in the Agency's QRA, OSHA estimates that the new PEL of 50 $\mu g/m^3$ for the current worker population would, in the scenario in which workers are uniformly exposed to silica for 45 years, prevent 41,293 cases of moderate-to-severe silicosis (2/1 or more) over a working life, or about 918 cases prevented annually.[10]

[9] As indicated previously, Rosenman found that the underlying cases of silicosis morbidity have changed little over time, remaining constant, even while reported fatalities have declined (Document ID 3425, p. 2).

[10] The unfiltered count of morbidity cases is reported only in Table VII-2. The Agency believes the actual number of morbidity-only cases prevented by the standard in the scenario in which workers are uniformly exposed for 45 years is somewhere between 918 and 984 cases annually, using Mannetje (2002)

As previously discussed, OSHA based its estimates of reductions in the number of silica-related diseases using estimates that reflect a working life of constant exposure for workers who are employed in a respirable crystalline silica-exposed occupation for their entire working lives, from ages 20 to 65.[11] In other words, these estimates reflect an assumption that workers do not enter or exit jobs with silica exposure mid-career or switch to other exposure groups during their working lives. While the Agency is legally obligated to examine the effect of exposures from a 45-year working lifetime of exposure,[12] in an alternative analysis purely for informational purposes, the Agency examined the effect of assuming that workers are exposed to silica for three other tenure lengths: 25, 13, and 6.6 working years. See Table VII-3a through Table VII-3c for number of cases and Table VII-5a through Table VII-5d for monetary benefits for all four tenure levels.

Table VII-3a presents cases for a worker exposed for 25 years. While each individual worker is estimated to have less cumulative exposure under the 25-years-of-exposure assumption, in fact 56 percent (25/45) as much, the effective exposed population over time is proportionately increased (due to the turnover of workforce for a constant number of jobs, and hence total exposure), over the same time period. A comparison of Table VII-3a to Table VII-1, reflecting exposures over 25 working years versus 45 working years, shows variations in the number of estimated prevented cases by health outcome. Estimated prevented cases of fatal end-stage renal disease are higher in the 25-year model, whereas cases of fatal non-malignant respiratory disease and silicosis morbidity are lower. In the case of lung cancer, the effect varies by model, with a decrease in the

---

to estimate the number of prevented silicosis fatalities (66) and excluding these fatalities from the estimated "morbidity-only" cases. While the Agency received no comment on its methodology for counting morbidity cases, in preparing the FEA OSHA discovered that the simultaneous accounting for morbidity in Buchanan's study of coal miners (2003) and pre-mortality morbidity in Park (2002) could result in a potential double-counting of morbidity valuation (discussed later in this chapter), as some of the Buchanan's cases diagnosed with 2/0+ silicosis at retirement could ultimately proceed to death. A precise estimate of the morbidity-only cases is not possible, as Buchanan also excluded a number of cases where the workers had already died, possibly from silicosis, so that Buchanan was, in turn, likely underestimating the total lifetime morbidity risk from silicosis. By relying on Mannetje, OSHA avoids any potential double counting of benefits.

[11] In construction, the analysis assumes that while workers gain additional exposure annually, they are not necessarily exposed to silica constantly, depending upon the demands of the job.

[12] Section 6(b)(5) of the OSH Act states: "The Secretary, in promulgating standards dealing with toxic materials or harmful physical agents under this subsection, shall set the standard which most adequately assures, to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health or functional capacity even if such employee has regular exposure to the hazard dealt with by such standard for the period of his working life." Given that OSHA must analyze significant risk over a working life, the Agency estimated benefits for the affected population over the same period.

Attfield and Costello, 2004 higher estimate and an increase in the ToxaChemica, Inc, 2004 lower estimate. Looking at overall totals, the midpoint estimate of the number of avoided fatalities under the new PEL of 50 μg/m^3 is 642 for 45 years, increasing to 772 for 25 years. For total morbidity, there instead is a decrease: from 918 cases avoided for 45 years down to 443 cases avoided for 25 years, Table VII-3b presents results for 13 years of exposure. For a 13 year job tenure, the midpoint for the number of fatalities avoided is 982 while the total number morbidity cases avoided is 246. Finally, Table VII-3c presents the results for 6.6 years of exposure. In this scenario, the midpoint for the number of fatalities avoided is 1,382 and the total number of morbidity cases avoided is 194. Looking across the tenure results shows that midpoint mortality significantly increases with lower tenure, while total morbidity has a large decrease with lower tenure.

A commenter, Joseph Liss, objected to the Agency's approach of simultaneously increasing the estimated exposed population—not because it was technically incorrect, but because it makes it harder to see the difference in risk to a particular exposed population (Document ID 1950, pp. 16-19).

OSHA reported in the PEA that in the construction industry, which has an unusually high rate of job turnover compared to other industries, BLS data show that the mean job tenure with one's current employer is 6.6 years (BLS, 2010a), and the median age of construction workers in the U.S. is 41.6 years (BLS, 2010b). OSHA further noted that BLS does not have data on occupational tenure within an industry, but that the Agency would expect that job tenure in the construction occupations as a whole would be substantially greater than the job tenure with a worker's current employer. None of the commenters disagreed. Furthermore, many workers may return to the construction industry after unemployment or work in another industry. Job tenure with the current employer, however, is longer in the other industries affected by the silica rule (BLS, 2010a).

Dr. Ronald Bird, submitting a comment on behalf of the U.S. Chamber of Commerce—as well as an unaffiliated commenter, Joseph Liss—suggested that OSHA's estimates of disease cases prevented from 45 years of silica exposure is unrepresentative of the typical tenure of workers affected by the standard, particularly in construction (Document ID 2368, p. 18; Document ID 1950, pp. 15-19). Dr. Bird suggested that workers will routinely change occupations in the course of their lifetime. From a probabilistic standpoint, he calculated that workers would, on average, likely work in an occupation for less than six years. The comments directly from the Chamber of Commerce go further, to say that "[n]o such 45-year career silica exposures exist in today's working world…" (Document ID 2288, p. 11).

The article (Rytina, 1983**)** that Dr. Bird cited for his data on occupational turnover also provides data that refute the assumptions of Dr. Bird's model. While Dr. Bird assumes that occupational turnover is constant without regard to age or length of occupational experience, the Rytina article states:

> Not surprisingly, occupational mobility rates declined sharply with age…The rate for workers age 35-44 was less than one fourth as high as that for workers 18 and 19 years of age. . . .[O]ccupational change among older workers occurs less frequently because of attachments to a particular occupation or the risks of losing income, job security, and pension rights, which might accompany an occupational shift (Rytina, 1983, p. 5).

Furthermore, the Rytina article shows that among workers 45 to 54 years of age, 16.5 percent of workers have been in the same occupation for 25 years or more, and among workers 55 and older, 32.9 percent have been in the same occupation for 25 years or more. By comparison, Dr. Bird's model suggests that, regardless of age, no more than 13 percent of workers will remain in a given occupation for more than 20 years.

Two commenters also provided evidence of the average tenures of their workers that is contrary to Dr. Bird's estimates. The National Industrial Sand Association (NISA) noted, "many NISA member company employees work at their workplaces for all or much of their worklives. In 2004, a study calculated the mean tenure for NISA member company employees fitting the definition of the study's cohort to be 19.7 years" (Document ID 2195, p. 19). Southern Company, an electric utility, noted that it "has approximately 8000 employees in job titles performing activities with potential exposures to silica-containing materials. The average tenure for these employees is 17 years; 37 % of these employees have over 20 years work experience" (Document ID 2185, p. 3).

Other commenters provided evidence to refute the Chamber of Commerce claim that that 45-year career silica exposures no longer exist in today's working world (Document ID 2288, p. 11). During the public hearing, participants on a panel comprised of members of the International Union of Bricklayers and Allied Craftworkers (BAC) were asked if they had colleagues who had worked longer than forty years in their trade. All six of the participants affirmed that they did (Document ID 3585, Tr. 3053). Further, several labor groups submitted evidence of lengthy worker tenure. The BAC noted that:

> A review of our International Pension Fund records documented 116 individuals who have worked for 40 years or more. We consider this figure to understate the work lives of Fund participants because many of these individuals had previous work experience in the construction industry before being represented by BAC. In additional, we believe this figure understates the number of participants with work lives of 45 years, because the Fund was established in 1972 and it was not until roughly a decade later that even half of BAC affiliates had commenced participation in the Fund (Document ID 4053, Attachment 1, p. 2).

Similarly, The United Association of Plumbers, Fitters, Welders, and HVAC Service Techs, submitted that "a review of membership records documented 35,649 active members who have worked 45 years or more while they have been a member of the union." They also echo the BAC statement that the number may be understated given previous work experience (Document ID 4073, Attachment 3, p. 1). And the International Union of Operating Engineers' Central Pension Fund found the average operating engineer has over 20 years of service in the trade with a range up to 49.93 years (Document ID 4025, Attachment 1, pp. 6-7).

For this FEA, OSHA is adding clarifying information and supplemental data on the issue of occupational tenure. Occupational tenure refers to the cumulative (although not necessarily consecutive) length of time a worker has been employed in a given occupation. Employer tenure (also referred to as job tenure), while similar sounding, refers to the continuous length of time a worker has been employed by his or her current employer. In the context of worker exposure to respirable crystalline silica, it is clear that the more relevant factor is occupational tenure in an at-risk occupation rather than at-risk employer tenure.[13]

It is reasonable to expect that workers will remain in one occupation for many years. Many occupations where workers are exposed to silica, such as certain construction trades, require specific education or skills. This makes it costly and difficult for some workers to change to a wholly new occupation and increases the likelihood that these workers will continuously or nearly continuously work in the same field or industry even if they have multiple employers throughout their working lives.

Unfortunately, most collected and reported data on worker tenure have been for employer tenure rather than occupational tenure, and the regular reporting of occupational tenure data has become increasingly scarce. Therefore, most available data on occupational tenure is at least 25 years old. On the other hand, there is little evidence that the older data are no longer relevant. Two factors support this position. First, employer tenure has not been decreasing over time. In fact, in the construction industry, which is by far the largest sector affected by the rule, job tenure has nearly doubled since 1983—from 2 years to 3.9 years, as shown in Table 1 below. The second factor is that one of the most significant demographic employment changes in recent decades has been the steady increase in the percentages of the workforce that are over 55 and over 65 years of age. Obviously, if workers tend to work for more years before retiring, other things equal, that will tend to increase occupational tenure.

Source: BLS CPS and CES

Cross-sectional data on occupational tenure is suggestive but limiting, in the sense that the relevant occupational tenure statistic is for cumulative tenure at the end of a working life. BLS occupational employment data from 1991 for the 35 occupations with the longest occupational tenure, for example, show that the construction occupations of brickmasons and stonemasons; electricians; and plumbers, pipefitters, and steamfitters have an average occupational tenure of about 12.6 years at an average median age of 38.3 years.[14] Since at this age these workers would have reached less than 50 percent of their

[13] Even better would be cumulative exposure to respirable crystalline silica over a working life, which could involve more than one occupation.

[14] No. 656. Occupational and Employer Tenure, by Occupation: 1991. Covers occupations with 50,000 or more workers. Based on Current Population Survey. Source: BLS, News, USDL 92-366 and

typical working life, it is reasonable to expect that their end of career occupational tenure would exceed 25 years.

Broadly speaking, occupational tenure will increase as workers age. The portion of the labor force most highly affected by the silica rule is older than the labor force in general, meaning that occupational tenure in the affected occupations is likely higher than for the labor force in general. A recent Forbes article cited a study by a consulting firm specializing in economic modeling (EMSI) that showed that

> [i]n 2012, 53 percent of skilled-trade workers in the U.S. were 45 years and older and 18.6 percent were between the ages of 55 and 64. (We are using the Virginia Manufacturers Association's definition of skilled trades [which, by and large, would be activities covered by the silica rule], which encompasses 21 particular occupations.) Contrast those numbers with the overall labor force, where 44 percent of workers were at least 45 years old, and 15.5 percent of jobs were held by the 55-to-64 demographic.[15]

A 1981 (BLS) publication on job tenure and occupational changes found that occupational tenure is strongly linked with age.[16] This study found that about 41 percent of workers age 35–46, about 55 percent of workers age 45-54, and about 67 percent of workers over the age of 55 had been in their current occupation for 10 or more years. In addition, about 17 percent and 33 percent of workers age 45-54 and age 55 and older, respectively were reported to have been in the same occupation for 25 years or more. Similar results were reported in an article from the Summer 1990 Occupational Outlook Quarterly (now referred to as the Career Outlook). This article showed that while median tenure across occupations was 6.6 years (from cross-sectional data), almost half of the workers approaching retirement (those who were ages 55-59) had been in their current occupation at least 20 years and almost 20 percent of workers aged 65-69 reported 40 years or more of tenure.[17] If workers are consistently retiring in construction trades, there is a reasonable likelihood that they did not first take up these trades in in their forties or fifties. This is supported by the number who report long tenures in their occupations.

[17] Carey, Max. "Occupational Tenure, Employer Tenure, and Occupational Mobility." *Occupational Outlook Quarterly;* 34, 2: pp. 54-60. Summer 1990.

Thus, from the evidence on the record and the supplemental data provided, occupational tenure at the end of a working life could easily average 20 to 25 years for occupations covered by the final rule, and a non-trivial percentage of workers covered by the rule will have working lives of 40 to 45 year or longer.

In conclusion, despite high average job turnover, many workers remain in the same occupation for decades. In addition, it should be noted that because silica is such a widespread occupational contaminant, it would not be at all unusual for someone to change occupations and encounter further cumulative silica exposure or to return to a silica-generating occupation.

Dr. Bird also objected to OSHA's approach of using a single representative exposure to measure lifetime exposure. He states: "If exposures are variable over the course of a year, the lifetime exposure pattern is contrary to OSHA's assumption and the benefits from the proposed reduction in the PEL would be considerably less" (Document ID 2368, p. 19). Dr. Bird apparently faults the Agency for not considering the possibility that future exposures may be lower than those observed on a given day. However, it is equally plausible that a worker's future exposures may be higher than on the day they were observed by OSHA. The single-day exposure data is the best available data in the record for those workers, and the Agency does not find any persuasive evidence in this record to suggest an obvious bias to characterizing exposure from a single day rather over the course of consecutive days.

Paragraph (i)(2)(v) of the general industry and maritime standard and paragraph (h)(2)(v) of the construction standard also contain specific provisions for diagnosing latent tuberculosis (TB) in the silica-exposed population and thereby reducing the risk of TB being spread to the population at large. OSHA currently lacks good methods for quantifying these benefits. Nor has the Agency attempted to assess benefits directly stemming from enhanced medical surveillance in terms of reducing the severity of symptoms from the illnesses that do result from present or future exposure to silica. Dr. Ruth Ruttenberg, an economist representing the AFL-CIO, noted this as a source of the underestimation of the benefits in her comments (Document ID 2256, Attachment 4, pp. 9-12). However, no commenters suggested how to quantify these effects.

OSHA's risk estimates are based on application of exposure-response models derived from several individual epidemiological studies as well as the pooled cohort studies of Steenland et al. (2001) and Mannetje et al. (2002). However, OSHA recognizes that, in addition to difference in point estimates, there is also uncertainty around any point estimates of risk derived from any single study. In its risk assessment (summarized in Section VI of the preamble), OSHA has made efforts to characterize some of the more significant sources of uncertainty to the extent that available data permit. This specifically includes characterizing statistical uncertainty by reporting the confidence intervals around each of the risk estimates (presented in the Preliminary Quantitative Risk Assessment, Document ID 1711); by quantitatively evaluating the impact of uncertainties in underlying exposure data used in the cohort studies; and by exploring the use of alternative exposure-response model forms. OSHA finds that these efforts reflect much, but not necessarily all, of the uncertainties associated with the approaches taken by investigators in their respective risk analyses. However, for reasons explained in Section VI of the preamble, OSHA concludes that characterizing the risks and benefits as a range of estimates derived from the full set of available studies, rather than relying on any single study as the basis for its estimates, better reflects the uncertainties in the estimates and more fairly captures the range of risks likely to exist across a wide range of industries and exposure situations.

Section VI of the preamble provides a more complete discussion of the source of uncertainty in the risk assessment functions used in this benefits analysis. The sources of uncertainty include the degree to which OSHA's risk estimates reflect the risk of disease among workers with widely varying exposure patterns. Some workers are exposed to fairly high concentrations of crystalline silica only intermittently, while others experience more regular and constant exposure. Risk models employed in the quantitative assessment are based on a cumulative exposure metric, which is the product of average daily silica concentration and duration of worker exposure for a specific task. Consequently, these models assume the same risk for a given cumulative exposure regardless of the pattern of exposure, reflecting a worker's long-term average exposure without regard to intermittencies or other variances in exposure. That is, the use of the cumulative exposure metric in these models assumes that there are no significant dose-rate effects in the relationship between silica exposure and risk. OSHA's reliance on a cumulative exposure metric to assess the risks of respirable crystalline silica is discussed in Section V of the preamble. Uncertainty with respect to the form of the statistical models used to characterize the relationship between exposure level and risk of adverse health outcomes is discussed in Section VI.

In its quantitative risk assessment, OSHA used the exposure-response models from the best available evidence (i.e., the key studies discussed at length in Section V, Health Effects and Section VI, Final Quantitative Risk Assessment and Significance of Risk) to estimate risks for 45 years of exposure to the previous PELs, revised PEL, and the action level. When examining the risk estimates specifically for silicosis mortality and morbidity in Table VI, one interesting observation is the apparent difference in the exposure-response relationship for these two endpoints. For example, for 45 years of exposure to the action level (25 μg/m^3), there would be an estimated 4 deaths from silicosis and 21 cases of silicosis (with chest X-ray ILO category of 2/1 or greater) per 1,000 workers; at the previous PEL (100 μg/m^3), there would be an estimated 11 deaths from silicosis and 301 cases of silicosis per 1,000 workers. In other words, nearly 20 percent of silicosis cases are estimated to be fatal at the relatively low exposure of 25 µg/m^3 but only about 4 percent are estimated to be fatal at the relatively high exposure of 100 µg/m^3.18 Moreover, as noted previously, morbidity and mortality estimates change in opposite directions in response to varying the assumption about workers' total length of exposure. Although this issue was not explicitly raised in the rulemaking record, OSHA notes and addresses it here.

OSHA attributes this apparent difference in the exposure-response relationships for silicosis mortality and morbidity to several factors. First, the silicosis mortality study (ToxaChemica, Inc., 2004) defined deaths using death certificate data, in which silicosis or unspecified pneumoconiosis was recorded as the underlying cause of death. In contrast, the silicosis morbidity study (Buchanan et al., 2003) defined silicosis cases using data from chest x-rays showing radiographic opacities. These radiographic signs of silicosis represent an early endpoint that is very different from silicosis death as the underlying cause of death. Such disparate endpoints are alone one reason why OSHA does not believe that the exposure-response curves should necessarily be proportional In addition, as discussed in Section V.E, Comments and Responses Concerning Surveillance Data on Silicosis Morbidity and Mortality, silicosis is well-known to be underreported on death certificates in that deaths due to silicosis could have been reported as tuberculosis or chronic obstructive pulmonary disease (Document ID 1089, pp. 724-725; 1030; 3425, p. 2; 3577, Tr. 855, 867; 4204, p. 17; 2175, p. 3; 3577, Tr. 772). Also, silica-exposed workers are at risk for other silica-related diseases, including lung cancer and renal disease, as well as other non-exposure-related causes of death such that many workers who contract silicosis will not ultimately die from silicosis. Therefore the reported silicosis deaths at any level are the lowest possible number of such deaths. Workers with higher cumulative exposures are also likely to be older, and therefore may have a higher rate of other conditions that could have been listed on death certificates. Furthermore, as discussed in Section VI, OSHA's risk assessment required some degree of extrapolation at high doses (e.g., 45 years of exposure to 250 and 500 µg/m^3 respirable crystalline silica) that result in cumulative exposures not experienced by many of the cohort members studied. Thus, OSHA attributes the apparent non-proportionality in the exposure-response curves for silicosis mortality and morbidity to these factors. It is possible nonetheless, that future research may shed additional light on this topic.

[18] Even if one subtracts off the Table VI-1 estimates of other silica-attributable diseases (e.g., lung cancer) from the 100 µg/m^3 denominator, on the assumption that those diseases cause mortality before silicosis has a chance to do so, the ratio of fatal silicosis cases to the remaining silicosis diagnoses is still no more than 6.6 percent at 100 µg/m^3, as opposed to the ratio of nearly 20 percent at 25 µg/m^3.

ESTIMATING A STREAM OF BENEFITS OVER TIME

Risk assessments in the occupational environment are generally designed to estimate the risk of an occupationally related illness over the course of an individual worker's lifetime. As demonstrated previously in this chapter, the current occupational exposure profile for a particular substance for the current cohort of workers can be matched up against the expected profile after the final standard takes effect, creating a "steady state" estimate of benefits. However, in order to annualize the benefits for the period of time after the silica rule takes effect, it is necessary to create a timeline of benefits for an entire active workforce over that period.

There are various approaches for modeling the workforce. As explained below, OSHA uses a model that considers the effect of lowering exposures for the entire working population. At one extreme, however, one could assume that all of the relevant silica exposures will occur after the standard goes into effect and none of the benefits occurs until after the worker retires, or at least 45 years in the future. In the case of lung cancer, that period would effectively be 60 years, since the 45 years of exposure must be added to a 15-year latency period during which it is assumed that lung cancer does not develop.[19] At the other extreme, one could assume that the benefits occur immediately, or at least immediately after a designated lag. Neither extreme reflects the reality that silica-related diseases that this standard aims to reduce significantly occur at various times during and after the working lives of these populations of workers, with the majority of cases occurring sometime after the typical worker is middle aged. Indeed, based on the various risk models (as detailed in model life tables in Appendix A to the QRA), which reflect real-world experience with development of disease over an extended period of time; it appears that the actual pattern occurs at some point between these two extremes.

The model OSHA uses, therefore, is one that considers the effect of lowering exposures for the entire working population. This population-based approach does not simply follow the pattern of the risk assessments, which are based in part on life tables, and observe that typically the risk of the illness grows gradually over the course of a working life and into retirement. While this would be a good working model for an individual exposed over a working life, it is not very descriptive of the exposed population as a whole. In the latter case, in order to estimate the benefits of the standard over time, OSHA considers that workers currently being exposed to silica are going to vary considerably in age. Since the health risks from crystalline silica exposure depend on a worker's cumulative exposure over a working lifetime, the overall benefits of the final

[19] This assumption is consistent with the 15-year lag incorporated in the lung cancer risk models used in OSHA's QRA.

standard will phase in over several decades, as the cumulative exposure gradually falls for all age groups, until those now entering the workforce reach retirement and the annual stream of silica-related illnesses reaches a new, significantly lowered “steady state.” However, the beneficial effects of the rule begin in the near term and increase over time until that "steady state" is reached; and, for a given level of cumulative exposure, the near-term impact of the final rule will be greater for workers who are now middle-aged or older, compared to younger workers with similar current levels of cumulative exposure. This conclusion follows from the structure of the relative risk models used in this analysis and the fact that the background mortality rates for diseases such as lung cancer, chronic obstructive pulmonary disease and renal disease increase with age.

In order to characterize the magnitude of benefits before the steady state is reached, OSHA created a linear phase-in model to reflect the potential timing of benefits. Specifically, OSHA estimated that, for all non-cancer cases, while the number of cases of silica-related disease would gradually decline as a result of the final rule, they would not reach the steady-state level until 45 years had passed. The reduction in cases in any given year in the future was estimated to be equal to the steady-state reduction (the number of cases in the baseline minus the number of cases in the new steady state) times the ratio of the number of years since the standard was implemented and a working life of 45 years; in other words, the number of non-malignant silica-related cases of disease avoided is assumed to increase in direct proportion to the number of years the standard is in effect until year 45, at which point the numbers hold steady. This formulation also assumes that the number of workers is constant over the entire time frame. Expressed mathematically:

$$N_t = (C - S) \times (t / 45),$$

where N_t is the number of non-malignant silica-related diseases avoided in year t; C is the current annual number of non-malignant silica-related diseases; S is the steady-state annual number of non-malignant silica-related diseases; and t represents the number of years after the final standard takes effect, with $t \leq 45$.

In the case of lung cancer, the function representing the decline in the number of silica-related cases as a result of the final rule is similar, but a 15-year lag before any reduction in cancer cases is achieved is added into the equation. Expressed mathematically, for lung cancer:

$$L_t = (C_m - S_m) \times ((t-15) / 45),$$

where $15 \leq t \leq 60$ and L_t is the number of lung cancer cases avoided in year t as a result of the final rule; C_m is the current annual number of silica-related lung cancers; and S_m is the steady-state annual number of silica-related lung cancers.

This model was extended to 60 years for all the health effects previously discussed in order to incorporate the 15 year lag, in the case of lung cancer, and a 45-year working life. (The left-hand columns in the tables in Appendix VII-A provide estimates using this model of the stream of prevented fatalities and illnesses due to the final silica rule.)

OSHA also has estimated the benefits using other job tenures. For this purpose, OSHA examined scenarios for the same number of years—60 years—but with the work force restarting exposure whenever the first job tenure cycle was complete.

In order to estimate the comparison of costs to benefits, OSHA assumes that economic conditions remain constant and that annualized costs will continue for the entire 60-year time horizon used for the benefits analysis (as discussed in Chapter V of this FEA). OSHA invited comments on this assumption in the PEA, for both the benefit and cost analysis. OSHA was particularly interested in what assumptions and time horizon should be used instead and why. The Agency did not receive any comments on this point.

MONETIZING BENEFITS

OSHA also estimates the monetary value of health and longevity improvements of the type associated with the final silica rule. These estimates are for informational purposes only because OSHA cannot use benefit-cost analysis as a basis for determining the PEL for a health standard. The Agency's methodology for monetizing benefits is based on both the relevant academic literature and on the approaches OSHA and other regulatory agencies have taken in the past for similar regulatory actions.

In explaining OSHA's methodology for monetizing health and longevity improvements, OSHA will rely on a 45 year occupational tenure. At the end of the section, OSHA will discuss monetization under alternative occupational tenures of 26, 13 and 6.6 years.

Placing a Monetary Value on Individual Silica-Related Fatalities Avoided

To estimate the monetary value of reductions in the number of silica-related fatalities, OSHA relied, as OMB recommends in its Circular A-4, on estimates developed from the willingness of affected individuals to pay to avoid a marginal increase in the risk of fatality. While a willingness-to-pay (WTP) approach clearly has theoretical merit, an *individual's* willingness to pay to reduce the risk of fatality may underestimate the total willingness to pay, which would include the willingness of others—particularly the immediate family—to pay to reduce that individual's risk of fatality.[20]

For estimates using the willingness-to-pay concept, OSHA relies on existing studies of the imputed value of fatalities avoided based on the theory of compensating wage differentials in the labor market. These studies rely on certain critical assumptions for their estimates, particularly that workers understand the risks to which they are exposed and that workers have legitimate choices between high- and low-risk jobs. Actual labor markets only imperfectly reflect these assumptions.[21] A number of academic studies, as summarized in Viscusi and Aldy (2003), have shown a correlation between higher job risk and higher wages, suggesting that employees demand monetary compensation in return for a greater risk of injury or fatality. The estimated trade-off between lower wages and marginal reductions in fatal occupational risk—that is, workers' willingness to pay for marginal reductions in such risk—yields an imputed value of an avoided fatality: the willingness-to-pay amount for a reduction in risk divided by the reduction in risk.[22]

OSHA has used this approach in many recent proposed and final rules (see, for example, 69 FR 59305 (Oct. 4, 2004) and 71 FR 10099 (Feb. 28, 2006), the preambles for the proposed and final hexavalent chromium rule.) Limitations to this approach (see, for example, Hintermann, Alberini and Markandya, (2010)), have been examined in a recent WTP analysis, by Kniesner et al. (2012), using panel data to examine the trade-off between fatal job risks and wages. This article addressed many of the earlier econometric criticisms by controlling for measurement error, endogeneity, and heterogeneity. Accordingly, OSHA views this analysis as buttressing the estimates in Viscusi and Aldy (2003), which the Agency is continuing to rely on for this FEA.[23]

---

[20] See, for example, Thaler and Rosen (1976), pp. 265-266; Sunstein (2004), p. 433; or Viscusi, Magat, and Forrest (1988), the last of whom write that benefits from improvement in public health ''consist of two components, the private valuation consumers attach to their own health, plus the altruistic valuation other members of society place on their health.'' That paper uses contingent valuation methods to suggest that the effect of altruism could significantly alter willingness-to-pay estimates for some kinds of health improvement. There are, however, many questions concerning how to measure the altruistic component and the conditions under which it might matter.

[21] On the former assumption, see the discussion in Chapter II of this FEA on imperfect information. On the latter, see, for example, the discussion of wage compensation for risk for union versus nonunion workers in Dorman and Hagstrom (1998).

[22] For example, if workers are willing to pay $50 each for a 1/100,000 reduction in the probability of dying on the job, then the imputed value of an avoided fatality would be $50 divided by 1/100,000, or $5,000,000. Another way to consider this result would be to assume that 100,000 workers made this trade-off. On average, one life would be saved at a cost of $5,000,000.

OSHA received several comments on the use of willingness-to-pay measures and estimates based on compensating wage differentials. For example, Peter Dorman, Professor of Economics, Evergreen State College, Eric Frumin of Change to Win, and Dr. Ruth Ruttenberg, representing the AFL-CIO, in addition to critiquing the academic studies used to develop the willingness-to-pay measure, cited the absence of effective labor markets for capturing a wage differential for hazardous work (Document ID 2260, Attachment 1; 2372, Attachment 1, pp. 4-15; 2256, Attachment 4, p. 9). OSHA acknowledges that there has been an absence of a wage premium for risk in certain labor markets, and cites this absence in Chapter II of this FEA as an example of market failure. Nonetheless, while the Agency agrees that the absence of a wage premium for risk demonstrates the need for regulatory intervention in the labor market, it does not, in itself, invalidate the use of the willingness-to-pay approach for the informational purposes for which OSHA calculates benefits, so long as there are some reasonably well-functioning parts of the labor market that can be used to estimate the willingness to pay for some subset of workers. OSHA finds that there are such sections of the labor market.

Several studies indicate that there are enough functional parts of the labor market to allow for some quantification of the risk, typically expressed as the value of a statistical life (VSL), a possible measure of willingness to pay. For example, Viscusi and Aldy (2003) conducted a meta-analysis of studies in the economics literature that use a willingness-to-pay methodology to estimate the imputed value of life-saving programs and found that each fatality avoided was valued at approximately $7 million in 2000 dollars. For the PEA, the Agency used the GDP Deflator (U.S. BEA, 2010) to convert this estimate to $8.7 million in 2009 dollars for each fatality avoided.[24] For this FEA, the base year has been further updated to 2012 using the GDP Deflator (U.S. BEA, 2013), yielding an estimate of $9.0 million per fatality avoided.

There are a number of factors that could influence the value of a statistical life (VSL) calculation in different labor markets, but for the purpose of its analysis OSHA has identified methods for normalizing the risk between markets. For example, in Kniesner, Viscusi, and Ziliak (2010), the authors addressed the issue of the heterogeneity of the VSL approach among various labor markets by developing analytical tools (quantile regressions) for differentiating by income. For the purpose of quantifying the effects of income growth over time on the value of a statistical life, OSHA relies on their data,

---

[24] An alternative approach to valuing an avoided fatality is to monetize, for each year that a life is extended, an estimate from the economics literature of the value of that statistical life-year (VSLY). See, for instance, Aldy and Viscusi (2007) for discussion of VSLY theory and FDA (2003), pp. 41488-9, for an application of VSLY in rulemaking. OSHA has not investigated this approach which was not recommended by any commenter in the record. It acknowledges, however, that such an approach would have the effect of lowering estimated benefits because silica-related health outcomes largely affect older workers and retirees as they approach actuarially expected life expectancies.

which generally show that VSL increases with increased worker income (as banded by quartile). Despite potential weaknesses in the VSL approach, Executive Order 12866 recommends monetization of regulatory benefits (including increases in longevity), and the Agency concludes this constitutes the best available method for this purpose.

Placing a Monetary Value on Individual Non-Fatal Silica-Related Diseases Avoided

In addition to the benefits that are based on the imputed value of fatalities avoided, workers also place a value on occupational injuries or illnesses avoided, which reflect their willingness to pay to avoid monetary costs (for medical expenses and lost wages) and quality-of-life losses as a result of occupational illness. Silicosis, lung cancer, and renal disease can be totally disabling and adversely affect individuals for years or even decades in non-fatal cases, or before ultimately proving fatal. Because monetary measures of the willingness to pay for avoiding these illnesses are rare and difficult to find OSHA has included a range based on a variety of estimation methods.

Consistent with Buchanan et al. (2003), OSHA estimated the total number of moderate-to-severe silicosis cases prevented by the rule, as measured by 2/1 or more severe x-rays (based on the ILO rating system). However, while radiological evidence of moderate-to-severe silicosis is evidence of significant risk of material impairment of health, placing a precise monetary value on this condition is difficult, in part because the severity of symptoms may vary significantly among individuals. For that reason, in the PEA, as well as in this FEA, the Agency has employed a broad range of valuation, which should encompass the range of severity these individuals may encounter. Using the willingness-to-pay approach, discussed in the context of the imputed value of fatalities avoided, OSHA has estimated a range in valuations (updated and reported in 2012 dollars) that runs from approximately $64,000 per case—which reflects estimates developed by Viscusi and Aldy (2003), based on a series of studies primarily describing simple accidents—to upwards of $5.2 million per case—which reflects estimates developed by Magat, Viscusi, and Huber (1996) for non-fatal cancer. The latter number is based on an approach that applies a willingness-to-pay value to avoid serious illness that is calibrated relative to the value of an avoided fatality. OSHA (2006) previously used this approach in the FEA supporting its hexavalent chromium final rule, and EPA (2003) used this approach in its Stage 2 Disinfection and Disinfection Byproducts Rule concerning regulation of primary drinking water. EPA used the study by Magat, Viscusi & Huber (1996) on the willingness to pay to avoid nonfatal lymphoma and chronic bronchitis as a basis for valuing a case of nonfatal cancer at 58.3 percent of the value of a fatal cancer.

OSHA's estimate of $5.2 million in 2012 dollars for an avoided case of non-fatal cancer is based on this 58.3 percent figure.[25]

There are several benchmarks for valuation of health impairment due to silica exposure, using a variety of techniques, which provide a number of mid-range estimates between OSHA's high and low estimates of $5.2 million and $64,000. For example, EPA (2008) recently estimated a cost of approximately $460,000, in 2008 dollars, per case of chronic bronchitis, which OSHA (2009) used as the basis for comparison with less severe lung impairments from diacetyl exposure. Another approach is to employ a cost-of-injury model. Combining estimates of productivity losses (i.e., lost wages, fringe benefits, and household production), medical costs (including hospitalizations), and loss of quality-of-life components, Miller (2005), using an enhanced cost-of-injury model, estimated the average silicosis disease cost the equivalent of $335,000 in 2012 dollars).[26]

Miller (2005) also estimated the morbidity costs of several different pneumoconioses other than silicosis and found the other cases to be even more costly to society than silicosis. While the full costs of renal disease are less well known, the medical costs alone of dealing with end-stage renal disease run over $64,000 annually per patient (Winkelmayer, 2002). This suggests that a more comprehensive analysis of the direct costs of renal disease, as well as for the various lung impairments, would produce an estimate well above the $64,000 estimate of injuries in Viscusi and Aldy (2003). Moreover, several studies (e.g., Alberini and Krupnick, 2000) have found that the cost of injury approach tends to significantly underestimate the true economic cost of an injury or illness, relative to the willingness to pay approach, which includes quality of life impacts and psychic costs as well as medical costs and lost income. In this way, looking only at specific elements of this valuation, such as a workers compensation payouts (to the extent they can be linked to a specific employer in a timely manner), would dramatically underestimate the cost of the illness to society.

Thus, the various studies presented in this section suggest that the imputed value of avoided morbidity associated with silica exposure, both for cases preceding death and for non-fatal cases, ranges between $64,000 and $5.2 million, depending in part on the model used to compute the value and in part on the severity and duration of the case. OSHA considers this wide range of estimates is descriptive of the value of preventing morbidity associated with moderate-to-severe silicosis, as well as the morbidity preceding mortality due to other causes enumerated here—lung cancer, lung diseases other than cancer, and

[25] In the PEA, the value for an avoided case of non-fatal cancer was reported as $5.1 million in 2009 dollars.

[26] Miller (2005) estimated the cost of a silicosis case, using an enhanced direct cost approach—including a quality-adjusted-life-years component—to be $265,808 in 2002 dollars.

renal disease. OSHA is therefore applying these values to monetize cases of avoided silica-related morbidity.[27] OSHA has included these estimates of silicosis morbidity throughout the analysis. For mortality, OSHA has included the midpoints of $64,000 and $5.2 million ($2.63 million) for all mortality cases. The high and low estimates in the remainder of this document for mortality not only reflect different point estimates, but different levels for the morbidity effect.

Public Comment on Valuing Non-Fatal Cases of Silicosis

OSHA requested public input on the issue of valuing the cost to society of non-fatal cases of moderate-to-severe silicosis, as well as the morbidity associated with other related diseases of the lung, and with renal disease. A number of commenters did not directly provide quantitative estimates of the cost of silicosis or other silica-related health effects, but provided qualitative descriptions of the heavy burden to health, work, and family life incurred by having silicosis.

For example, Alan White, of the United Steelworkers Local Union 593, who developed silicosis after working in a foundry for 16 years as a general helper, described the practical implications of developing silicosis:

> First of all, for me, there was the growing problem of being out of breath sooner than I used to. That's a difficult situation for a competitor, especially since I didn't know why. Then, I received a big surprise during the conversation with the first doctor when I found out that I have silicosis and that I will lose my job. He and the other doctors all agreed that the diagnosis is silicosis. Watching your wife and other loved ones cry as they figure out what silicosis is was a big hit and then, shortly afterward, there was the radical pay cut from a transfer out of the foundry to a department where I knew nothing because I chose my health over money…There are also difficulties outside of work and issues for me to look forward to in the future. Walking while talking on a cell phone is very exhaustive, as well as walking up the stairs from my basement to my second floor apartment. I have increasing difficulty on my current job. Certain irritants like air fresheners, potpourri and cleaners make home life

[27] For the purpose of simplifying the estimation of the monetized benefits of avoided illness and death, OSHA simply added the monetized benefits of morbidity preceding mortality to the monetized benefits of mortality at the time of death, and both would be discounted at that point. In theory, however, the monetized benefits of morbidity should be recognized (and discounted) at the onset of morbidity, as this is what a worker's willingness to pay is presumed to measure—that is, the risk of *immediate* death or an *immediate* period of illness that a worker is willing to pay to avoid—a practice that would increase the present value of discounted morbidity benefits. A parallel tendency toward underestimation occurs with regard to morbidity not preceding mortality, since it implicitly assumes that the benefits occur at retirement, as per the Buchanan model, but many, if not most, of the 2/0 or higher silicosis cases will have begun years before (with those classifications, in turn, preceded by a 1/0 classification). As a practical matter, however, the Agency lacks sufficient data at this time to refine the analysis in this way.

> increasingly difficult and I was told that it's downhill from here for both work and home life (Document ID 3477, p. 2).

Mr. White also described how the foundry went to considerable expense to hire people to do the job he previously had done, including the costs to the foundry for mistakes made by the trainees replacing him. Such personnel costs to the employer would not be captured by either the willingness-to-pay approach or cost-of-injury approach.

In addition to questioning the underlying willingness to pay approach, at least one commenter indicated various ways in which the approach employed by OSHA would tend to underestimate the economic benefits of the rulemaking. Dr. Ruttenberg argued that the WTP approach does not include costs to third parties of silica-related illnesses and injuries, starting with a number of government programs:

> In its *Preliminary Economic Analysis*, OSHA says that it wants public input on the issue of valuing the cost to society of non-fatal cases of moderate-to severe silicosis, as well as the morbidity associated with other related diseases of the lung, and with renal disease. (PEA, p. VII-15) This is a key request because adding such societal costs can double the benefits of preventing these diseases. In an article by a lawyer and two economists looking at the social cost of dangerous products, Shapiro, Ruttenberg, and Leigh argue that a large economic burden is borne by private insurance, government programs, the business community and the victims and their families. Those affected by occupational exposures, such as silica, may become eligible for a range of cash or in-kind assistance. Such programs may include unemployment compensation, food stamps, Medicaid, Medicare, State Children's Health Insurance Program (SCHIP), Temporary Assistance for Needy Families (TANF), Social Security Disability, and Old Age, Survivors and Disability Insurance. There are also costs for use of military hospitals and clinics (Document ID 2256, Attachment 4, pp. 9-10)(citations omitted).

Part of the cost of the injury or fatality may be borne in substantial part by the victim's family:

> There is another group of costs that can easily double, or even triple, the direct and indirect totals. These are social and economic impacts that are also caused by an incident. They often involve third-party payments, or stress on the victim or his/her family members. The financial pressures on a family can include the need for a caregiver, need for additional income from children or spouse to fill the gap between previous earnings and workers compensation, or psychotherapy for family members to cope with harsh new realities. When children lose their chance at college and higher future earnings, the impact can be hundreds of thousands of dollars (Document ID 2256, Attachment 4).

Dr. Ruttenberg pointed to an existing Department of Transportation study, which suggested that only a fraction of the economic cost of motor vehicle accidents was actually borne by the victim, with the remainder of the costs split between governmental bodies, insurers, and other parties (Document ID 2256, Attachment 4, p. 11).[28]

The Center for Progressive Reform argued that there is value to reducing economic inequities created by occupational illnesses related to silica exposure:

> The proposal's implications for fair treatment of workers also deserve more attention. The proposed standards would benefit a population comprising mostly construction workers (more than 85% of the total affected population). This is an industry that is a bastion for middle class workers and those striving to attain middle class status. It is also an industry that employs a significant number of foreign-born and non-union workers, groups who typically have limited power to negotiate improved working conditions. Ensuring that these workers' health is better protected against the hazards of silica exposure is an important step toward reducing socioeconomic inequality, given the linkages between individual health and social mobility. Other federal agencies, including the National Highway Traffic Safety Administration (NHTSA) and Department of Justice (DOJ), have gone so far as to argue that equity and other non-monetizable benefits are sufficient to justify rules for which the monetized costs far outweigh the monetized benefits. (As with the OSH Act, the authorizing statutes under which NHTSA and DOJ were acting do not require cost-benefit analysis, much less require the agencies to produce rules with monetized benefits that outweigh monetized costs) (Document ID 2351, p. 7)(citations omitted).

The Agency recognizes that, as with third party effects, there are aspects of economic equity issues related to occupational injury, illness, and mortality that merit attention for policy making. As noted previously, however, the OSH Act requires that OSHA policy for toxic substances be ultimately determined by issues of risk and feasibility, as opposed to cost-benefit criteria.

Adjusting Monetized Benefits to Reflect Rising Future Value

In the PEA, OSHA suggested, provided estimates, and requested comment on adjusting future values of illness and mortality prevention to account for changes in real income over time. Ronald White of the Center for Effective Government favored integrating this

---

[28] The Agency acknowledges this is a likely and potentially substantial source of underestimation of morbidity costs and is currently investigating ways to capture this currently unquantified dimension of benefits for potential use in future rulemakings.

element into the monetized benefits analysis (Document ID 2341, p. 3).[29] No commenters argued against it. For the reasons provided in the PEA and described below, the Agency is adopting this approach.

OSHA's estimates of the monetization approach are based on the imputed value of each avoided fatality and each avoided silica-related disease. As previously discussed, these, in turn, are derived from a worker's willingness-to-pay to avoid a fatality (with an imputed value per fatality avoided of $9.0 million in 2012 dollars) and to avoid a silica-related disease (with an imputed value per disease avoided of between $64,000 and $5.2 million in 2012 dollars). Two related factors suggest that these values will tend to increase over time and help to better identify the amount that a worker would be willing to pay to avoid a fatality.

First, economic theory and empirical evidence from the relevant studies indicate that the value of reducing life-threatening and health-threatening risks—and correspondingly the willingness of individuals to pay to reduce these risks—will increase as real per capita income increases.[30] With increased income, an individual's health and life becomes more valuable relative to other goods because, unlike other goods, they are without close substitutes. Expressed differently, as income increases, consumption will increase but the marginal utility of consumption will decrease. In contrast, added years of life (in good health) are, in the model of Hall and Jones (2007), not subject to the same type of diminishing returns and, indeed, may be viewed as the ultimate good.

Second, real per capita income has broadly been increasing throughout U.S. history, including during recent periods.[31] For example, for the period 1950 through 2000, real per capita income grew at an average rate of 2.31 percent a year (Hall and Jones, 2007),[32]

[29] The estimates of monetized benefits to reflect changes in real income over time developed in the PEA contained an error in the formulas (an inconsistent discount rate was used) that resulted in underestimated benefits. That error has been corrected in the estimates presented in this FEA.

[30] Simple modeling can show this directly. For example, Rosen (1988) demonstrates that the value of life can be expressed as the marginal rate of substitution between wealth and the probability of survival. An increase in wealth or income will therefore increase an individual's willingness to pay.

[31] In addition, as Costa (1998) and Costa and Kahn (2004) point out, elderly health, longevity, and well-being in the United States have historically been improving, which also has the effect of increasing the imputed value of life. Of course, improvements in elderly health, longevity, and well-being are not independent of increases in per capita income over the same period.

[32] The results are similar if the historical period includes a major economic downturn (such as the United States has recently experienced). From 1929 through 2003, a period in U.S. history that includes the Great Depression, real per capita income still grew at an average rate of 2.22 percent a year (Gomme and Rupert, 2004).

although real per capita income for the recent 25 year period 1983 through 2008 grew at an average rate of only 1.3 percent a year (U.S. Census Bureau, 2010). More important is the fact that real U.S. per capita income is estimated to grow significantly in future years. The Annual Energy Outlook (AEO) estimates, prepared by the Energy Information Administration (EIA) in the Department of Energy (DOE), estimate an average annual growth rate of per capita income in the United States of 2.7 percent for the period 2011-2035.[33] The U.S. Environmental Protection Agency prepared its economic analysis of the Clean Air Act using the AEO estimates. However, based on the fact that the estimated increase in real per capita income in the United States has flattened in recent years and could remain so, OSHA has selected an estimate of 1.4 percent as the average annual future increase in the growth rate of per capita income in the United States. This estimate is more in keeping with recent trends while allowing for some modest increase in growth rates in future years.

On the basis of the estimated increase in real per capita income in the United States over time and the expected resulting increase in the value of avoided fatalities and diseases, OSHA has adjusted its estimates of the benefits of the final rule to reflect the anticipated increase in their value over time. This type of adjustment has been supported by EPA's Science Advisory Board (EPA, 2000b)[34] and applied by EPA.[35] OSHA accomplished this adjustment by modifying benefits in year i from $[B_i]$ to $[B_i * (1 + k)^i]$, where "k" is the estimated annual increase in the magnitude of the benefits of the final rule.[36]

What remains is to estimate a value for "k" with which to increase benefits annually in response to annual increases in real per capita income, where "k" is equal to $(1 + g) * (\eta)$, "g" is the expected annual percentage increase in real per capita income, and "η" is the income elasticity of the value of a statistical life. Probably the most direct evidence of the value of "k" comes from the work of Costa and Kahn (2003, 2004). They estimate repeated labor market compensating wage differentials from cross-sectional hedonic regressions using census and fatality data from the Bureau of Labor Statistics for 1940, 1950, 1960, 1970, and 1980. In addition, with the imputed income elasticity of the value of life on per capita GNP of 1.7 derived from the 1940-1980 data, they then predict the

[33] The EIA used DOE's National Energy Modeling System (NEMS) to produce the Annual Energy Outlook (AEO) estimates (EIA, 2011). Future per capita GDP was calculated by dividing the estimated real gross domestic product each year by the estimated U.S. population for that year.

[34] Supplementary evidence in support for this type of adjustment comes from EPA (2010) and U.S. Department of Transportation (2014) guidelines.

[35] See, for example, EPA (2003, 2008).

[36] This precise methodology was suggested in Ashford and Caldart (1996).

value of an avoided fatality in 1900, 1920, and 2000. Given the change in the value of an avoided fatality over time, it is possible to estimate a value of "k" of 3.4 percent a year from 1900-2000; of 4.3 percent a year from 1940-1980; and of 2.5 percent a year from 1980-2000.[37]

Other, more indirect evidence comes from estimates in the economics literature on the income elasticity of the value of a statistical life. Viscusi and Aldy (2003) performed a meta-analysis on 49 wage-risk studies and concluded that the confidence interval upper bound on the income elasticity did not exceed 1.0 and that the point estimates across a variety of model specifications ranged between 0.5 and 0.6.[38] Applied to a long-term increase in per capita income of about 2.7 percent a year, this would suggest a value of "k" of about 1.5 percent a year.

More recently, Kniesner, Viscusi, and Ziliak (2010), using panel data quintile regressions, developed an estimate of the overall income elasticity of the value of a statistical life of 1.44. Applied to a long-term increase in per capita income of about 1.4 percent a year, this would suggest a value of "k" of about 2 percent a year.

Based on the preceding discussion of these three approaches and the recent decline in real per capita income in the United States, OSHA has selected a value for "k" of 2 percent a year over the next 60 years.

Thus, based on the best current thinking and data on willingness to pay and its relationship to income elasticity as income increases, OSHA concludes that a 2 percent increase in benefits per year, as measured by a corresponding anticipated increase in VSL, is a reasonable, mid-range estimate. However, OSHA recognizes the uncertainties surrounding these estimates and has subjected them to sensitivity analysis, as discussed below.

Accordingly, OSHA concludes that the rising value, over time, of health benefits is a real phenomenon that should be taken into account. Table VII-4, in the following section, and the monetized results that follow it, show estimates with this adjustment integrated into the valuation. OSHA provides a sensitivity analysis of the effects of this approach later in this chapter.

---

[37] These estimates for "k" were not reported in Costa and Kahn (2003, 2004) but were derived by OSHA from the data presented. The changes in the value of "k" for the different time periods mainly reflect different growth rates of per capita income during those periods.

[38] These results conflict with the more recent work by Hall and Jones (2007), which concludes that the income elasticity of the value of life should be larger than 1.

Summary of Estimates of Monetized Benefits

Table VII-4 presents, for the scenario in which workers are uniformly exposed to silica for 45 years, the estimated annualized (over 60 years, using a 0 percent discount rate) benefits from each of these components of the valuation, and the range of estimates, based on the use of different studies (notably in the case of lung cancer), and the range of uncertainty regarding valuation of morbidity. Mid-point estimates of the undiscounted benefits for each of the first 60 years are provided in the middle columns of Table VII-A-1 in Appendix VII-A at the end of this chapter. The estimates by year reach a peak of $32.4 billion in the 60th year. As will be discussed further, the application of the QRA functions shows that the 45-year results represent the lowest possible estimates because the increasing population exposed more than makes up for the reductions in risk.

As shown, the range of monetized benefits that OSHA quantified, undiscounted, for the new PEL of 50 μg/m^3 runs from $7.3 billion annually, in the case of the lowest estimate of lung cancer risk and the lowest valuation for morbidity, up to $19.3 billion annually, for the highest of both. Notably, the value of total benefits (ranging from $7.9 billion to $18.5 billion, given estimates at the midpoint of the lung cancer models) is more sensitive to the valuation of morbidity than to the lung cancer model used (which ranges from $12.5 to $13.8 billion, given estimates at the midpoint of the morbidity valuation).[39]

This result comports with the very wide range of valuation for morbidity. At the low end of the valuation range, the total value of the benefits is dominated by mortality ($7.7 billion out of $7.9 billion at the case frequency midpoint), whereas at the high end the majority of the benefits are attributable to morbidity ($11.2 billion out of $18.7 billion at the case frequency midpoint). Also, the analysis illustrates that most of the morbidity benefits are related to silicosis cases that are not ultimately fatal. At the valuation and case frequency midpoint of $13.3 billion, $7.7 billion in benefits are attributable to mortality, $2.0 billion are attributable to morbidity preceding mortality, and $3.5 billion are attributable to morbidity not preceding mortality.

[39] As previously indicated, these valuations include all the various estimated health endpoints. In the case of mortality this includes lung cancer, non-malignant respiratory disease and end-stage renal disease. OSHA highlighted lung cancers in this discussion due to the model uncertainty. In calculating the monetized benefits of the final PEL of 50 μg/m^3, the Agency is typically referring to the midpoint of the high and low ends of potential valuation—in this case, the undiscounted midpoint of $7.7 billion and $19.5 billion.

* Results are estimates based on the assumption outlined throughout this chapter.

DISCOUNTING OF MONETIZED BENEFITS

As previously noted, the stream of benefits arising from the silica rule will not be constant from year to year, both because of the 45 year delay after the rule takes effect until all active workers obtain reduced silica exposure over their entire working lives and because of, in the case of lung cancer, a 15 year latency period between reduced exposure and a reduction in the probability of disease. An appropriate discount rate is needed to reflect the timing of benefits over the 60 year period after the rule takes effect and to allow conversion to an equivalent steady stream of annualized benefits.[40]

Alternative Discount Rates for Annualizing Benefits

Following OMB (2003) guidelines, OSHA has estimated the annualized benefits of the final rule using separate discount rates of three percent and seven percent. Consistent with the Agency's own practices in recent proposed and final rules,[41] OSHA has also estimated, for benchmarking purposes, undiscounted benefits—that is, benefits using a zero percent discount rate.

The "appropriate" or "preferred" discount rate to use to monetize health benefits is a controversial topic, which has been the source of scholarly economic debate for several decades.[42] However, in simplest terms, the basic choices involve a social opportunity cost of capital approach or social rate of time preference approach. OSHA analyzes the benefits of this rule under both approaches.

The social opportunity cost of capital approach reflects the fact that private funds spent to comply with government regulations have an opportunity cost in terms of foregone private investments that could otherwise have been made. The relevant discount rate in this case is the pre-tax rate of return on the foregone investments (Lind, 1982b, pp. 24-32).

---

[40] This essential point was missed in a comment by Dr. Ruttenberg, which claimed that OSHA's estimates of the benefits of an avoided fatality were forty percent below the VSL estimate of $8.7 million (in 2009 dollars) that the Agency was using (Document ID 2256, Attachment 4, p. 9). The difference is due to the fact that the avoided fatalities occurred over a 60 year period and had to be discounted.

[41] See, for example, 69 FR 59305 (Oct. 4, 2004) and 71 FR 10099 (Feb. 28, 2006), the preambles for the proposed and final hexavalent chromium rule.

[42] For a more detailed discussion of the major issues, see, for example, Lind (1982a, 1982b, and 1990); EPA (2000a), Chapter 6; and OMB (2003), pp. 31-37.

The rate of time preference approach is intended to measure the tradeoff between current consumption and future consumption, or in the context of the final rule, between current benefits and future benefits. The *individual* rate of time preference is influenced by uncertainty about the availability of the benefits at a future date and whether the individual will be alive to enjoy the delayed benefits. By comparison, the *social* rate of time preference takes a broader view over a longer time horizon—ignoring individual mortality and the riskiness of individual investments (which can be accounted for separately).[43]

A usual method for estimating the social rate of time preference is to calculate the pre-tax real rate of return on long-term, risk-free assets, such as U.S. Treasury securities (OMB, 2003, p. 33). A variety of studies have estimated these rates of return over time and reported them to be in the range of approximately 1 - 4 percent.[44]

OMB Circular A-4 (2003) recommends using discount rates of 3 percent (representing the social rate of time preference) and 7 percent (a rate estimated using the social cost of capital approach) to estimate benefits and net benefits. Ronald White of the Center for Effective Government endorsed the use of a 3 percent discount rate—since it "appropriately reflects a social rate of time preference approach consistent with recommendations for benefits evaluation by the U.S. Environmental Protection Agency" (Document ID 2341, pp. 3-4). Charles Gordon argued for a 0 percent discount rate:

> The economic literature indicates that the social discount rate should be 2 percent or 3 percent. But I believe the social discount rate should be zero, because if you were asked the question, do you want yourself saved from crystalline silica exposure…or do you want your son to be saved from crystalline silica death 20 years from now, you could not answer that question. You could not give a preference (Document ID 3588, Tr. 3789-90).

[43] It is not always possible to explicitly model all forms of uncertainty that are relevant to a regulatory cost-benefit analysis (e.g., medical innovations that allow for more successful treatment of illnesses or changes in industrial practices or locations that in turn change the exposure profile of workers subject to a regulation). Because these uncertainties tend to increase as the time horizon being analyzed lengthens, application of a discount rate provides a reduced-form approach to less heavily weighting the least-certain estimated benefits and costs.

[44] For example, the Congressional Budget Office (CBO, 1988) has estimated the cost of government borrowing to be 2 percent. Farber and Hemmersbaugh (1993) cite rates of return on long-term government securities ranging from approximately 0.5 percent to 3.0 percent. OMB (2003) calculates that the pre-tax yield on 10-year Treasury notes has averaged 3.1 percent in real terms over the 30 years prior to publication of its Circular A-4 in 2003. Newell and Pizer (2003) report real rates of return of nearly 4 percent on 30-year Treasury securities. Nordhaus (2008), page 170, cites a real rate of return of 2.7 percent in 2007 on 20-year Treasury securities.

In accordance with OMB Circular A-4, the Agency is presenting results using both a 3 percent discount rate and a 7 percent discount rate.

Summary of Estimates of Annualized Benefits under Alternative Discount Rates

Table VII-5a through Table VII-5d presents OSHA's estimates of the sum of the annualized benefits of the final rule, under various occupational tenure assumptions, using alternative discount rates of 0, 3, and 7 percent, with a breakout between construction and general industry/maritime, with each table presenting these results for a different tenure level. All of these benefits calculations reflect willingness-to-pay values that, as previously discussed, increase in real value at 2 percent a year.

Given that the stream of benefits extends out 60 years, the value of future benefits is highly sensitive to the choice of discount rate. As previously established in Table VII-4, the undiscounted benefits (i.e., using the 0 percent discount rate) for the scenario in which workers are uniformly exposed to silica for 45 years range from $7.3 billion to $19.3 billion annually. In Table VII-5a, for 45 years tenure, using a 3 percent discount rate, the annualized benefits range from $4.8 billion to $12.6 billion. Using a 7 percent discount rate, the annualized benefits range from $2.7 billion to $6.9 billion. As can be seen, going from undiscounted benefits (with a midpoint of $13.3 billion) to benefits calculated at a 7 percent discount rate (with a midpoint of $4.8 billion) has the effect of cutting the annualized benefits of the final rule by 64 percent. Tables VII-A-1 and VII-A-2 in Appendix VII-A demonstrate how annualized benefits are derived (over the 60 years after the silica rule becomes effective), using the midpoint value of annualized benefits for alternate discount rates of 3 and 7 percent (with the annualized undiscounted benefits—using a 0 percent discount rate—derived in the middle columns of each table in Appendix VII-A).

Comparing across tenure levels for representative benefits, Table VII-5a for 45 years tenure has total benefits at the midpoint estimate of $8.7 billion at a 3 percent discount rate and $4.8 billion at 7 percent discount rate. Table VII-5b for 25 years tenure has total benefits at the midpoint estimate of $10.0 billion at a 3 percent discount rate and $5.5 billion at 7 percent discount rate. Table VII-5c for 13 years tenure has total benefits at the midpoint estimate of $12.3 billion at a 3 percent discount rate and $6.8 billion at 7 percent discount rate. Finally, Table VII-5d for 6.6 years tenure has total benefits at the midpoint estimate of $16.1 billion at a 3 percent discount rate and $9.0 billion at 7 percent discount rate.

As previously mentioned, OSHA has not attempted to estimate the monetary value of less-severe silicosis cases, measured at 1/0 to 1/2 on the ILO scale. The Agency believes the economic loss to individuals with less severe cases of silicosis could be substantial, insofar as those individuals may have a lifetime of medical surveillance and lung damage may potentially require a change in career, or diminished work productivity, with resulting lower wages. Dr. Ruttenberg noted this as a source of underestimation of the benefits (Document ID 2256, Attachment 4, pp. 9-10). The Center for Progressive Reform suggested that the economic effect was potentially significant, as many of these workers may continue working, but at diminished productivity (Document ID 2351). However, the Agency did not attempt to estimate the monetary value of this benefit because many of these effects can be difficult to isolate and measure in economic terms, particularly when there is no obvious existing effect on physiological function or performance.

ESTIMATES OF NET BENEFITS OF THE FINAL RULE

OSHA has estimated, as shown in Table VII-6, the monetized and annualized net benefits of the final rule (with a PEL of 50 µg/m^3 in general industry and construction and Table 1 governing almost all controls in Construction), based on the benefits model and costs previously presented in this chapter and in Chapter V of this FEA. Net benefits are the difference between benefits and costs.

As previously noted, the OSH Act requires the Agency to set standards based on eliminating significant risk to the extent feasible. An alternative criterion of maximizing net (monetized) benefits may result in very different regulatory outcomes. Thus, this analysis of estimated net benefits has not been used by OSHA as the basis for its decision concerning the choice of a PEL or of ancillary requirements for the final silica rule. Instead, it is provided to pursuant to Executive Orders 12866 and 13563. OSHA has used the 45 year occupational tenure in its main analysis. OSHA has also examined other possible tenures and provided the results. The occupational tenure results are such the benefits are higher the shorter the occupational tenure. Examination of shorter tenure would actually increase the net benefits because more workers are exposed to silica, albeit for a shorter time each.

Table VII-6 also shows results of estimates of annualized net benefits for an alternative PEL of 100 µg/m^3. Under this regulatory alternative, the PEL would be changed from 50 µg/m^3 to 100 µg/m^3 for all industries covered by the final rule, and the action level would be changed from 25 µg/m^3 to 50 µg/m^3 (thereby keeping the action level at one-half of the PEL). The ancillary provisions of the standard, such as the medical surveillance provisions, would remain the same in this alternative as in this final rule, but would be impacted by factors such as changes in respirator use and effects on other provisions such as medical surveillance. For example, in the construction sector where medical surveillance requirements are triggered by respirator use, a reduction in respirator use would result in a decrease in the costs associated with medical surveillance. Under this alternative, OSHA determined in the PEA that Table 1 requirements for respirator use would be eliminated and that only abrasive blasters and some underground construction workers, which are not included in Table 1, would be required to wear respirators. However, the number of mortalities and morbidities would rise if workers were exposed to higher levels of silica. OSHA did not receive comment on its analysis of this alternative.

Table VII-6 shows net benefits using alternative discount rates of 0, 3, and 7 percent for benefits and costs, including the previously discussed adjustment to monetized benefits to reflect increases in real per capita income over time. An expanded version of Table VII-6, with a breakout of net benefits between construction and general industry/maritime, is provided in Table VII-B-1 in Appendix B, at the end of this chapter.

As previously noted in this chapter, the choice of discount rate for annualizing benefits has a significant effect on annualized benefits. The same is true for net benefits. For example, the net benefits using a 7 percent discount rate for benefits are considerably smaller than the net benefits using a 0 percent discount rate, declining by more than half to two-thirds under all scenarios. (Conversely, as noted in Chapter V of this FEA, the choice of discount rate for annualizing costs has only a very minor effect on annualized costs.)

The estimates of net benefits in Table VII-6 show that:

- While the net benefits of the final rule vary considerably—depending on the choice of discount rate used to annualize benefits and on whether the calculated benefits are in the high, midpoint, or low range—benefits exceed costs for the 50 μg/m^3 PEL in all scenarios that OSHA considered (i.e., the highest estimate for costs is lower than the lowest estimate for benefits).

- The Agency's best estimate of the net annualized benefits of the final rule—using a uniform discount rate for both benefits and costs of 3 percent—and cognizant of the uncertainties inherent in the analysis, is between $3.8 billion and $11.6 billion, with a midpoint value of $7.7 billion.

- The alternative of a 100 μg/m^3 PEL has lower net benefits under all assumptions, relative to the 50 μg/m^3 PEL. However, for this alternative PEL, benefits were also found to exceed costs in all scenarios that OSHA considered.

One commenter, the Mercatus Institute, argued that the benefits for the proposed rule were overestimated due to OSHA's assumption of full compliance, and that this simultaneously underestimated costs, since the cost of complying with existing rules is assumed away. This commenter stated that the Agency should not assume that firms will necessarily comply with the Agency's rules and the benefits estimates should therefore be lower (Document ID 1819, p. 9). OSHA makes three points in response. First, the argument is logically inconsistent—if the Agency did not assume full compliance with the previous PELs and assumes compliance with the new PEL, as Mercatus advocates, it is true that the estimated costs would increase, but so would the estimated benefits. Second, the logic for the Mercatus Institute's argument seems to be undercut by the Mercatus Institute's own observation that the Agency has had success in reducing silicosis, which suggests that in the long run, at least, firms actually do comply with OSHA rules (Document ID 1819, pp. 4-5). Finally, as discussed in the engineering controls section of Chapter V of this FEA, the Agency has determined that the best way for it to calculate costs and benefits is to estimate the incremental costs and benefits of the standard by assuming full compliance. OSHA also emphasizes that the compliance assumption applies to both costs and benefits so that the comparison of one to the other is not necessarily unduly weighted in either direction (an exception would be a hypothetical scenario in which extremely high non-compliance by a few employers changed benefits estimates substantially but cost estimates only slightly).[45]

[45] If this rulemaking has the potential to increase compliance with existing regulations, it would be appropriate for the analysis conducted under Executive Order 12866 and 13563 to include both cost and benefits estimates that reflect the new compliance. This is not, however, a legal requirement of the OSH

ESTIMATES OF INCREMENTAL BENEFITS OF THE FINAL RULE

Incremental costs and benefits are those that are associated with increasing the stringency of the standard. A comparison of incremental benefits and costs provides an indication of the relative economic efficiency of the final PEL and the alternative PEL on which OSHA solicited comment in the NPRM. Again, OSHA has conducted these calculations for informational purposes only and has not used these results as the basis for selecting the PEL for the final rule, for which the legally determinative inquiry is whether the final PEL is the lowest level feasible at which significant risk of material health impairment remains.

Tables VII-7A and VII-7B show result of estimates of the costs and benefits of reducing exposure levels from the preceding PELs of approximately 250 µg/m^3 (for construction and maritime) and 100 µg/m^3 (for general industry) to the final rule PEL of 50 µg/m^3 and to the alternative PEL of 100 µg/m^3, using the alternative discount rates of 3 and 7 percent. These tables also introduce a second alternative PEL. Under this second alternative standard, addressed in Tables VII-7A and VII-7B, the PEL would be lowered from 50 µg/m^3 to 25 µg/m^3 for all industries covered by the final rule, while the action level would remain at 25 µg/m^3 (because of difficulties in accurately measuring exposure levels below 25 µg/m^3). For the construction sector under this second alternative, Table 1 requirements would also be modified to include respiratory protection for all workers covered under Table 1 (because all exposures for Table 1 activities are assumed to be above 25 µg/ m^3), and all these covered workers would be subject to the medical surveillance provision.[46]

Table VII-7A breaks out costs by provision and benefits by type of disease and by morbidity/mortality, while Table VII-7B breaks out costs and benefits by major industry sector or construction task sector. As Table VII-7A shows, at a discount rate of 3 percent, a PEL of 50 µg/m^3, relative to a PEL of 100 µg/m^3, imposes incremental costs of $381 million per year; incremental benefits of $4.3 billion per year, and additional net benefits of $3.9 billion per year. The final PEL of 50 µg/m^3 also has higher net benefits than 100 µg/m^3 either at a 3 percent or 7 percent discount rate.

Table VII-7B continues this incremental analysis but with breakdowns between construction and general industry/maritime. As shown, both sectors show strong positive net benefits, which are greater for the final PEL of 50 µg/m^3 than the alternative of 100 µg/m^3.

Act. OSHA knows of no way to make such estimates and lacks any persuasive evidence in this rulemaking record that this rulemaking would affect compliance with the preceding PEL.

[46]As with general industry and maritime employees, the limited number of construction workers not covered by Table 1 and estimated to exceed 25 µg/m^3 currently, such as abrasive blasters, are assumed to need respiratory protection under this alternative.

The estimates in Tables VII-7A and VII-7B indicate that, across all discount rates, there are net benefits to be achieved by lowering exposures from the preceding PEL (250 $\mu g/m^3$ or 100 $\mu g/m^3$) to 100 $\mu g/m^3$ and then, in turn, lowering them further to 50 $\mu g/m^3$ and then to 25 $\mu g/m^3$), and the lower the PEL, the greater the net benefits.[47] Net benefits decline across all incremental changes in PELs as the discount rate for annualizing benefits increases. The incremental net benefit of reducing the PEL from 100 $\mu g/m^3$ to 50 $\mu g/m^3$ is greater than the incremental net benefit of reducing the PEL from 50 $\mu g/m^3$ to 25 $\mu g/m^3$ under both the 3 percent discount rate and the 7 percent discount rate.

However, the majority of the benefits and costs that OSHA estimates for the final rule (PEL of 50 $\mu g/m^3$) are from the initial effort to lower exposures from the preceding PEL of 250 $\mu g/m^3$ in both construction and maritime to 100 $\mu g/m^3$, as shown in the 100 $\mu g/m^3$ column and the Incremental Costs/Benefits column between the 100 $\mu g/m^3$ column and the 50 $\mu g/m^3$ column in Table VII-7A. The majority of the costs and benefits attributable to lowering exposures to 100 $\mu g/m^3$ are in the construction industry. OSHA did not estimate any costs or benefits for general industry employers lowering exposures to an alternative of 100 $\mu g/m^3$ because the preceding PEL was already 100 $\mu g/m^3$, but a relatively small amount of costs and benefits would be attributed to maritime employers lowering exposures to the alternative of 100 $\mu g/m^3$ from the preceding PEL of 250 $\mu g/m^3$. Because a single standard would cover both general industry and maritime employers, those costs and benefits are grouped together in Table VII-7A and VII-7B.

In addition to examining alternative PELs, OSHA also examined alternatives to other provisions of the standard. These alternatives are discussed in the following Chapter VIII of this FEA: Regulatory Alternatives.

---

[47] The lowest PEL considered as an alternative was 25 $\mu g/m^3$. In addition, the costs exceed the benefits using the 7 percent discount rate for the 100 $\mu g/m^3$ alternative, since quantified benefits for this FEA are based entirely on the various quantitative risk assessments, and the PEL for general industry is already set at 100 $\mu g/m^3$. (There would, however, be net benefits for construction.) . As noted previously, the Agency is claiming no quantified benefits for the various ancillary provisions, such as medical surveillance.

* Benefits are assessed over a 60-year time horizon, during which it is assumed that economic conditions remain constant, except that the value of VSLs increase with income and then annualized. Costs are annualized over ten years, with the exception of equipment expenditures, which are annualized over the life of the equipment. Annualized costs are assumed to continue at the same level for sixty years, which is consistent with assuming that economic conditions remain constant for the sixty year time horizon.

SENSITIVITY ANALYSIS

In this section, OSHA presents the results of two different types of sensitivity analysis. In the first type of sensitivity analysis, OSHA made a series of isolated changes to individual cost and benefit input parameters in order to determine their effects on the Agency's estimates of annualized costs, annualized benefits, and annualized net benefits. In the second type of sensitivity analysis—a so-called "break-even" analysis—OSHA also investigated isolated changes to individual cost and benefit input parameters, but with the objective of determining how much they would have to change for annualized costs to equal annualized benefits.

Again, the Agency has conducted these calculations for informational purposes only and has not used these results as the basis for selecting the PEL or any other provisions for the final rule.

Analysis of Isolated Changes to Inputs

The methodology and calculations underlying the estimation of the costs and benefits associated with this rulemaking are generally linear and additive in nature. Thus, the sensitivity of the results and conclusions of the analysis will generally be proportional to isolated variations in a particular input parameter. For example, if the estimated time that employees need to travel to and from medical screenings is doubled, the corresponding labor costs double as well.

OSHA evaluated a series of such changes in input parameters to test whether and to what extent the general conclusions of the economic analysis held up. OSHA separately considered changes to input parameters that affected only costs and then changes to input parameters that affected only benefits. Each of the sensitivity tests on cost parameters had only a very minor effect on total costs or net benefits. Much larger effects were observed when the benefits parameters were modified. On the whole, OSHA found that the conclusions of the analysis are reasonably robust. The results of the individual sensitivity tests are summarized in Tables VII-8A and B and are described in more detail below.

For this FEA, OSHA has tailored the sensitivity analysis to examine issues raised by commenters, particularly with respect to costs. (For more detail, see Chapter V of this FEA.) For each alternative, the estimated cost increase is equivalent to the estimated decrease in net benefits (except for minor rounding discrepancies). For instance, in the first example of sensitivity testing, when OSHA doubled the estimated portion of the affected self-employed population from 25 to 50 percent, and estimates of other input parameters remained unchanged, Table VII-8A shows that the estimated total costs of the final rule increased by $17.9 million annually, or by about 1.7 percent, while estimated net benefits also declined by $17.9 million, from $7,657 million to $7,639 million annually.

OSHA recognizes that there is not one uniform approach to estimating the marginal cost of labor. For the economic analysis in support of the final rule, OSHA has estimated the marginal costs of labor as wages plus a fringe benefit rate of 46.2% (which includes some fixed costs such as health insurance). However, this approach does not account for overhead costs. For illustrative purposes in the context of this sensitivity analysis, OSHA has modified the cost estimates by including an overhead rate when estimating the marginal cost of labor. It is important to note that there is not one broadly accepted overhead rate in academic literature and estimating the most appropriate overhead rate for this FEA would require significant modeling. Further, the Department has not further analyzed an appropriate quantitative adjustment. Therefore, DOL adopted for the purposes of this specific exercise an overhead rate of 17%. This rate has been used by the EPA in its final rules (see for example, EPA Electronic Reporting under the Toxic Substances Control Act Final Rule, June 17, 2013), and is based upon a Chemical Manufacturers Association study.

Using an overhead rate of 17% would increase costs by $22.5 million per year, or 2.2 percent above the best estimate of costs. (See Table VII-8A) One explanation as to why including overheads would not have a significant impact on final costs estimates in this FEA is that marginal labor costs do not account for a significant share of overall costs.

Table VII-8A

Sensitivity Tests-Costs

Impact Variable	OSHA's Best Estimate	Sensitivity Test	Impact on Annualized Costs	Percentage Impact on Costs	Adjusted Annualized Costs	Adjusted Annualized Net Benefit*
OSHA's Best Estimate of (a) Annualized Total Cost and (b) Annualized Net Benefits					*(a)* *$1,029,781,777*	*(b)* *$7,657,131,438*

* Benefits are assessed over a 60-year time horizon, during which it is assumed that economic conditions remain constant except that the value of VSLs increase with income. Costs are annualized over ten years, with the exception of equipment expenditures, which are annualized over the life of the equipment. Annualized costs are assumed to continue at the same level for sixty years, which is consistent with assuming economic conditions remain constant for the sixty year time horizon.

** Except as otherwise noted in this FEA, OSHA accounted for respirator use for all workers whose exposures would still exceed the PEL after all feasible controls are in place. In addition, OSHA added to that number an additional 10% of the remaining population to account for special circumstances in which additional workers would require respirators. For this sensitivity analysis, the additional 10% was doubled to 20%.

In the second example, OSHA doubled the estimated familiarization time needed to understand the requirements of the new standard relative to OSHA's best estimate, which ranged from 4 to 40 hours depending on establishment size (see Chapter V for more detail). As shown in Table VII-8A, if OSHA's estimates of other input parameters remained unchanged, the total estimated costs of the final rule increased by $15.9 million annually, or by about 1.5 percent, while net benefits declined by the same amount annually, from approximately $7,657 million to $7,641 million annually.

In the third example, OSHA doubled the estimated daily amount of housekeeping per worker necessary to comply with the standard, from 10 minutes to 20 minutes. As shown in Table VII-8A, if OSHA's estimates of other input parameters remained unchanged, the total estimated costs of the final rule increased by $12.5 million annually, or by about 1.2 percent, while net benefits declined by the same amount annually, from approximately $7,657 million to $7,645 million annually.

In the fourth example, OSHA examined the effect of increasing its estimate of the frequency with which thorough cleaning of the workplace would be performed in general industry. The Agency examined the effect of increasing the frequency from only one initial thorough cleaning to the initial cleaning *plus* an annual thorough cleaning, or alternately, a thorough cleaning every 5 years. As shown in Table VII-8A, if thorough cleaning were an annual cost, the total estimated costs of the final rule increased by $17.2 million annually, or by about 1.7 percent, while net benefits declined by the same amount annually, from $7,657 million to $7,640 million annually. In the second variation of this test, for a thorough cleaning every 5 years, as shown in Table VII-8, the increase in annual costs is only 0.2 percent.

In the fifth example, OSHA increased its estimate of respirator use. In Chapter V of this FEA, OSHA explained that it calculated the costs of respirators for general industry and maritime workers who will still be exposed above the PEL after all feasible controls are in place. In addition, to be conservative, OSHA added costs to provide respirators to 10 percent of the remaining population. For this sensitivity test, OSHA doubled its estimate of the amount of additional respirator use in general industry from 10 percent to 20 percent. As shown in Table VII-8A, the total estimated costs of the final rule increased by $20.0 million annually, or by about 1.9 percent, while net benefits decreased by the same amount annually, from approximately $7,657 million to $7,637 million annually.

In the sixth example, reflecting in part the range of comments the Agency received on the issue (discussed in detail in Chapter V), OSHA explored the effect of increasing, and alternately decreasing, by 50 percent the size of the productivity impact arising from the use of engineering controls in construction. As shown in Table VII-8A, if OSHA's estimates of other input parameters remained unchanged, under the first variation, the total estimated costs of the final rule increased by $99.6 million annually, or by about 9.7 percent, while net benefits declined by the same amount annually, from $7,657 million to $7,558 million annually. Under the second variation, the decrease in costs and increase in net benefits would be of the same magnitude, with final estimated net benefits rising to $7,757 million.

As shown in Table VII-8B, OSHA also performed sensitivity tests on several input parameters used to estimate the benefits of the final rule. In the first two tests, in an extension of results previously presented in Table VII-5, the Agency examined the effect on annualized net benefits of employing the high-end estimate of the benefits, as well as the low-end estimate. As discussed previously, the Agency examined the sensitivity of the benefits to both the valuation of individual silica-related disease cases prevented, as well as the number of lung cancer deaths prevented. Table VII-8B presents the effect on annualized net benefits of using the extreme values of these ranges, the high count of cases prevented *and* the high valuation per case prevented, and the low count *and* the low valuation per case prevented. As indicated, using the high estimate of cases prevented and their valuation, the benefits rise by 45 percent to $12.6 billion, yielding net benefits of $11.5 billion. For the low estimate of both cases prevented and their valuation, the benefits decline by 45 percent, to $4.8 billion, yielding net benefits of $3.8 billion.

In the third sensitivity test of benefits, OSHA examined the effect of raising the discount rate for benefits to 7 percent. The fourth sensitivity test of benefits examined the effect of removing the adjustment to monetized benefits to reflect increases in real per capita income over time. The results of the first of these sensitivity tests for net benefits was previously shown in Table VII-6 and is repeated in Table VII-8B. Raising the interest rate to 7 percent lowers the estimated benefits by 45 percent, to $4.8 billion, yielding annualized net benefits of $3.8 billion. Removing the two-percent annual increase to monetized benefits to reflect increases in real per capita income over time decreases the benefits by 50 percent, to $4.3 billion, yielding net benefits of $3.3 billion.

“Break-Even” Analysis

OSHA also performed sensitivity tests on several other parameters used to estimate the net costs and benefits of the final rule. However, for these, the Agency performed a “break-even” analysis, examining how much the various cost and benefits inputs would have to vary in order for the costs to equal, or break even with, the benefits estimates. The results are shown in Table VII-9.

In the first break-even test on cost estimates, OSHA examined how much costs would have to increase in order for costs to equal estimated benefits. As shown in Table VII-9, this point would be reached if costs increased by $7.7 billion

In a second test, looking specifically at the estimated engineering control costs, the Agency found that these costs would also need to increase by $7.7 billion for costs to equal estimated benefits.

In a third sensitivity test, on benefits, OSHA examined how much its estimated monetary valuation of an avoided illness or an avoided fatality would need to be reduced in order for the costs to equal the benefits. Since the total valuation of prevented mortality and morbidity are each estimated to exceed at least $2.6 billion, while the estimated costs are $1.0 billion, an independent break-even point for each is impossible. In other words, for example, if no value is attached to an avoided illness associated with the rule, but the estimated value of an avoided fatality is held constant, the rule still has substantial net benefits. Only through a reduction in the estimated net value of both components is a break-even point possible.

OSHA, therefore, examined how large an across-the-board reduction in the monetized value of all avoided illnesses and fatalities would be necessary for the benefits to equal the costs. As shown in Table VII-9, for costs to equal estimated benefits, the estimated value per life saved would have to decline to $1.1 million per life saved, and an equivalent percentage reduction to about $0.3 million per illness prevented.

In a break-even sensitivity test, OSHA estimated how many silica-related fatalities and illnesses would be required for benefits to equal costs. As shown in Table VII-9, a reduction of 88 percent, relative to the morbidity and mortality estimates is required to reach the break-even point—566 fewer fatalities prevented annually, and 809 fewer silica-related illnesses prevented annually.

Table VII-9

Break-Even Sensitivity Analysis

	OSHA's Best Estimate of Annualized Cost or Benefit Factor	Factor Value at which Benefits Equal Costs	Required Factor Dollar/Number Change	Percentage Factor Change
Total Costs	$1,029,781,777	$8,686,913,216	$7,657,131,438	743.6%
Engineering Control Costs	$661,456,736	$8,318,588,174	$7,657,131,438	1157.6%
Benefits Valuation per Case Avoided				
Monetized Benefit per Death Avoided*	$9,000,000	$1,066,896	-$7,933,104	-88.1%
Monetized Benefit per Illness Avoided*	$2,632,000	$312,008	-$2,319,992	-88.1%
Cases Avoided				
Deaths Avoided*	642	76	-566	-88.1%
Illnesses Avoided*	918	109	-809	-88.1%

*Note: These numbers represent a reduction in the composite valuation of an avoided fatality or illness or in the composite number of cases avoided.

* Net Benefits for the combined General Industry/Maritime sector may be negative for some assumptions for the alterative PEL of 100 μg/m³ because all quantified benefits are calculated solely on the reduction of the PEL, which is already 100 μg/m³ for General Industry. As noted, the

Agency anticipates substantial benefits from ancillary provisions such as medical surveillance, but these have quantified costs, with no offsetting quantified benefits.

APPENDIX VII-C

PROBABILITY DISTRIBUTION ANALYSIS:

COSTS, BENEFITS, AND NET BENEFITS

PROBABILITY DISTRIBUTION ANALYSIS: COSTS, BENEFITS, AND NET BENEFITS

OSHA's best estimate, as presented in Chapter V of this FEA, is that the annualized cost of the silica rule will exceed $1 billion. Therefore, in accordance with OMB's Circular A-4, OMB's standard guidance document on conducting cost-benefit analysis for government agencies, the Agency has developed, as described below, a formal analysis of uncertainty—a probability distribution analysis—of the costs, benefits, and net benefits of the silica rule.[48]

The Agency is providing this analysis for informational purposes only; OSHA's economic feasibility determinations conducted to comply with the OSH Act must be determined by OSHA's best estimates derived from the information in the record rather than these hypothetical statistical simulations.

OSHA conducted the simulations both for the benefits model and the cost model using a 3 percent discount rate. OSHA also combined the results to produce statistical measures of net benefits as well. The various mechanics of the calculations are explained first, and then the results are presented in a series of tables.

To develop its probability analysis, OSHA used a Monte Carlo simulation approach to probe the effects of changes in the magnitude of various key cost and benefit input variables on important cost and benefit outputs.[49] Monte Carlo analysis consists of randomly drawing from specified distributions for various pre-determined input variables and recording the relevant output variables created as the input values flow through the full calculations of the model. This random drawing process is repeated a large number of times, and the resulting dataset of output numbers can then be analyzed (for example, sample statistics of the mean and the 95% confidence interval) to give a picture of how outputs change in accordance with a specified statistical uncertainty in input values.

OSHA's based the data simulations on the full cost and benefit spreadsheets prepared for this FEA, which, along with the Monte Carlo simulation spreadsheets, are available in the public docket of this rule. The Agency's best estimates of the key input magnitudes and the resulting costs and benefits were previously presented in this FEA. In general, OSHA's selection of input variables to test in these simulations was based on a judgment as to which variables would have the largest effect on the Agency's estimates of costs and benefits and would therefore be most likely to create a significant effect on the

[48] Circular A-4 states: "For major rules involving annual economic effects of $1 billion or more, you should present a formal quantitative analysis of the relevant uncertainties about benefits and costs. In other words, you should try to provide some estimate of the probability distribution of regulatory benefits and costs. In summarizing the probability distributions, you should provide some estimates of the central tendency (e.g., mean and median) along with any other information you think will be useful such as ranges, variances, specified low-end and high-end percentile estimates, and other characteristics of the distribution." (OMB, 2003, p. 40)

[49] This analysis was conducted using the software package @RISK, Version 7, of Palisades Corporation.

results of the Monte Carlo analysis. OSHA limited its analysis to uncertainty in the variable values and did not address uncertainties arising from alternative functional forms in the cost and benefit models. For a more complete discussion of uncertainties in the risk assessment, see the Quantitative Risk Assessment section of the preamble. In all, OSHA chose 15 input variables specific to costs and 7 input variables specific to benefits. No input variable was common to both.

Below is a list of the 15 cost input variables, with their Monte Carlo simulation name and the baseline simulation estimate in parentheses:

1. The percentage of all engineering control costs in general industry and maritime attributable to compliance with the new PEL ("100 PEL compliance factor," 50);

2. The average capital and operating cost of local exhaust ventilation (LEV) per cubic foot per minute (cfm) in general industry or maritime ("CFM cost," $13.34);

3. The average additional number of minutes of routine housekeeping needed per day per affected worker in general industry and maritime ("Cleaning time," 10 minutes);

4. The average number of hours needed for an employer to develop a written exposure control plan ("Control Plan Development," 4 hours)[50];

5. The average number of hours needed for a construction employer to revise the written exposure control plan to tailor direct access control to the specific conditions of a new job worksite ("Control Plan Job Revision," 0.25 hours);

6. For the employee notification or briefing option when implementing the written exposure control plan in construction, the average number of hours needed per job to brief each at-risk crew member ("Control Plan Communicate," 0.1 hours);

7. Other than workers that the Agency's technological feasibility analysis has determined will require respirators, the percentage of the remaining workers currently exposed above 50 $\mu g/m^3$ in general industry or maritime that will require respirators ("Default respirator use factor," 10%);

8. The cost for an industrial hygienist to perform initial exposure monitoring ("Industrial Hygienist daily rate," $2,500)[51];

9. The cost per square foot for an initial thorough cleaning of a facility in general industry or maritime ("Initial cleaning per sq ft," $0.15);

---

[50] Four hours is the point estimate for establishments with between 20 and 499 employees. The number of hours for other-sized establishments was calculated in proportion to four hours, based on the ratio of the point estimates. (For example, for establishments with fewer than 20 employees, the ratio applied was 25 percent, since the point estimate in the PEA was 1 hour for establishments of this size.) Similarly, the time needed to review, evaluate, and update the plan annually was calculated relative to (50 percent of, in all cases) the time needed to develop the plan.

[51] The same cost was applied for an industrial hygienist to perform exposure monitoring at construction or hydraulic fracturing sites, which are sites that generally will not have been previously well characterized. For routine periodic monitoring at sites in general industry and maritime that have previously been well characterized, the cost was set at 50 percent of initial exposure monitoring cost (consistent with the estimates developed in the FEA).

10. The average cost for an initial health screening for current employees in general industry or maritime ("Medical visit costs," $421)[52];

11. For exposure monitoring in general industry or maritime, the percentage of workers requiring an additional sample annually due to a change in working conditions ("Monitoring for change," 25%);

12. In construction, a productivity penalty multiplier applied to the various productivity penalty point estimates for various construction tasks ("Productivity impact," 1);

13. In construction, the ratio of the number of full-time-equivalent (FTE) at-risk self-employed workers imposing engineering control costs on host employers relative to the number of FTE at-risk employees ("Self employment," 4.6%);

14. The average number of minutes of training each at-risk worker needs to comply with the silica rule, with no baseline training other than that already required by the Hazard Communication standard ("Training time," 60); and

15. For establishments in general industry or maritime with 20 or more workers, the number of workers per control—only for controls that OSHA has estimated have 4 or more workers per control ("Workers per control," 4)[53].

Below is a list of the seven benefit input variables, with their Monte Carlo simulation name and the baseline simulation estimate in parentheses:

1. The baseline risk coefficient for the "lower" point estimate lung cancer silica exposure risk model ("ToxaChemica LC—lower," 0.06);

2. The baseline risk coefficient for the "higher" point estimate lung cancer silica exposure risk model ("Attfield LC—higher," 0.19);

3. The baseline risk coefficient for the selected lung-disease-other-than-cancer silica exposure risk model ("Park LDOC," 0.547);

4. The baseline risk coefficient for the selected end-stage-renal-disease silica exposure risk model ("Steenland Renal Disease," 0.269);

5. The value of a statistical life (VSL) to be applied to every fatality prevented by the silica rule ("VSL," $9,000,000);

[52] This cost of $421 is the point estimate for an initial health screening for current employees in general industry or maritime working in an establishment with between 20 and 499 employees. Proportional costs are estimated for initial health screenings for new hires, periodic health screenings, health screenings in construction, and for any combination of the above. Again, the various health screening costs are calculated in proportion to the $421 point estimate, based on the ratio of the various other point estimates to $421. Note that the cost of an examination by a specialist was not included in the simulations.

[53] Controls in establishments with 20 or more employees that OSHA has estimated have fewer than 4 workers per control were excluded from this simulation. For establishments in general industry or maritime with fewer than 20 employees and at least 2 workers per control, the number of workers per control was estimated at 50 percent of the number of controls for establishments with 20 or more employees. Controls for all establishments were constrained in the simulation not to be less than 1 worker per control, in accordance with OSHA's FEA cost estimates.

6. The annual increase in the magnitude of the benefits (in 2012 dollars) of the final rule ("Income growth rate," 2%); and

7. The average number of years of workplace exposure to respirable crystalline silica over a working lifetime ("Working years," 25.8)[54].

Table VII-C-1 below presents all input variables along with assumed distributional parameters. All distributions were assumed to be normally distributed, so these are fully specified by their mean and standard deviation. All mean values were set at the best estimates developed and presented earlier in this FEA. For cost variables other than "100 PEL compliance factor," which are all ratios multiplying a specific variable, the mean value was set at one. The record and data only allowed the Agency to estimate point values for cost variables, so the Agency applied a standard deviation of 25% of the mean (which means there is a 95% confidence interval of about 50% to 150% of the mean) as a reasonable range for exploring uncertainty in the analysis.

For benefit variables, in many cases OSHA had estimates of uncertainty from the risk studies used in the FEA that could be used in the simulations. Specifically, most of the risk models present an associated standard error to the estimated coefficient on cumulative exposure, which for each risk model is the variable OSHA is simulating. The one exception is Park LDOC, which does not present a standard error. Instead, the standard error for Park LDOC was selected such that the coefficient would just be statistically significant at the 95% confidence level. These coefficients were then simulated in the risk portion of the benefits model. The VSL standard deviation was based on the original estimation of the VSL in Viscusi and Aldy (2003). Finally, the two percent income growth rate factor has a standard deviation that was again chosen using the 25% above/below mean rule.

These benefit simulations with these given parameters were not constrained to have positive values for certain variables that a priori cannot be negative, such as the risk model coefficients. As a result, there are a few cases where the simulation generated either a negative coefficient on cumulative exposure in a specific risk model (i.e., yielding more fatalities as a result of reduced exposure to respirable crystalline silica) or the VSL was negative. These perverse simulation results were considered an artifact of the simulation method used and were simply dropped from the output dataset. An adjustment for this deletion of negative values was performed by dropping the same number of cases at the high end of each variable. Out of an original 3,000 simulations, 171 had such a negative number in some variable, with about 33% of the 171 simulations having a negative VSL, and the rest arising among the Park and ToxaChemica input variables, with Park having about twice as many perverse cases as ToxaChemica. OSHA initially performed 3,000 simulations to be sure to obtain 2,500 valid simulations, so after these 171 negative cases and the associated number of positive cases were dropped,[55]

[54] OSHA selected 25.8 years as the baseline simulation estimate because it is the mean of the high and low work-life estimates (45 and 6.6 work-years) that the Agency analyzed.

[55] In practice, only 161 positive cases were dropped because 10 of the negative cases also contained a high-end variable which would have (otherwise) caused the case to be dropped.

OSHA then randomly selected among the remainder to obtain the target of 2,500 simulations. These 2,500 benefit simulations were then randomly assigned one of the 2,500 cost simulations. These 2,500 pairs were then fixed to create net benefit statistics.

Table VII-C-1: Simulation Input Variables and Distribution Parameters

Variable	Mean	Standard Deviation
Cost Input Variables		
100 PEL compliance factor	0.5	0.125
CFM cost	1	0.25
Cleaning time	1	0.25
Control Plan Development	1	0.25
Control Plan Job Revision	1	0.25
Control Plan Communicate	1	0.25

The results of the Monte Carlo simulation are reflected in the output variables, which are presented in three tables separately for costs, benefits, and net benefits. Table VII-C-2 shows total cost simulations, with total annualized costs for general industry and maritime at a 95% confidence interval of $309 million to $431 million. Total annualized construction costs simulations have a range of $561 million to $749 million, with overall total annualized cost simulations for the silica rule ranging from $899 million to $1,144 million.

Table VII-C-3 presents the outputs of the benefits simulations and shows a 95% confidence interval for general industry and maritime with the total number of mortality cases prevented of 56 to 207 and a mean of 119. The total general industry monetized benefits generated through this simulation, using the midpoint values, have a 95% confidence interval of $427 million to $4,906 million. For construction, the range for the total number of mortality cases prevented is 328 to 1,435, with construction monetized benefits ranging from $1,703 million to $20,566 million. The 95% confidence interval for the overall total number of mortality cases prevented is 388 to 1,638, while overall total monetized benefits from these simulations range from $2,155 million to $25,373 million.

Finally, Table VII-C-4, the simulated net benefits table, first repeats total costs and benefits from the previous tables for convenience and then presents the net benefits from the simulations. The 95% confidence interval for simulated net benefits is $1,147 million to $24,387 million.

Table VII-C-2: Simulated Cost Variable Outputs

Name	5%	Mean	95%
Self employment	2.7%	4.6%	6.5%
Workers per control	2.4	4.0	5.6

CHAPTER VIII: REGULATORY ALTERNATIVES

This chapter discusses several major regulatory alternatives to the final OSHA silica standard, as required by Executive Orders 13653 and 12866. The focus in this chapter is OSHA's estimate of the costs and benefits of these alternatives—in monetized terms where possible. A more comprehensive, but qualitative, discussion of the various possible alternatives to the final rule—including comments in the record concerning possible alternatives and the Agency's responses to them—is presented in Section XV of the preamble, Summary and Explanation of the Standards.

The presentation of regulatory alternatives in this chapter serves two important functions. The first is to demonstrate that OSHA explored less costly ways (compared to the final rule) to provide workers an adequate level of protection from exposure to respirable crystalline silica. The second is tied to the Agency's statutory requirement, which underlies the final rule, to reduce significant risk to the extent feasible. If OSHA had been unable to support its findings of significant risk and feasibility based on evidence presented during notice and comment, the Agency would then have had to consider regulatory alternatives that do satisfy its statutory obligations.

Each regulatory alternative presented here is described and analyzed relative to the final rule. Where relevant, the Agency notes that some regulatory alternatives are not permissible based on the required legal findings OSHA has made regarding significant risk and feasibility. The regulatory alternatives have been organized into four categories similar to those used in the PEA: (1) alternative PELs to the PEL of 50 $\mu g/m^3$, with corresponding changes to Table 1 in construction; (2) regulatory alternatives that affect ancillary provisions; (3) a regulatory alternative that would modify the methods of compliance; and (4) regulatory alternatives concerning when different provisions of the final rule would take effect.

Some commenters suggested a different alternative in which OSHA simply enforced the previous silica rules (which consist solely of different PELs), rather than adopting any regulatory alternative. However, OSHA has already been actively enforcing the previous silica rule, as well as undertaken significant silica compliance assistance initiatives (as described in Section III of the preamble), and has concluded that, within the context of the Agency's limited resources, it will not be able to achieve a significant increase in worker protection through increased enforcement of the previous rules, which would remain permanently in effect under this alternative. Furthermore, section (6)(b)(5) of the OSH Act requires that when the Agency engages in rulemaking to promulgate standards dealing with toxic materials or harmful physical agents such as respirable crystalline silica, the Agency must select the "standard which most adequately assures, to the extent feasible … that no employee will suffer material impairment of health or functional capacity." Given that OSHA has demonstrated that the final rule significantly reduces worker risk from silica exposure and that the final rule is both technologically and economically feasible, OSHA views the final rule as the rulemaking option that most adequately furthers the purposes of the OSH Act and concludes that merely preserving the status quo, perhaps with enhanced enforcement or compliance outreach, would be significantly less protective of workers and not supported by the weight of evidence in the rulemaking record.

THE FINAL RULE

OSHA selected a new PEL for respirable crystalline silica of 50 $\mu g/m^3$ for all industries covered by the final rule and developed and included Table 1 for many work activities within the construction sector. The final rule is based on the requirements of the Occupational Safety and Health Act (OSH Act) and court interpretations of the Act. For health standards issued under section 6(b)(5) of the OSH Act (29 U.S.C. 655(b)(5)), OSHA is required to promulgate a standard that reduces the risk of material impairment of health to the extent that it is technologically and economically feasible to do so. See Section II of the preamble, Pertinent Legal Authority, for a full discussion of the legal requirements for promulgating new health standards under the OSH Act.

OSHA conducted an extensive review of the literature on the adverse health effects associated with exposure to respirable crystalline silica. The Agency also developed estimates of the risk of silica-related diseases, assuming exposure over a working lifetime at the PEL and action level, as well as at OSHA's previous PELs. OSHA's preliminary analyses on these topics were presented in a background document entitled "Occupational Exposure to Respirable Crystalline Silica – Review of Health Effects Literature and Preliminary Quantitative Risk Assessment" (Document ID 1711) and its final findings are described in the preamble to the final rule in Section V, Health Effects, and Section VI, Final Quantitative Risk Assessment and Significance of Risk. The available evidence indicates that employees exposed to respirable crystalline silica well below the previous PELs are at increased risk of lung cancer mortality and silicosis mortality and morbidity. Occupational exposures to respirable crystalline silica also can result in the development of kidney and autoimmune diseases and in death from other nonmalignant respiratory diseases. As discussed in Section VI, Final Quantitative Risk Assessment and Significance of Risk, in the preamble, OSHA finds that worker exposure to respirable crystalline silica at the previous and new PELs constitutes a significant risk and that the final standard will substantially reduce this risk.

Section 6(b)(5) of the OSH Act (29 U.S.C. 655(b)(5)) requires OSHA to determine that its standards are technologically and economically feasible. OSHA's examination of the technological and economic feasibility of the final rule is presented in this FEA and summarized in Section VII of the preamble. For general industry and maritime, OSHA has concluded that the PEL of 50 μg/m^3 is technologically feasible for all affected industries. In other words, OSHA has found that engineering and work practice controls will be sufficient to reduce and maintain silica exposures to the PEL of 50 μg/m^3 or below in most operations most of the time in the affected industries in general industry, and the rule is also feasible in maritime (feasibility for maritime (shipyards) partly depends on it being subject to other standards regulating abrasive blasting). For those few operations where the PEL cannot be achieved even when employers install all feasible engineering and work practice controls, employers in general industry and maritime can supplement controls with respirators to achieve exposure levels at or below the PEL.

For construction, OSHA has determined that the engineering and work practice controls specified in Table 1 are feasible for all affected activities and in most cases will keep exposures at or below 50 μg/m^3 most of the time. For those few activities where the engineering and work practice controls specified in Table 1 are not sufficiently protective of worker health, Table 1 specifies respirator use to supplement those controls. A limited number of activities, such as tunneling and abrasive blasting, are not dealt with under Table 1, but are governed more directly by the PEL of 50 μg/m^3, as in general industry and maritime. For construction, while a few tasks like abrasive blasting and those specified on Table 1 as requiring respirators cannot achieve the PEL most of the time with engineering and work practice controls alone, OSHA has concluded that the PEL of 50 μg/m^3 is technologically feasible for the construction industry overall because most operations can meet the PEL using the specified controls in Table 1or under the traditional approach.

OSHA developed quantitative estimates of the compliance costs of the final rule for each of the affected industries. The estimated compliance costs were compared with industry revenues and profits to provide a screening analysis of the economic feasibility of complying with the revised standard and an evaluation of the potential economic impacts. Industries with unusually high costs as a percentage of revenues or profits were further analyzed for possible economic feasibility issues. After performing these analyses, OSHA has concluded in Chapter VI of this FEA that compliance with the requirements of the final rule will be economically feasible in every affected industry.

ALTERNATIVE PELS

As discussed in the Benefits section of Chapter VII of this FEA, incremental costs and benefits are those that are associated with increasing the stringency of the standard. A comparison of incremental benefits and costs provides an indication of the relative efficiency of the final PEL and the alternative PEL. Again, OSHA has conducted these calculations for informational purposes only and has not used these results as the basis for selecting the PEL for the final rule. The following discussion of Alternatives #1 and #2 is also included in the Estimates of Net Benefits section of Chapter VII, and Tables VIII-1 and VIII-2 correspond to Tables VII-7A and VII-7B, respectively.

Tables VIII-1 and VIII-2 show the costs and estimates of benefits of reducing exposure levels from the preceding PELs of 250 $\mu g/m^3$ (for construction and maritime) and 100 $\mu g/m^3$ (for general industry) to the final rule PEL of 50 $\mu g/m^3$ and to the first alternative PEL of 100 $\mu g/m^3$ (Alternative #1), all at the alternative discount rates of 3 and 7 percent. These tables also introduce a second alternative PEL. Under this second alternative (Alternative #2), also addressed in Tables VIII-1 and VIII-2, the PEL would be lowered from 50 $\mu g/m^3$ to 25 $\mu g/m^3$ for all industries covered by the final rule, while the action level would remain at 25 $\mu g/m^3$ (because of potential difficulties in accurately measuring exposure levels below 25 $\mu g/m^3$). For the construction sector under this second alternative, Table 1 requirements would also be modified to include respiratory protection for all workers covered under Table 1 (because none are expected to be mostly under 25 $\mu g/m^3$ for any of the tasks), and all these covered workers would be subject to the medical surveillance provision.[1]

Table VIII-1 breaks out costs by provision and estimates benefits by type of disease and by morbidity/mortality, while Table VIII-2 breaks out costs and benefits by major industry sector. As Table VIII-1 shows, at a discount rate of 3 percent, a PEL of 50 $\mu g/m^3$, relative to a PEL of 100 $\mu g/m^3$, imposes additional costs of $381 million per year.

Table VIII-2 continues this incremental analysis but with breakdowns between construction and general industry/maritime.

Tables VIII-1 and VIII-2 would demonstrate that, across all discount rates, there are estimated net benefits to be achieved by lowering exposures from the preceding PEL (250 $\mu g/m^3$ or 100 $\mu g/m^3$) to 100 $\mu g/m^3$ and then, in turn, lowering them further to 50

[1] As with general industry and maritime employees, the limited number of construction workers not covered by Table 1 and estimated to exceed 25 $\mu g/m^3$ currently, such as abrasive blasters, are also assumed to need respiratory protection under this alternative.

μg/m^3 and then to 25 μg/m^3.[2] Consistent with the previous analysis, net benefits decline across all increments as the discount rate for annualizing benefits increases. The incremental net benefit of reducing the PEL from 100 μg/m^3 to 50 μg/m^3 is greater than the incremental net benefit of reducing the PEL from 50 μg/m^3 to 25 μg/m^3 under both the 3 percent discount rate and the 7 percent discount rate.

However, the majority of the benefits and costs attributable to the final rule (PEL of 50 μg/m^3) are from the initial effort to lower exposures from the preceding PEL of 250 μg/m^3 in both construction and maritime to 100 μg/m^3, as shown in the 100 μg/m^3 column and the Incremental Costs/Benefits column in between the 50 μg/m^3 column and the 100 μg/m^3 column in Table VIII-1. The majority of the costs and benefits attributable to lowering exposures to 100 μg/m^3 are in the construction industry. There would not be any costs or benefits for general industry employers lowering exposures to an alternative of 100 μg/m^3 because the preceding PEL was already 100 μg/m^3, and OSHA assumes full compliance with the preceding PEL for purposes of this analysis, but a relatively small amount of costs and benefits would be attributed to maritime employers lowering exposures to the alternative of 100 μg/m^3 from the preceding PEL of 250 μg/m^3. Because a single standard will cover the general industry and maritime employers, those costs and benefits are grouped together in Table VIII-1 and VIII-2.

[2] The costs exceed the benefits using the 7 percent discount rate for the 100 μg/m^3 alternative, since quantified benefits for this FEA are based entirely on the various quantitative risk assessments, and the PEL for general industry is already set at 100 μg/m^3. As noted previously, the Agency is claiming no quantified benefits for the various ancillary provisions, such as medical surveillance.

* Benefits are assessed over a 60-year time horizon, during which it is assumed that economic conditions remain constant, except that the value of VSLs increase with income and then annualized. Costs are annualized over ten years, with the exception of equipment expenditures, which are annualized over the life of the equipment. Annualized costs are assumed to continue at the same level for sixty years, which is consistent with assuming that economic conditions remain constant for the sixty year time horizon.

**No benefits or costs related to achieving the preceding general industry PEL of 100 μg/m3 are included in these estimates.

As shown in Tables VIII-1 and VIII-2, going from the final rule to Regulatory Alternative #2 (PEL of 25 μg/m^3) is estimated to prevent, annually, an additional 282 silica-related fatalities and an additional 173 cases of silicosis. These estimates support OSHA's finding that there is significant risk remaining at the final PEL of 50 μg/m^3. However, The Agency has determined that a PEL of 25 μg/m^3 is not technologically feasible for most sectors or operations, and for that reason, has not selected it. See the introduction to Chapter IV of this FEA.

REGULATORY ALTERNATIVES THAT AFFECT ANCILLARY PROVISIONS

Section 6(b)(7) of the OSH Act, 29 U.S.C. 655(b)(7), requires standards to prescribe, where appropriate, the monitoring or measuring of employee exposure for the protections of employees. Section 6(b)(7) also requires the standards to prescribe, where appropriate, the type and frequency of medical exams to be provided by employers "in order to most effectively determine whether the health of [exposed] employees is adversely affected by such exposure." The final rule contains several ancillary provisions (provisions other than the PEL), including requirements for exposure assessment, medical surveillance, familiarization and training, regulated areas (in general industry and maritime), and a written exposure control plan.

OSHA's reasons for including each of the ancillary provisions are detailed in Section XV of the preamble, Summary and Explanation of the Standards. In particular, OSHA has determined that requirements for exposure assessment (or alternately, using specified exposure control methods for selected construction operations) provide a basis for ensuring that appropriate measures are in place to limit worker exposures. Medical surveillance is particularly important because workers exposed at levels below the new PEL are still at significant risk of death and illness (OSHA's decision not to lower the PEL further was due to limitations on technological feasibility, rather than a determination that significant risk was eliminated at the new PEL). Medical surveillance will allow for identification of respirable crystalline silica-related adverse health effects at an early stage so that appropriate intervention measures can be taken. Regulated areas and a written exposure control plan are important in part because they help limit exposure to respirable crystalline silica to as few employees as possible. Finally, worker training is necessary to inform employees of the hazards to which they are exposed, along with associated protective measures, so that employees understand how they can minimize potential health hazards. Worker training on silica-related work practices is particularly important in controlling silica exposures because engineering controls frequently require action on the part of workers to function effectively.

As shown in Table VIII-1, these ancillary provisions represent approximately $379 million (or about 37 percent) of the total annualized costs of the final rule of $1,030 billion (using a 3 percent discount rate). The three most expensive of the ancillary provisions are the requirements for medical surveillance, with annualized costs of $96 million; the requirements for training and familiarization, with annualized costs of $946 million; and exposure assessment, with annualized costs of $96 million.

The requirements for exposure assessment in general industry and maritime are triggered by the action level. The exposures of workers in construction for whom all Table 1 requirements have been met do not have to be assessed, but if Table 1 requirements are not met, the requirements for exposure assessment in construction would also be triggered by the action level. As described in the preamble, OSHA has defined the action level for the standard as an airborne concentration of respirable crystalline silica of 25 $\mu g/m^3$ calculated as an eight-hour time-weighted average. In this final rule, as in other OSHA health standards, the action level has been set at one-half of the PEL.

As explained in Chapter IV of this FEA, OSHA finds that proper implementation of engineering and work practice controls, particularly those specified in Table 1, will eliminate much of the variability in silica exposure that characterizes baseline conditions in the general industry, maritime, and construction sectors. OSHA recognizes, however, that some variability is unavoidable and uncontrollable even with such controls. Because of this variability of employee exposures to airborne concentrations of respirable crystalline silica, maintaining exposures below the action level should provide reasonable assurance that employees will not be exposed to respirable crystalline silica at levels above the PEL on days when no exposure measurements are made. Even when all measurements on a given day fall between the PEL and the action level, there is some chance that on another day, when exposures are not measured, actual exposure may exceed the PEL. When exposure measurements are below the PEL but above the action level, the employer cannot be certain that employees have not been exposed to respirable crystalline silica concentrations in excess of the PEL during at least some part of the work week. Therefore, requiring periodic exposure measurements when the action level is exceeded provides the employer with a reasonable degree of confidence in the results of the exposure monitoring.

As specified in the final rule, all workers in general industry and maritime exposed to respirable crystalline silica at or above the action level of 25 $\mu g/m^3$ are subject to the medical surveillance requirements. In the construction sector, medical surveillance is triggered by respirator use for 30 days or more per year (which generally corresponds to a risk of exposure above 50 $\mu g/m^3$ that prompted the Table 1 respirator requirement), For the final rule, the medical surveillance requirements will apply to an estimated 141,594 workers in general industry and 270,581 workers in construction. OSHA estimates that 989 possible ILO 2/0 silicosis cases will be referred to specialists annually as a result of this medical surveillance.

OSHA's conclusion is that the requirements triggered by the action level will result in a very real and necessary, but non-quantifiable, reduction in risk beyond that provided by the PEL alone. OSHA has determined that these ancillary provisions (periodic exposure assessment, medical surveillance in general industry/maritime) will reduce significant risk in at least three ways: (1) providing economic incentives to employers to reduce exposures to below 25 $\mu g/m^3$ to avoid the costs of medical surveillance and exposure monitoring; (2) helping to ensure the PEL is not exceeded;, and (3) providing medical exams to workers exposed at the action level, resulting in additional specialist referrals for X-ray findings consistent with silicosis and allowing employees who find out they have a silica-related disease to take action, such as changing jobs or wearing a respirator for additional protection. In sum, the ancillary provisions triggered by the action level in the final rule provide significant benefits to worker health by providing additional layers and types of protection to employees exposed to respirable crystalline silica. Not least, the OSH Act requires OSHA to adopt ancillary measures that further reduce a significant health risk and are feasible to implement (Pub. Citizen Health Research Grp., 796 F.2d 1479, 1505 (D.C. Cir. 1986). The Supreme Court has described an additional benefit to the type of ancillary provisions OSHA is including here: "It should also be noted that, in setting a permissible exposure level in reliance on less-than-perfect methods, OSHA would have the benefit of a backstop in the form of monitoring and medical testing. Thus, if OSHA properly determined that the permissible exposure limit should be set at 5 ppm, it could still require monitoring and medical testing for employees exposed to lower levels. By doing so, it could keep a constant check on the validity of the assumptions made in developing the permissible exposure limit, giving it a sound evidentiary basis for decreasing the limit if it was initially set too high. Moreover, in this way it could ensure that workers who were unusually susceptible to benzene could be removed from exposure before they had suffered any permanent damage." Indus. Union Dep't, AFL-CIO v. Am. Petroleum Inst., 448 U.S. 607, 657-658 (1980) (Benzene plurality opinion). Medical surveillance is particularly important for this rule because those exposed at the action level are still at significant risk of illness. OSHA did not estimate, and the benefits analysis does not include, monetary benefits resulting from early discovery of illness. OSHA's choice of using an action level for exposure monitoring of one-half of the PEL is based on the Agency's enforcement experience with other standards, including those for inorganic arsenic (29 CFR 1910.1018), ethylene oxide (29 CFR 1910.1047), benzene (29 CFR 1910.1028), and methylene chloride (29 CFR 1910.1052).

In response to comments on the proposed rule and PEA, among other changes discussed in Chapter V, OSHA added familiarization costs and increased estimated training costs in this FEA, and increased the cost of an industrial hygienist when conducting exposure monitoring. These changes, however, were the result of OSHA revisions to its cost estimates, not changes to the text of the regulation. Medical surveillance and exposure assessments were the ancillary provisions that were the focus of regulatory alternatives in the PEA. For these reasons, the Agency has examined four regulatory alternatives (Regulatory Alternatives #3, #4, #5, and #6) involving changes to one or the other of these two ancillary provisions. These four regulatory alternatives are defined below and the incremental cost impact of each is summarized in Table VIII-3. In addition, OSHA has qualitatively considered a regulatory alternative (Regulatory Alternative #7) that would remove all ancillary provisions.

Table VIII-3: Cost of Regulatory Alternatives Affecting Ancillary Provisions

	Cost			Incremental Cost Relative to Final Rule		
3% Discount Rate

Source: OSHA, Directorate of Standards and Guidance, Office of Regulatory Analysis

Under Regulatory Alternative #3, the action level would be raised from 25 μg/m^3 to 50 μg/m^3 in the standard for general industry and maritime, while keeping the PEL at 50 μg/m^3. As a result, exposure monitoring and medical surveillance requirements would be triggered only if workers were exposed above 50 μg/m^3. No changes would be made to the construction standard because the medical surveillance trigger for that standard is respirator use, not an action level. As shown in Table VIII-3, Regulatory Alternative #3 would reduce the annualized cost of the final rule by about $72 million, using a discount rate of 3 percent, and about $107 million using a discount rate of 7 percent.

Under Regulatory Alternative #4, the action level in general industry and maritime would remain at 25 μg/m^3 but medical surveillance would now be triggered by the PEL, not the action level. As a result, medical surveillance requirements would be triggered only if workers in general industry and maritime were exposed above the PEL of 50 μg/m^3. No changes would be made to the construction standard. This alternative is similar to Alternative #3, but because the action level would remain lower, the amount of exposure monitoring would not decrease in Alternative #4 (applicable to general industry and maritime (and for construction employers following the exposure monitoring method of compliance)), exposure monitoring is required when levels exceed the action level). As shown in Table VIII-3, Regulatory Alternative #4 would reduce the annualized cost of the final rule by about $23 million, using a discount rate of 3 percent and about $50 million using a discount rate of 7 percent).

Under Regulatory Alternative #5, the only change to the final rule would be to the medical surveillance frequency requirements. Instead of requiring qualifying workers to be offered a medical check-up every three years, an annual medical check-up would be required to be offered. Assuming all workers will accept this offer, as shown in Table VIII-3, Regulatory Option #5 would increase the annualized cost of the final rule by about $110 million, using a discount rate of 3 percent (and by about $87 million, using a discount rate of 7 percent).

Under Regulatory Alternative #6, medical surveillance would be triggered by the PEL (in general industry and maritime), not the action level, and all workers (including in construction) subject to medical surveillance would be required to have a medical check-up annually rather than triennially. As shown in Table VIII-3, Regulatory Alternative #6 would cause a net increase of the annualized cost of the final rule by about $53 million, using a discount rate of 3 percent (and by about $19 million, using a discount rate of 7 percent).

OSHA has not calculated any changes in benefits for the medical surveillance alternatives in relation to the benefits of the final rule because OSHA did not quantify any benefits attributable to medical surveillance for the final rule. While the Agency expects there will be substantial benefits related to its ancillary provisions, it does not have the same quantitative basis for estimating benefits, and therefore does not have quantitative estimates for the benefits of the preceding four regulatory alternatives.

The final regulatory alternative affecting ancillary provisions, Regulatory Alternative #7, would eliminate all of the ancillary provisions of the final rule, including exposure assessment, medical surveillance, training, regulated areas, and the written exposure control plan. This alternative would be difficult to justify legally in light of 29 U.S.C. 655(b)(5) and (b)(7) along with case law requiring OSHA to use ancillary provisions to reduce significant risk remaining at the PEL when these provisions result in more than a de minimis benefit to workers (see Section II, Pertinent Legal Authority). In any event, it should be noted that elimination of the ancillary provisions does not mean that all costs for ancillary provisions would disappear. In order to meet the PEL, employers would still commonly need to conduct exposure monitoring, train workers on the use of controls, and set up some kind of regulated areas (in general industry and maritime) to indicate where respirator use would be required. It is also likely that some employers would follow the many recommendations to provide medical surveillance for employees and establish a written exposure control plan. OSHA has not attempted to estimate the extent to which the costs of these activities would be reduced if they were not formally required.

OSHA finds that the benefits estimated under the final rule will not be fully achieved if employers do not implement the ancillary provisions of the final rule. For example, OSHA believes that the effectiveness of the final rule depends on regulated areas and the written exposure control plan to further limit exposures and on medical surveillance to identify disease cases when they do occur. For construction work, the written exposure control plan is an integral part of the overall scheme to protect workers engaged in activities covered by Table 1. Without this provision, workers would risk exposures from the activities of others and exposure monitoring would need to be significantly increased to ensure protection for those workers.

Both industry and worker groups have recognized that a comprehensive standard, as opposed to a PEL alone, is needed to protect workers exposed to respirable crystalline silica. For example, the industry consensus standards for crystalline silica, ASTM E 1132 – 06, Standard Practice for Health Requirements Relating to Occupational Exposure to Respirable Crystalline Silica, and ASTM E 2626 – 09, Standard Practice for Controlling Occupational Exposure to Respirable Crystalline Silica for Construction and Demolition Activities, as well as the draft proposed silica standard for construction developed by the Building and Construction Trades Department, AFL-CIO, have each included comprehensive programs. These recommended standards include provisions for methods of compliance, exposure monitoring, training, and medical surveillance (Document ID 1466; 1504; 1509.

A REGULATORY ALTERNATIVE THAT MODIFIES THE METHODS OF COMPLIANCE

The final standard in general industry and maritime requires employers to implement engineering and work practice controls to reduce employees' exposures to or below the PEL. Where engineering and/or work practice controls are insufficient, employers are still required to implement them to reduce exposure as much as possible, and to supplement them with a respiratory protection program. Under the final construction standard, employers are given two options for compliance. The first option specifies, in Table 1 of the final rule, the exposure control methods and respiratory protection required for compliance when performing the specified task or operating the specified machines. Employers choosing this option must fully and properly implement the control methods and respiratory protection on the table to be considered to be in compliance with Table 1. The second option largely follows the requirements in the general industry and maritime standard: employers must conduct exposure monitoring and provide sufficient controls to ensure that their workers are not exposed above the PEL.

One regulatory alternative (Regulatory Alternative #8) involving methods of compliance would be to eliminate Table 1 as a compliance option in the construction sector. This was suggested by one commenter (Document ID 1950), as a means of promoting innovation.

As discussed in the Summary and Explanation in detail, OSHA fashioned the final rule as a sensible compromise between providing clear direction for employers, in a manner that reduces compliance burdens, and allowing for flexibility and innovation when desired. Table 1 is an option in the final rule that promotes both goals. While OSHA assumes that most establishments will choose to follow Table 1, in part to avoid the cost of monitoring, it is not a requirement. Employers are free to follow the other option (paragraph (d) of the standard) and conduct the required monitoring and devise their own means of complying with the PEL if they choose. To eliminate Table 1, therefore, would actually provide less flexibility and impose additional costs upon employers. OSHA therefore did not quantify costs or benefits for eliminating Table 1. Nonetheless, the Agency seriously doubts that there would be any additional benefits under Alternative #8, and concludes that removing the Table 1 option would significantly increase exposure monitoring costs by taking away a carefully crafted "safe harbor" provision from employers.

REGULATORY ALTERNATIVES THAT AFFECT THE TIMING OF THE

STANDARD

The final rule will become effective 90 days following publication of the final rule in the Federal Register. The provisions outlined in the construction standard will become enforceable one year following the effective date, except for those governing sample analysis (two years). The provisions set forth in the general industry and maritime standards will become enforceable two years following the effective date, with the exception that the engineering and work practice control requirements in the hydraulic fracturing industry will become enforceable five years after the effective date.

There are many theoretical options that OSHA could explore with regard to compliance dates. These include: requiring the fracking industry to follow the same compliance schedule as all other general industry and maritime employers; going back to the dates originally proposed (one year for engineering controls, two years for laboratories, six months for all other provisions); allowing more time for all employers to comply with the final rule; or allowing less time for all employers to come into compliance. These options are explored in detail in the Summary and Explanation for "Dates." As indicated in that discussion, there are technical issues, and there may be additional costs, associated with advancing the compliance dates ahead of those laid out in the final rule; in all cases, pushing back the compliance deadlines will also push back the onset of benefits generated by the final rule. OSHA has not quantified the costs or benefits of either advancing or delaying any of the compliance dates because the timing of the effective dates has the same percentage effect on both benefits and costs.

Chapter IX: Final Regulatory Flexibility Analysis

The Regulatory Flexibility Act, as amended in 1996, requires an agency to prepare a Final Regulatory Flexibility Analysis (FRFA) whenever it promulgates a final rule that is required to conform to the notice-and-comment rulemaking requirements of section 553 of the Administrative Procedure Act (APA). See 5 U.S.C. 601-612. For OSHA rulemakings, the FRFA analysis must contain:

1. a statement of the need for, and objectives of, the rule;

2. a statement of the significant issues raised by the public comments in response to the initial regulatory flexibility analysis, a statement of the assessment of the agency of such issues, and a statement of any changes made in the proposed rule as a result of such comments;

3. the response of the agency to any comments filed by the Chief Counsel for Advocacy of the Small Business Administration (SBA) in response to the proposed rule, and a detailed statement of any change made to the proposed rule in the final rule as a result of the comments;

4. a description of and an estimate of the number of small entities to which the rule will apply or an explanation of why no such estimate is available;

5. a description of the estimated reporting, recordkeeping and other compliance requirements of the rule, including an estimate of the classes of small entities which will be subject to the requirement and the type of professional skills necessary for preparation of the report or record; and

6. a description of the steps the agency has taken to minimize the significant economic impact on small entities consistent with the stated objectives of applicable statutes, including a statement of the factual, policy, and legal reasons for selecting the alternative adopted in the final rule and why each one of the other significant alternatives to the rule considered by the agency which affect the impact on small entities was rejected; and for a covered agency, as defined in section 609(d)(2), a description of the steps the agency has taken to minimize any additional cost of credit for small entities. 5 U.S.C. 604.

The Regulatory Flexibility Act further states that the required elements of the FRFA may be performed in conjunction with or as part of any other agenda or analysis required by any other law if such other analysis satisfies the provisions of the FRFA. 5 U.S.C. 605.

In addition to these elements, OSHA also includes, in this section, the recommendations from the Small Business Advocacy Review (SBAR) Panel and OSHA's responses to those recommendations.

While a full understanding of OSHA's analysis and conclusions with respect to costs and economic impacts on small entities requires a reading of the complete FEA and its supporting materials, this FRFA summarizes the key aspects of OSHA's analysis as they affect small entities.

THE NEED FOR, AND OBJECTIVES OF, THE RULE

Exposure to crystalline silica has been shown to increase the risk of several serious diseases. Crystalline silica is the only known cause of silicosis, which is a progressive respiratory disease in which respirable crystalline silica particles cause an inflammatory reaction in the lung, leading to lung damage and scarring, and, in some cases, to complications resulting in disability and death. In addition, many well-conducted investigations of exposed workers have shown that exposure increases the risk of mortality from lung cancer, chronic obstructive pulmonary disease (COPD), and renal disease. OSHA's detailed analyses of the scientific literature and silica-related health risks were presented in OSHA's Review of Health Effects Literature and Preliminary QRA in the NPRM (Document ID 1711, pp. 7-229), and are included in Section VI Significance of Risk in the preamble to the final rule.

OSHA reviewed numerous studies and found that they all demonstrated positive, statistically significant exposure-response relationships between exposure to crystalline silica and lung cancer mortality. (See the Health Risk section in the preamble for more detail). In addition, OSHA noted that in 2009 the International Agency for Research on Cancer (IARC) reaffirmed its finding that respirable crystalline silica is a human carcinogen, identifying in its analysis an overall positive exposure-response relationship between cumulative exposure to crystalline silica and lung cancer mortality (see Section VI. Significance of Risk; Document ID 1711, pp. 269-292). Based on studies, OSHA estimates that the lifetime lung cancer mortality excess risk associated with 45 years of exposure to respirable crystalline silica ranges from 11 to 54 deaths per 1,000 workers at the preceding general industry PEL of 100 $\mu g/m^3$ respirable crystalline silica, with that risk reduced to 5 to 23 deaths per 1,000 workers at the new PEL of 50 $\mu g/m^3$ respirable crystalline silica.

OSHA has also quantitatively evaluated the mortality risk from non-malignant respiratory disease, including silicosis and COPD. Risk estimates for silicosis mortality are based on a study by Mannetje et al. (2002b, Document ID 1089), as reanalyzed by ToxaChemica, Inc. (2004, Document ID 0469), which pooled data from six worker cohort studies to derive a quantitative relationship between silica exposure and death rate for silicosis. For non-malignant respiratory disease generally, risk estimates are based on an epidemiologic study of diatomaceous earth workers, which included a quantitative exposure-response analysis (Park et al., 2002, Document ID 0405). For 45 years of exposure to the preceding general industry PEL, OSHA's estimates of excess lifetime risk are 11 silicosis deaths per 1,000 workers for the pooled analysis and 85 non-malignant respiratory disease deaths per 1,000 workers based on Park et al.'s (2002) estimates. At the new PEL, OSHA estimates silicosis and non-malignant respiratory disease mortality at 7 and 44 deaths per 1,000, respectively. As noted by Park et al. (2002), it is likely that silicosis as a cause of death is often misclassified as emphysema or chronic bronchitis; thus, Mannetje et al.'s analysis of deaths may tend to underestimate the true risk of silicosis mortality, while Park et al.'s (2002) analysis would more fairly capture the total respiratory mortality risk from all non-malignant causes, including silicosis and COPD.

OSHA also identified five studies that quantitatively described relationships between exposure to respirable crystalline silica and silicosis morbidity, as diagnosed from chest radiography. Based on the results of these studies, OSHA estimates a cumulative risk for silicosis morbidity of 60 to 773 cases per 1,000 workers for a 45-year exposure to the preceding general industry PEL of 100 μg/m^3 respirable crystalline silica, and 20 to 170 cases per 1,000 workers exposed at the new PEL of 50 μg/m^3 (see Section VI. Significance of Risk, Table VI-1).

OSHA's estimates of crystalline silica-related renal disease mortality risk are derived from an analysis by Steenland et al. (2002, Document ID 0448), in which data from three cohort studies were pooled to derive a quantitative relationship between exposure to silica and the relative risk of end-stage renal disease mortality. The cohorts included workers in the U.S. gold mining, industrial sand, and granite industries. OSHA's analysis for renal disease mortality shows estimated lifetime excess risk of 39 deaths per 1,000 workers at the preceding general industry PEL of 100 μg/m^3 respirable crystalline silica, and 32 deaths per 1,000 workers exposed at the new PEL of 50 μg/m^3 (see Section VI. Significance of Risk, Table VI-1).

The objective of the final rule is to reduce the numbers of fatalities and illnesses occurring among employees exposed to respirable crystalline silica in general industry, maritime, and construction sectors. This objective will be achieved by requiring employers to install engineering controls where appropriate and to provide employees with the equipment, respirators, training, exposure monitoring, medical surveillance, and other protective measures necessary for them to perform their jobs safely. The legal basis for the rule is the responsibility given to the U.S. Department of Labor through the Occupational Safety and Health Act of 1970 (OSH Act). The OSH Act provides that, in promulgating health standards dealing with toxic materials or harmful physical agents, the Secretary “shall set the standard which most adequately assures, to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health or functional capacity even if such employee has regular exposure to the hazard dealt with by such standard for the period of his working life.” 29 U.S.C. 655(b)(5).

See Section II of the preamble for a more detailed discussion.

SUMMARY OF SIGNIFICANT ISSUES RAISED BY COMMENTS ON THE INITIAL REGULATORY FLEXIBILITY ANALYSIS (IRFA) AND OSHA’S ASSESSMENT OF, AND RESPONSE TO, THOSE ISSUES

Small business representatives commented on all aspects of this rule, and their comments and OSHA’s responses are covered throughout the preamble and this FEA. This section of the FRFA focuses only on comments that directly concern this FRFA or the screening analysis that precedes it.

One commenter questioned the use of SBA definitions for small businesses, arguing that some definitions include firms with 500 employees or more, which, according to the commenter, are too large to constitute “small” businesses. The commenter commended OSHA for also including an analysis of very small entities with fewer than 20 employees (Document ID 2351, Attachment 1, p. 8). OSHA determined that both the analysis of the impacts on SBA-defined small entities and the analysis of the impacts on very small entities (those with fewer than twenty employees) are useful and important for examining small business impacts.

Two commenters were concerned that their industries had not been covered in the IRFA. The American Railroad Association noted that small railroads had not been covered (Document ID 2366, Attachment 1, p. 4). The commenter is correct that OSHA did not examine small entities in this sector in the IRFA. For this FEA, OSHA has added a discussion of small entities in the railroad industry to Chapter VI, Economic Impacts. The Sorptive Minerals Institute also stated that their industry was not covered in the IRFA (Document ID 4230, Attachment 1, p. 16). As discussed in Chapter IV, the sorptive mineral industry was covered as part of a larger industry. In any case, OSHA has excluded exposures that result from the processing of sorptive clays from the scope of the final rule.

Many commenters were concerned that OSHA had not used economic data that included the effects of the recent “great recession”. This issue was addressed in the Chapter VI, Introduction, but some commenters specifically discussed this topic in reference to small entities (Document ID 1822, Attachment 1, p. 1; 2187, Attachment 1, p. 2; 2322, p. 13; 3433, p. 8; 4231, Attachment 1, pp. 15-17). Complete data of the kind that OSHA needs for a thorough analysis of economic impacts were not yet available at the time the PEA was developed. As discussed in Chapter II, Industrial profile, this FEA, including this FRFA, uses 2012, the most recent year with complete data, as a base year and used average profits from years including the recession and surrounding years.

Some commenters were concerned with OSHA's estimates of small business profits. One commenter pointed out that OSHA had relied entirely on C corporation data, even though many affected firms might be S corporations, partnerships or sole proprietorships (Document ID 2296, Attachment 1, p. 23). This is true, but there are no published data on S corporation, partnership, or sole proprietorship profits, and thus C corporation data is the best available data. As another commenter pointed out, reported profits of small business are generally lower than the total returns earned by owners who also act as executives for their firms. The same commenter explained that smaller firms have a great deal of flexibility in deciding what portions of entity gains are reported as profits, what portions are reported as management salaries, and what portions are reported as management bonuses (Document ID 2163, Attachment 1, p. 7). As a result, it is possible that OSHA has underestimated small firm profits and thus overestimated potential impacts on profits.

Stuart Sessions argued that OSHA should have analyzed whether smaller firms have higher or lower profits than larger firms (Document ID 4231, Attachment 1, pp. 11-12). The limited data supplied by Mr. Sessions, however, did not show that small firms either had larger or smaller profits than bigger firms on an across-industry basis (Document ID 4231, Attachment 1, p. 11). Mr. Sessions developed an economic model that used a combination of multiple data sources to determine profit rates of small firms (RMA and BizMiner). In Chapter III Industrial Profile, Revenue and Profit, OSHA discusses why the Agency's analysis does not use these alternate data sources suggested by Mr. Sessions. Mr. Sessions, testifying on behalf of the Construction Industry Safety Coalition, also testified that the use of data aggregated to the four-digit NAICS code level in OSHA's analysis shields small businesses from being captured properly in the analysis, and that "the analysis at the six-digit level would show substantial impacts for masonry contractors who are small business …, which the analysis currently doesn't show" (Document ID 3580, Tr. 1402). Mr. Sessions further claimed that, even though OSHA analyzed the costs to employers with 20 or fewer employees, the analysis still "hid" a lot of small businesses (Document ID 3580, Tr. 1402). The use of Internal Revenue Service's Corporation Source Book profit data at a four-digit NAICS code level is explained in Chapter III along with a discussion explaining why alternative data sources suggested by Mr. Sessions are not applied in this FEA.

At least one commenter argued that OSHA might have inaccurately estimated small firm revenues as a result of OSHA's method of estimating revenues for years when Census data are not available (Document ID 4231, Attachment 1, pp. 15-17). This argument is now moot, as OSHA is using data from the 2012 Economic Census, and is not using estimated revenues in this analysis.

Some commenters argued that OSHA had not adequately accounted for diseconomies of scale in small firms (Document ID 4231, Attachment 1, pp. 2-5; 2307, Attachment 10, p. 25; 2322, Attachment 1, pp. 15-16). During his testimony, Stuart Sessions testified that it was his "guess . . . that small businesses are substantially more likely to be noncompliant currently than large businesses," and requested that OSHA conduct additional analysis to "handle the differential compliance rates between small and large business" (Document ID 3580, Tr. 1399). As discussed in Chapter V, OSHA has changed its approach to estimating costs of small firms to account for diseconomies of scale in small firms. However, there is no evidence, other than Mr. Sessions's "guess," that small firms are less compliant than large firms.

Janet Kaboth, testifying on behalf of a small company in the brick manufacturing industry, stated that small businesses are more impacted by the rule because they have more difficulty accessing capital to upgrade engineering controls:

> "[Engineering controls] must be purchased and paid for in the first year of compliance. … It is extremely unlikely that a small entity such as Whitacre Greer would be able to obtain a bank loan … for something that does not reduce costs or increase revenue and additionally adds cost (Document ID 3589, Tr. 3397-3399).

As discussed in Chapter VI, Economic Impacts, small firms will typically be able to pay for the first year costs of engineering controls from a single year's profits. Thus, there is no need to account for possible difficulties in obtaining credit.

A different commenter requested that OSHA provide additional guidance in Table 1 of the construction standard as a way to mitigate the impact on small businesses (Document ID 2322, p. 6). OSHA has done so, and agrees that it will likely ease compliance for small construction businesses because it provides them with task-specific guidance that will allow them to avoid more complicated exposure monitoring processes.

Many companies, associations, and private individuals submitted comments requesting a new SBAR Panel based a number of changes that have occurred since the SBAR Panel for this rule was held in 2003. The first and most common concern was that the economic data and information gathered during the Panel have become outdated and do not represent the dramatic changes in economic conditions that have resulted from the boom and bust economic cycle that occurred in the years following 2003 (Document ID 2224, p. 2; 2004, p. 1; 3580, Tr. 1274-1276; 1779, p. 2; 1767, p. 2; 1783, p. 1; 2140, p. 1; 3495, p. 2; 1798, p. 6; 1811, pp. 1-2; 2023, p. 1; 2222, p. 1; 2224, p. 2; 2230, p. 1; 2248, Attachment 1, p. 5; 2294, p. 2; 2300, p. 2; 2305, p. 13; 2279, p. 11; 2289, p. 9; 2391, p. 2; 3275, pp. 2-3; 2075, p. 4; 2083, p. 1; 2114, Attachment 1, p. 2; 2150, p. 2; 2170, Attachment 1, p. 1; 2210, Attachment 1, pp. 1-2; 4194, p. 5; 4210, Attachment 1, p. 2; 4217, Attachment 1, p. 7). Some commenters claimed that their industries have not recovered from the recession of 2008 and feel that their economic circumstances as small entities have changed as a result (Document ID 1779, p. 2; 1767, p. 2; 1783, p. 1; 2140, p. 1; 3495, p. 2).

OSHA conducted the SBAR Panel early in the rulemaking process in order to address small business concerns during the development of the proposed rule. The Agency used information gathered during the SBAR Panel to make significant changes to the proposed rule itself, as well as to the cost, impact, and other analyses contained in the proposal. OSHA's proposal contained six pages of tables that described every recommendation from the SBAR Panel, along with the Agency's responses.

OSHA's extensive rulemaking process included small business feedback not only from the original SBREFA review in 2003, but also from the subsequent written comment period in 2013 and 2014, as well as from the public hearings held in 2014. The rulemaking record shows the major issues that arose with respect to technological feasibility, costs, economic feasibility, and possible alternatives to the proposed rule represented largely the same issues addressed by small entity representatives (SERs) in 2003. To the extent there may be new issues that have arisen since the SBAR Panel made its recommendations, OSHA is confident that commenters, including small entities and the Small Business Administration's Office of Advocacy, were able to raise those issues and express whatever concerns they had about them later in the rulemaking process. OSHA has addressed comments regarding recent and current economic conditions under which small businesses are operating by considering this information in developing the final rule and supporting analyses.

A second concern raised by commenters who were advocating for OSHA to hold a new SBAR Panel, related to the changes in technology and work practices that have taken place over the last ten years. For example, one commenter claimed that the comments of the SERs were not reflective of the greater use of tools with dust collection capability, and other devices currently being used that release water at the point of cutting, to control silica dust (Document ID 2210, Attachment 1, p. 1). However, the commenters who wanted OSHA to account for improved technology and work practices did not generally provide information to supplement or update the information OSHA received from the SERs, despite opportunities to do so.

While there has been progress in the development and adoption of technologies that reduce silica exposures, the record (including comments from the commenters calling for a new Panel) brought out few, if any, fundamentally new technologies for reducing silica exposure. In any event, the advancement of technologies that would improve silica control or reduce the cost impact of the final rule would not necessitate a new SBAR panel.

There were also a number of construction firms that expressed disappointment at not being able to comment on Table 1, as presented in the proposed rule, prior to the proposed rule being issued (Document ID 2187, p. 22; 4217, Attachment 1, p. 7; 3580, Tr. 1274-1276). It is typical for OSHA to modify a rule as a result of the SBREFA process. The SBREFA process is a one-time requirement, not a requirement to conduct a new Panel every time a rule is altered in response to SBAR Panel recommendations. The commenters, who did have the opportunity to comment on Table 1 once it was proposed, did not present any compelling argument regarding how the timing of their opportunity to comment impacted their ability to communicate their recommendations about Table 1 to OSHA. The Agency notes that it has made a number of significant changes to Table 1 since the proposal, most in response to post-proposal comments, so it is clear that commenters had ample opportunities to recommend improvements to Table 1.

No SERs from the hydraulic fracturing industry were included in the 2003 SBAR panel. OSHA did not determine that this industry would be affected by this rule until the preparation of the NPRM and the PEA. As a result, OSHA has received comments from associations and businesses requesting a new SBAR Panel that would allow a more detailed analysis of the potential impacts on small entities in this industry. Commenters pointed out that the unique economic circumstances of the hydraulic fracturing industry were not presented for public comment or analysis on regulatory alternatives and small business impacts during the Agency’s 2003 SBAR Panel (Document ID 2301, Attachment 1, p. 63; 3589, pp. 15-16; 2288, p. 5).

OSHA is not required to assure that every industry affected by a rule is represented on the Panel by a SER. The hydraulic fracturing industry had extensive opportunities to comment throughout this rulemaking process. In fact, a number of commenters, including several trade associations, submitted comments and testified at the hearing, providing extensive analysis of the hydraulic fracturing industry for the record. OSHA sees no indication that the record would be better developed by convening a different SBAR panel with a SER from the hydraulic fracturing industry. OSHA has, however, extended the compliance deadline for these firms to install the required engineering controls required by this final rule to five years; three more years than for establishments in general industry and four more years than for construction firms.

RESPONSE TO COMMENTS BY THE CHIEF COUNSEL FOR ADVOCACY OF THE SMALL BUSINESS ADMINISTRATION AND OSHA'S RESPONSE TO THOSE COMMENTS

The Chief Counsel for Advocacy of the Small Business Administration ("Advocacy") provided OSHA with comments on this rule on February 11, 2014 (Document ID 2349). Advocacy provided comment on OSHA's risk assessment and benefits analysis; technological feasibility analysis; cost analysis; current economic conditions; preferred alternatives; and procedural issues.

Risk Assessment and Benefits Issues

With respect to the risk assessment, Advocacy was concerned that OSHA was attributing benefits to reducing the PEL to 50 $\mu g/m^3$ that perhaps would better be attributed to eliminating exposures above the existing PEL of 100 $\mu g/m^3$ (Document ID 2349, pp. 3-4). OSHA does not think this is the case. As discussed in the section on significant risk, OSHA did not assess the risk of silica exposure by attributing existing known cases of silicosis or any other disease to various PELs. Rather, OSHA examined risk assessment studies that assessed the long term consequences of various levels of exposure to silica. Such studies focus on estimating the morbidity and mortality that result from changing lifetime exposure levels from the preceding PELs of 100 $\mu g/m^3$ in general industry and 250 $\mu g/m^3$ in construction to the new PEL of 50 $\mu g/m^3$.

Advocacy also expressed concerns about the accuracy of older exposure data (Document ID 2349, p. 4). OSHA's exposure profile, used for examining feasibility and benefits, now shows only exposures measured after 1990 and includes data from OSHA's OIS system for 2011 to 2014.

Advocacy was also concerned that OSHA might not have adequately accounted for varying risk levels associated with different types of silica (Document ID 2349, p. 4). OSHA carefully considered this issue in the risk assessment section and found there were insufficient data to demonstrate significant risk for silica exposures that result from processing sorptive clays. As a result, OSHA excluded this processing activity from the scope of the final standard. OSHA found that, while the risk from other forms of silica may vary, there is evidence of significant risk for all of the other forms of respirable crystalline silica.

Advocacy also reported that small business representatives were concerned that “OSHA’s assumption that silica exposure occurs over a working life of eight hours per day for 45 years does not reflect modern working conditions” (Document ID 2349, p. 4). OSHA is required by the OSH Act to consider the risk of a hazard over a worker’s entire working life. See 29 U.S.C. 655(b)(5). In Chapter VII of this FEA, OSHA also examined other possible average tenure assumptions and found that varying the tenure assumption made little difference to estimated benefits. With lower r tenure OSHA estimates lower morbidity but higher fatalities, such that the net effect was higher estimated benefits.

Advocacy also reported that small business representatives “noted the uncertainty of assessing silica-related risk because of confounding factors, such as smoking or exposure to other chemicals, and the long latency period for silica-related illness to appear” (Document ID 2349, p. 4). OSHA notes in Section VI, Significance of Risk, in the preamble to the final rule that study after study finds that incidence of the diseases caused by exposure to silica rises with increasing exposures to silica. In order to see this type of result, and for those results to be driven by smoking as a confounding factor, it would be necessary not just that the silica-using population smoke more than the comparable non-silica using population, but also that smoking rates rise as silica exposures increase. This seems very unlikely and there is no evidence in the record that this is the case.

Technological Feasibility Issues

Advocacy noted that small business representatives had raised many concerns about whether the controls OSHA indicated as appropriate to achieve the PEL were feasible in all circumstances and could, in fact, allow an employer to fully achieve the PEL (Document ID 2349, p. 4). OSHA has thoroughly examined all comments on this kind of issue across all affected industries in Chapter IV of this FEA, and OSHA notes that employers may raise infeasibility as a defense in enforcement actions[1]. Advocacy also noted that small business representatives were concerned about whether available methods of measuring exposure were sufficiently accurate to correctly measure the action level and PEL (Document ID 2349, p. 4). OSHA has explained in Chapter IV of this FEA why existing equipment is sufficiently accurate to correctly measure airborne respirable silica at the levels established by the new PEL and action level.

Advocacy said that one small business representative “noted that increasing the volume of air needed for additional ventilation could result in a violation of a facility’s air permit”

[1] An employer can establish an affirmative defense of infeasibility if it shows that: (1) compliance with the requirements of a standard is impossible or would prevent performance of required work; and (2) it took reasonable alternative steps to protect employees or there are no alternative means of employee protection available. Establishing this defense will excuse the employer from a citation that has otherwise been documented. *See Field Operations Manual*, CPL 02-00-159, Ch. 5, Sec. VI (Oct. 1, 2015).

(Document ID 2349, p. 5). While the Agency does not believe that most small employers exhaust large enough volumes of air that the additional ventilation required by this final standard will result in needing to alter air permits, OSHA does acknowledge that this may be an issue for some employers. In order to reduce the burden, should this be the case, OSHA has given general industry employers an additional year to meet the PEL, and has added costs for firms subject to air permitting requirements to alter their permits to more fully assess the economic feasibility of this rule.

Advocacy also said that one small business representative "noted that creating regulated areas is not feasible in many open-design facilities" (Document ID 2349, p. 5). Regulated area requirements have been a part of OSHA health standards for many years and employers have consistently found ways to make them work. The Agency does not expect that establishing a regulated area for silica would be any more difficult than establishing such an area for any of the other substances for which OSHA has regulated area requirements. In addition, OSHA does not have a regulated area requirement in construction where workplaces (such as in road building or repair) are more mobile.

Cost Issues

Advocacy stated that small business representatives generally felt that OSHA underestimated costs, and were particularly concerned about OSHA's "cost per exposed worker" approach and OSHA's estimates of the number of workers whose exposures are controlled per engineering control (Document ID 2349, p. 5). The specific methodological issues that Advocacy mentions are issues for OSHA's general industry and maritime cost estimates, but not for construction cost estimates because the cost estimation methodologies for the construction sector are quite different and do not use the "cost per exposed worker" approach. OSHA has provided detailed responses to comments on costs in Chapter V. In general industry and maritime, OSHA continues to use the cost per exposed worker approach and defends this approach in Chapter V. OSHA has lowered its estimate of the number of workers whose exposures are reduced per engineering control in response to comments from small business representatives and others.

Advocacy also noted that small business representatives objected to OSHA focusing on the incremental cost of moving from the preceding PELs to the new PEL. Advocacy reported that small business representatives believed OSHA should have included the costs of reaching the preceding PEL in its analysis (Document ID 2349, p. 5). Contrary to Advocacy's suggestion, OSHA did not conduct the analysis this way because it would require an assumption that employers are not complying with OSHA's existing requirements to meet the preceding PEL, but would now choose to comply with a more stringent requirement. OSHA's exposure profiles do indicate that many employers are failing to meet the preceding PELs, but the question that the Agency has to address with this analysis for this rulemaking is whether OSHA should require employers to meet a lower PEL than the preceding PEL. The costs of meeting the preceding PEL are not relevant to that decision.

Issues Concerning Current Economic Conditions

Advocacy reported that "small business representatives stated that OSHA was using older economic data that does not reflect current economic conditions, and [thus] that OSHA's cost pass-through assumptions are unrealistic" (Document ID 2349, p. 5). For this FEA, OSHA is using 2012 as the base year for economic data and includes data from the recent recession in analyzing average industry profits and historical changes in profits and prices. OSHA has updated its findings on the ability of firms to pass costs on to buyers in light of the updated data, resolving Advocacy's concern on this issue.

Regulatory Alternatives

Advocacy commended OSHA for following the advice of small business representatives and adopting the Table 1 approach for the construction sector, but urged OSHA to make the table clearer, more workable, and more specific, and to relieve employers of any remaining duty to conduct exposure monitoring when engaged in Table 1 tasks (Document ID 2349, p. 6). OSHA has revised Table 1, as Advocacy and small business representatives suggested, to provide employers with a clear alternative to exposure monitoring and to provide greater clarity and specificity in the descriptions of controls.

Advocacy also urged OSHA to consider the option of leaving the PEL unchanged and instead improving enforcement, noting that this was the option most favored by small business representatives (Document ID 2349, p. 3). However, the OSH Act commands OSHA to protect workers from harmful substances by setting

> the standard which most adequately assures, to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health or functional capacity even if such employee has regular exposure to the hazard dealt with by such standard for the period of his working life." 29 U.S.C. 655(b)(5).

The record does not indicate that workers are currently protected in accordance with the Act. There are currently two entirely different PELs, 100 $\mu g/m^3$ in general industry and 250 $\mu g/m^3$ in construction. The record does not suggest either that employers in construction cannot feasibly reach a lower PEL or that there is no significant risk below 250 $\mu g/m^3$. The record shows that most employers in construction currently reach a PEL of 50 μg/m^3 most of the time (see Chapter IV) and that it is economically feasible to do so (see Chapter VI).

OSHA did consider the option of lowering the construction PEL to 100 μg/m^3 and leaving the general industry PEL unchanged. However, this action would not be in accordance with the OSH Act given that there is still significant risk at a PEL of 100 μg/m^3 and that a lower PEL is both technologically and economically feasible. Moreover, as discussed in the regulatory alternatives section, the adopted option of a PEL of 50 μg/m^3 for both general industry and construction results in greater estimated net benefits. As shown in OSHA's risk assessment, there is still significant risk of material impairment of health at levels all the way down to a lower PEL of 25 μg/m^3, but OSHA found compliance with the lower PEL of 25 μg/m^3 to be technologically infeasible for all industries.

Finally, Advocacy urged OSHA to consider the option of abandoning the hierarchy of controls, which is OSHA's longstanding policy of preferring engineering controls and administrative controls over personal protective equipment such as respirators (Document ID 2349, pp. 4-5). This issue is addressed in the summary and explanation section discussion of the methods of compliance provision. It should also be noted that OSHA defines technological feasibility in terms of what can be accomplished with engineering controls, not in terms of what can be accomplished with respirators.

Issues with Respect to Small Business Participation

Advocacy also expressed concern that small businesses did not have adequate opportunity for participation in the rulemaking process and that the SBAR panel was held over ten years before the proposed rule was issued (Document ID 2349, p. 7). OSHA responded to these concerns in section two of this FRFA.

A DESCRIPTION AND ESTIMATE OF THE NUMBER OF SMALL ENTITIES TO WHICH THE RULE WILL APPLY

OSHA has analyzed the impacts associated with this final rule, including the type and number of small entities to which the standard will apply. In order to determine the number of small entities potentially affected by this rulemaking, OSHA used the definitions of small entities developed by the Small Business Administration (SBA) for each industry.

OSHA estimates that approximately 646,000 small business or government entities would be affected by the silica standard. Within these small entities, roughly 1.4 million workers are exposed to crystalline silica and would be protected by this final standard. A breakdown, by industry, of the number of affected small entities is provided in Table III-6 in Chapter III of this FEA.

OSHA estimates that approximately 579,000 very small entities would be affected by the silica standard. Within these very small entities, roughly 785,000 workers are exposed to crystalline silica and would be protected by the standard. A breakdown, by industry, of the number of affected very small entities is provided in Table III-7 in Chapter III of this FEA.

A DESCRIPTION OF THE ESTIMATED REPORTING, RECORDKEEPING, AND OTHER COMPLIANCE REQUIREMENTS OF THE RULE

Tables IX-1 and IX-2 show the average costs of the silica standard and the costs of compliance as a percentage of profits and revenues by NAICS code for, respectively, small entities (classified as small by SBA) and very small entities (those with fewer than 20 employees). The costs for SBA defined small entities ranges from a low of $295 per entity for entities in NAICS 238200 Building Equipment Contractors, to a high of about $161,651for NAICS 213112 Support Activities for Oil and Gas Operations.

The cost for very small entities, ranges from a low of $223 for entities in NAICS 238200 Building Equipment Contractors, to a high of about $119,072 for entities in NAICS 213112 Support Activities for Oil and Gas Operations.

Table IX-3a and IX-3b shows the unit costs which form the basis for OSHA's cost estimates for the average small entity and very small entity.

Table IX-1: Average Costs and Impacts for Small Entities Affected by the Final Silica Standard for General Industry, Maritime, and Construction (2012 dollars)

NAICS	Industry	Cost per Affected Entity	Cost to Profit	Cost to Revenue
213112	Support Activities for Oil and Gas Operations	$161,651	18.15%	1.29%
324121	Asphalt Paving Mixture and Block Manufacturing	$610	0.07%	0.00%
324122	Asphalt Shingle and Coating Materials Manufacturing	$10,782	0.81%	0.05%
325510	Paint and Coating Manufacturing	$887	0.29%	0.01%
327110	Pottery, Ceramics, and Plumbing Fixture Manufacturing	$8,161	38.57%	0.52%
327120	Clay Building Material and Refractories Manufacturing	$34,727	33.59%	0.45%
327211	Flat Glass Manufacturing	$3,282	1.72%	0.05%
327212	Other Pressed and Blown Glass and Glassware Manufacturing	$6,171	7.50%	0.20%
327213	Glass Container Manufacturing	$81,273	2.20%	0.06%
327320	Ready-Mix Concrete Manufacturing	$9,821	11.51%	0.16%
327331	Concrete Block and Brick Manufacturing	$9,363	13.11%	0.19%
327332	Concrete Pipe Manufacturing	$12,926	14.53%	0.21%
327390	Other Concrete Product Manufacturing	$9,139	18.59%	0.27%
327991	Cut Stone and Stone Product Manufacturing	$7,343	24.70%	0.43%
327992	Ground or Treated Mineral and Earth Manufacturing	$16,878	9.60%	0.17%
327993	Mineral Wool Manufacturing	$8,768	5.76%	0.10%
327999	All Other Miscellaneous Nonmetallic Mineral Product Manufacturing	$21,200	20.90%	0.37%
331110	Iron and Steel Mills and Ferroalloy Manufacturing	$1,194	0.16%	0.00%
331210	Iron and Steel Pipe and Tube Manufacturing from Purchased Steel	$1,262	0.17%	0.00%
331221	Rolled Steel Shape Manufacturing	$1,210	0.16%	0.00%
331222	Steel Wire Drawing	$1,254	0.38%	0.01%
331314	Secondary Smelting and Alloying of Aluminum	$1,249	0.17%	0.00%
331420	Copper Rolling, Drawing, Extruding, and Alloying	$1,280	0.11%	0.00%
331492	Secondary Smelting, Refining, and Alloying of Nonferrous Metal (except Copper and Aluminum)	$1,218	0.12%	0.00%
331511	Iron Foundries	$38,050	6.38%	0.28%
331512	Steel Investment Foundries	$26,727	4.64%	0.20%

Table IX-1: Average Costs and Impacts for Small Entities Affected by the Final Silica Standard for General Industry, Maritime, and Construction (2012 dollars) continued

NAICS	Industry	Cost per Affected Entity	Cost to Profit	Cost to Revenue
331513	Steel Foundries (except Investment)	$31,446	6.97%	0.30%
331524	Aluminum Foundries (except Die-Casting)	$8,437	4.06%	0.18%
331529	Other Nonferrous Metal Foundries (except Die-Casting)	$6,092	2.67%	0.12%
332111	Iron and Steel Forging	$1,199	0.19%	0.01%
332112	Nonferrous Forging	$1,186	0.19%	0.01%

[1] During the recession, some industries had a negative "net income." For example, NAICS code 3361, Motor Vehicle Manufacturing (the four digit NAICS industry that includes the six digit NAICS industries 336111 Automobile Manufacturing, 336112 Light Truck and Utility Vehicle Manufacturing, and 336120 Heavy Duty Truck Manufacturing), had a large negative "net income" for 2008 and 2009, pulling the average profit rate down to -7.76 percent. Similarly, NAICS code 237200, Land Subdivision, had a large negative "net income" for 2008 through 2010, pulling the average profit rate down to -2.7 percent. Such negative average profit rates resulted in negative cost to profit ratios for some of the industries in this table.

[2] Costs and impact to rail transportation were estimated separately. See the discussions in Chapter V and Chapter VI for more information

Table IX-2: Average Costs for Very Small Entities (<20 employees) Affected by the Final Silica Standard for General Industry, Maritime, and Construction (2012 dollars)

NAICS	Industry [1]	Cost per Affected	Cost to Profit	Cost to Revenue
213112	Support Activities for Oil and Gas Operations	$119,072	29.46%	2.09%
324121	Asphalt Paving Mixture and Block Manufacturing	$234	0.07%	0.00%
324122	Asphalt Shingle and Coating Materials Manufacturing	$3,670	1.44%	0.09%
325510	Paint and Coating Manufacturing	$325	0.48%	0.02%
327110	Pottery, Ceramics, and Plumbing Fixture Manufacturing	$4,542	90.64%	1.21%
327120	Clay Building Material and Refractories Manufacturing	$8,136	58.51%	0.78%
327211	Flat Glass Manufacturing	$3,969	20.44%	0.54%
327212	Other Pressed and Blown Glass and Glassware Manufacturing	$3,951	22.66%	0.59%
327213	Glass Container Manufacturing	$3,927	6.66%	0.17%
327320	Ready-Mix Concrete Manufacturing	$4,291	15.91%	0.23%
327331	Concrete Block and Brick Manufacturing	$4,322	19.52%	0.28%
327332	Concrete Pipe Manufacturing	$4,612	22.11%	0.32%
327390	Other Concrete Product Manufacturing	$3,912	29.24%	0.42%
327991	Cut Stone and Stone Product Manufacturing	$3,835	30.81%	0.54%
327992	Ground or Treated Mineral and Earth Manufacturing	$6,671	16.33%	0.29%
327993	Mineral Wool Manufacturing	$3,966	17.42%	0.31%
327999	All Other Miscellaneous Nonmetallic Mineral Product Manufacturing	$12,216	51.05%	0.89%
331110	Iron and Steel Mills and Ferroalloy Manufacturing	NA	NA	NA
331210	Iron and Steel Pipe and Tube Manufacturing from Purchased Steel	NA	NA	NA

N/A = Not applicable.

[1] In the PEA, OSHA identified a number of industries as having captive foundries and estimated that some very small entities in those industries would have captive foundries. For this FEA, the Agency determined that this assumption was incorrect and that entities with fewer than 20 employees would not have enough workers to perform foundry operations as well as their primary business operations. For the sake of comparability between the PEA and FEA, OSHA has left those industries in this table but shows that very small entities in those industries will have no costs associated with this final rule.

[2] Costs and impact to rail transportation were estimated separately. See the discussions in Chapter V and Chapter VI for more information.

[3] During the recession some industries had a negative “net income”. For example, the NAICS code 237200, Land Subdivision, had a large negative “net income” for 2008 through 2011, pulling the average profit rate down to -2.7 percent. This negative average profit rate resulted in a negative cost to profit ratio for this industry.

Table IX-3a: Source Information for the Unit Cost Estimates Used in OSHA's Final Cost Analysis for General Industry and Maritime

Control [a]	Description	Ventilation Airflow (cfm)	Capital Cost [b]	Operating Cost	Annualized Capital Cost	Comment or Source
Local exhaust ventilation (LEV)	Average capital and operating cost assumptions; per cfm	NA	$13.34	$3.70	$1.56	Estimated by industrial ventilation consultants, capital cost [a]; operating costs reflect current energy prices
Conveyor covers (unventilated)	Conveyor covers (2 ft. bed, including all hardware); per linear foot	NA	$20.73	NA	$2.43	$17.10 per linear foot for 100 ft. (Landola, 2003) [a]
Maintenance percentage	Standard rate for maintenance of capital equipment	NA	NA	NA	NA	10% - estimated as a percentage of capital cost
Dust suppressants	Kleen Products 50lb poly bag green sweeping compound	NA	NA	$676.47	$0.00	$0.28/lb, 2 lbs/day; 5 minutes/day (www.fastenal.com).
HEPA vacuum for housekeeping	NILFISK VT60 wet/dry hepa vac, 15 gal	NA	$3,632.58	$511.20	$793.19	Nilfisk, HEPA vacuum (http://www.sylvane.com/nilfisk.html)
HEPA vacuum for housekeeping	NILFISK, large capacity	NA	$8,002.49	$988.90	$1,747.38	Nilfisk, HEPA vacuum (McCarthy, 2003)
Saw enclosure	8x8x8 wood/plastic	NA	$526.90	$52.69	$115.05	Fabrication costs estimated by ERG, assuming in-plant work. Five-year life.
Cab enclosures	Enclosed cabs	NA	$15,762	$5,517	$3,441.81	ERG estimate based on vendor interviews.

Table IX-3a: Source Information for the Unit Cost Estimates Used in OSHA's Final Cost Analysis for General Industry and Maritime(continued)

Control [a]	Description	Ventilation Airflow (cfm)	Capital Cost [b]	Operating Cost	Annualized Capital Cost	Comment or Source
LEV for hand held grinders	Shrouds + vacuum	NA	$1,737.51	$608.13	$379.39	Vacuum plus shroud adapter (http://www.proventilation.com/products/productDetail.asp?id=15); 35% for maintenance and operating costs.
Upgraded abrasive blast cabinet	Improved maintenance and purchases for some	NA	$4,850	$1,000	$568.57	Assumes addit. maint. (of up to $2,000) or new cabinets ($8,000) (Norton, 2003) [a]
Yard dust suppression	100 ft, 1" contractor hose and nozzle	NA	$212.19	$0.00	$110.89	Contactor hose and nozzle; 2 year life; (www.pwmall.com) [a]
Wet methods to clean concrete mixing equip.	10 minutes per day per operator	NA	$0.00	$1,024.04	$0.00	10 mins per day per mixer operator
HEPA vacuum substitute for compressed air	Incremental time to remove dust by vacuum	NA	NA	$536.47	$0.00	5 min per day per affected worker
Spray system for wet concrete finishing	Shop-built sprayer system	NA	$213.42	$21.34	$111.54	Assumes $100 in materials and 4 hours to fabricate. Also 10% for maint.
Improved spray booth for pottery	Maintenance time & materials	NA	$121.25	$118.42	$239.67	Annual: $100 materials plus 4 hours maintenance time [a]
Improved LEV for ceramics spray booth	Increased air flow; per cfm	NA	$3.33	$0.92	$3.33	25% of installed CFM price
Exhaust for saw, cut stone industry	Based on saw LEV (e.g., pg. 10-158, 159, 160, ACGIH, 2001)	645	$8,602.67	$2,385.88	$1,008.50	Includes 545 cfm for saw base and 100 cfm for blade guard; updated to ACGIH 2013; VS-65-02, pg. 13-79
LEV for hand chipping in cut stone	Granite cutting and finishing; (pg. 10-94, ACGIH, 2001)	600	$8,002.49	$2,219.43	$938.14	ERG estimate of CFM requirements
Exhaust trimming machine	Based on abrasive cut-off saw; (pg. 10-134) (ACGIH, 2001)	500	$6,668.74	$1,849.52	$781.78	Opening of 2 sq ft assumed, with 250 cfm/sq.ft

Table IX-3a: Source Information for the Unit Cost Estimates Used in OSHA's Final Cost Analysis for General Industry and Maritime(continued)

Control [a]	Description	Ventilation Airflow (cfm)	Capital Cost [b]	Operating Cost	Annualized Capital Cost	Comment or Source
Bag opening	Bag opening station; (pg. 10-19, ACGIH, 2001)	1,513	$20,179.60	$5,596.66	$2,365.66	3.5'x1.5' opening; with ventilated bag crusher (200 cfm)
Conveyor ventilation	Conveyor belt ventilation; (pg. 10-70, ACGIH, 2001)	700	$9,336.23	$2,589.33	$1,094.49	Per take-off point, 2' wide belt.
Bucket elevator ventilation	Bucket elevator ventilation (pg. 10-68; ACGIH,2001)	1,600	$21,339.96	$5,918.47	$2,501.69	2'x3'x30' casing; 4 take-offs @250 cfm; 100 cfm per sq ft of cross section
Bin and hopper ventilation	Bin and hopper ventilation (pg. 10-69; ACGIH, 2001)	1,050	$14,004.35	$3,884.00	$1,641.74	350 cfm per ft2; 3' belt width
Screen ventilation	Ventilated screen (pg. 10-173, ACGIH, 2001)	1,200	$16,004.97	$4,438.86	$1,876.27	4'x6' screen; 50 cfm per ft2
Batch operator workstation	Bin & hopper ventilation for unvented mixers (pg. 10-69, ACGIH, 2001)	1,050	$14,004.35	$3,884.00	$1,641.74	ERG estimate of CFM requirements
LEV for hand grinding operator (pottery)	Hand grinding bench (pg. 10-135, ACGIH, 2001)	3,750	$50,015.54	$13,871.42	$5,863.35	ERG estimate of CFM requirements
LEV, mixer and muller hood	Mixer & muller hood (pg. 10-87, ACGIH, 2001)	1,050	$14,004.35	$3,884.00	$1,641.74	ERG estimate of CFM requirements
LEV for bag filling stations	Bag filling station (pg. 10-15, ACGIH, 2001)	1,500	$20,006.21	$5,548.57	$2,345.34	Includes costs for air shower
Installed manual spray mister	Manual controls, system covers 100 ft of conveyor	NA	$10,609.36	$1,060.94	$1,243.74	National Environmental Services Company (Kestner, 2003). [a]
Install cleaning hoses, reslope floor, drainage	Plumbing for hose installations, floor resloping and troughs	NA	$36,412.40	$3,323.52	$4,268.64	ERG estimate. Includes cost of water and labor time.
Substitute alt., non-silica, blasting media	Alternative media estimated to cost 22 percent more	NA	$0.00	$5,156.25	$0.00	Based on 220,000 square feet of coverage per year per crew
Shakeout conveyor enclosure	Ventilated shakeout conveyor enclosure	10,000	$133,374.76	$36,990.46	$15,635.59	ERG estimate

Table IX-3a: Source Information for the Unit Cost Estimates Used in OSHA's Final Cost Analysis for General Industry and Maritime(continued)

Control [a]	Description	Ventilation Airflow (cfm)	Capital Cost [b]	Operating Cost	Annualized Capital Cost	Comment or Source
Shakeout side-draft ventilation	Shakeout double side-draft table (pg. 10-23, ACGIH, 2001)	28,800	$384,119.32	$106,532.52	$45,030.50	ERG estimate of CFM requirements
Shakeout enclosing hood	Ventilated enclosing hood (pg. 10-23, ACGIGH, 2001); 4'x4' openings	7,040	$93,895.83	$26,041.28	$11,007.46	ERG estimate of opening size required
Small knockout table	Portable grinding table pg. 10-136), ACGIH, 2001), 3'x3' opening	1,350	$18,005.59	$4,993.71	$2,110.80	ERG estimate of opening size required
Large knockout table	Hand grinding table (pg. 10-135), ACGIH, 2001), 4'x6' surface	4,800	$64,019.89	$17,755.42	$7,505.08	ERG estimate of bench surface area
Ventilated abrasive cutoff saw	Ventilated cut-off saw (pg. 10-134, ACGIH, 2001, 2'x3' opening	1,500	$20,006.21	$5,548.57	$2,345.34	ERG estimate of opening size required
Hand grinding bench (foundry)	Bench with LEV (pg. 10-135, ACGIH, 2001); 3'x5'	3,750	$50,016	$13,871.42	$5,863.35	ERG estimate of CFM requirements; 250 cfm/sq. ft.
Forming operator bench (pottery)	Bench with LEV (pg. 10-149, ACGIH, 2001), 3'x4'	1,400	$18,672	$5,178.66	$2,188.98	ERG estimate of CFM requirements; 125 cfm per linear foot
Hand grinding bench (pottery)	Bench with LEV (pg. 10-135, ACGIH, 2001); 3'x4'	2,400	$32,010	$8,877.71	$3,752.54	ERG estimate of CFM requirements; 200 cfm/sq. ft.
Hand tool hardware	Retrofit suction attachment	200	$464	$739.81	$54.42	ERG estimate of CFM requirements [a]
Clean air island	Clean air supplied directly to worker	2,500	$33,343.69	$9,247.61	$3,908.90	ERG estimate of CFM requirements; 125 cfm/sq. ft. for 20 square feet
Water fed chipping equipment drum cleaning	Shop-built water feed equipment	NA	$242.50	$0.00	$242.50	ERG estimate. $200 in annual costs [a]
Ventilation for drum cleaning	Ventilation blower and ducting	NA	$823.98	$205.99	$179.92	Electric blower (1,277 cfm) and 25 ft. of duct. Northern Safety Co. (p. 193) [a]

Table IX-3a: Source Information for the Unit Cost Estimates Used in OSHA's Final Cost Analysis for General Industry and Maritime(continued)

Control [a]	Description	Ventilation Airflow (cfm)	Capital Cost [b]	Operating Cost	Annualized Capital Cost	Comment or Source
Control room	10'x10' ventilated control room with HEPA filter	200	$20,327.53	$739.81	$2,383.01	ERG estimate based on Means, 2003, ACGIH, 2001
Control room improvement	Repair and improve control room enclosure	NA	$2,240	NA	$262.60	ERG estimate. Assumes repairs are 20% of new control room cost.
Improved bag valves	Bags with extended polyethylene valve, incremental cost per bag	NA	$0.01	NA	NA	Cecala et. al., 1986 [a]
Respirator	Half-mask respirator	NA	NA	NA	$520.32	ERG, 2003 [Economic Analysis of APF rule], Updated to 2012
Improved maintenance on process equipment enclosures (concrete II)	Maintenance time & materials	NA	$303.12	$250.59	$553.71	Annual: $250 materials plus 8 hours maintenance time [a]
Improved maintenance on process equipment enclosures (Mineral Proc.)	Maintenance time & materials	NA	$303.12	$257.08	$560.21	Annual: $250 materials plus 8 hours maintenance time [a]
Initial cleaning	Thorough initial cleaning, per square foot	NA	$0.00	$0.15	$0.15	ERG estimate
Self-contained dust collection system			$800.00	$80.00	$93.78	Self-contained dust collection system. Darby Dental Lab Supply, 2005 (www.darbylab.com)

[a] For local exhaust ventilation (LEV), maintenance, and conveyor covers, OSHA applied the following estimates:

LEV: capital cost=$13.34 per cfm; operating cost=$3.70 per cfm; annualized capital cost=$1.56 per cfm; based on current energy prices and the estimates of consultants to ERG (OSHA, 2016).

Maintenance: estimated as 10% of capital cost

Conveyor Covers: estimated as $17.10 per linear foot for 100 ft. (Landola, 2003); capital cost=$20.73 per linear ft., including all hardware; annualized capital cost=$2.84 per linear ft.

[b] Adjusted from 2003 price levels using an inflation factor of 1.212 based on GDP Implicit price deflator for 2003 and 2012.

[c] Mean expense per office-based physician visit to a pulmonary specialist for diagnosis and treatment, based on data from the 2004 MEPS. Inflated to 2012 levels using the consumer price index for medical services. Inflation based on the BLS Consumer Price Index for Urban Consumers for medical services.

Table IX-3b: Source Information for the Unit Cost Estimates Used in OSHA's Final Cost Analysis for Construction (continued)

Control Equipment	Equipment Cost	Average Lifetime (yrs)	Average Annualized Cost	Average Ann. Cost/Day of Use [a]	Maintenance and Operating Cost/Day [b]	Total Ann. Cost/Day of Use	Source; Comments
Dustless drywall sander	$133	1	$133.33	$0.89	$0.19	$1.08	Home Depot, 2009; LSS 2009; Dustless Tech, 2009
Water misting cannon	$19,190	10	$2,249.65	$15.00	$3.15	$18.15	New Jersey Used Equipment, 2015
Cab enclosure /w ventilation and air conditioning	$13,000	10	$1,524.00	$10.16	$2.13	$12.29	Estimates from equipment suppliers and retrofitters
Foam dust suppression system	$14,550	10	$1,706	$11.37	$2.39	$13.76	Midyett, 2003.
Water tank, engine driven discharge, 5000 gal.	NA	NA	NA	$121.50 [c]	$0.00 [c]	$121.50	RS Means - based on monthly rental cost
Water tank, engine driven discharge, 10,000 gal	NA	NA	NA	$168.38 [c]	$0.00 [c]	$168.38	RS Means - based on monthly rental cost
Half-face respirator	$27	2	$468.74	$3.12	$0.66	$3.78	[d]
Dust booth	$10,605	10	$1,243	$8.29	$1.74	$10.03	ERG estimate based on Cerala, et al, 2002 & 2005
Tunnel dust suppression system supplement	$7,928	5	$1,731.03	$11.54	$2.42	$13.96	Raring, 2003.

NA=Not applicable. For cost items that are assumed to be leased or rented (as on a per job basis), equipment lifetimes are not relevant and have not been defined.

[a] Except where noted, daily equipment cost is based on the annualized equipment cost divided by 150 to reflect the assumed average number days of use per year.

[b] Except where noted, daily operating and maintenance costs are calculated as 10% and 25%, respectively, of annualized equipment costs divided by 250.

[c] Daily equipment costs derived from RS Means monthly rental rates which include maintenance and operating costs.

[d] Derived by ERG based on vendor-derived capital cost of $27.00, 2 year equipment life, accessory cost of $295.52. Also includes annualized training cost of $50.34, fit test cost of $26.45, and respirator cleaning cost of $81.49 to derive total annual costs of $468.74.

DESCRIPTION OF THE STEPS OSHA HAS TAKEN TO MINIMIZE THE SIGNIFICANT ECONOMIC IMPACT ON SMALL ENTITIES CONSISTENT WITH THE STATED OBJECTIVES OF APPLICABLE STATUTES AND STATEMENT OF THE REASONS FOR SELECTING THE ALTERNATIVE ADOPTED IN THE FINAL RULE

OSHA has made a number of changes in the final silica rule that will serve to minimize significant impacts on small entities consistent with the objectives of the OSH Act.

First, OSHA has made two changes to the scope of the rule that will minimize impacts for small business. OSHA has eliminated from the scope of the rule exposures that result from the processing of sorptive clays. OSHA's analysis did not determine whether any or all of the processers of sorptive minerals are small businesses, but to the extent they are, this change will reduce impacts on such entities. OSHA has also rewritten the scope of the rule with respect to the coverage of employers whose employees are exposed to silica at levels below the action level. The final rule does not apply to employers in general industry and maritime where the employer has objective data demonstrating that employee exposure to respirable crystalline silica will remain below 25 μg/m^3 as an 8-hour time-weighted average under any foreseeable conditions, and does not apply in construction where employee exposure will remain below 25 μg/m^3 as an 8-hour time-weighted average under any foreseeable conditions (see Scope in Section XV of the preamble). OSHA expects that these changes may remove all compliance duties for some small businesses, possibly including carpenters, plumbers, and electricians, whose employees' only exposures to respirable crystalline silica is in small amounts for short-duration tasks that are performed infrequently.

OSHA also revised Table 1 for the construction industry in ways that will minimize impacts on small businesses. OSHA requested comment on the approach for construction in the NPRM. After carefully reviewing the comments received on this issue, the Agency significantly revised the structure of the construction rule to focus on the tasks known to generate high exposures to respirable crystalline silica and to expand Table 1 to cover almost all of them (tunnel boring and abrasive blasting are the exceptions). Under this final rule, where employers fully and properly implement the specified engineering controls, work practices, and respiratory protection for each employee engaged in a task identified on Table 1, the employer is not also required to conduct exposure assessments to determine compliance with the PEL. Specifying the kinds of dust controls for construction tasks that are expected to reduce exposures to the 50 μg/m^3 target, as an option in lieu of a performance-oriented approach involving a PEL and regular exposure assessment, will make compliance easier for construction employers. Some commenters indicated that this specific guidance is particularly beneficial to small businesses that may not have as many resources to develop their own compliance plans (see, e.g., Document ID 2322-A1, p. 16). The Agency also revised the notes and specifications on Table 1 to clarify what is required for employers to fully and properly implement the specified engineering controls, work practices, and respiratory protection for tasks on Table 1 (see Specified Exposure Control Methods in Section XV of the preamble).

After carefully reviewing the comments received on respiratory protection requirements for the construction standard and the exposure data in the record (described in Chapter IV of the FEA), OSHA identified those situations where respiratory protection is necessary and made significant revisions to the respiratory protection requirements specified on Table 1 based on those findings. The result is that respiratory protection is not required for most of the tasks covered by Table 1 (see Specified Exposure Control Methods in Section XV of the preamble).

For this final rule, the Agency has significantly revised the requirements for initial exposure assessment and periodic exposure assessment in order to provide employers with greater flexibility. The standard allows the employer to use either the performance option or the scheduled monitoring option for initial and periodic exposure assessments. OSHA also clarified that the performance option provides employers with flexibility in the methods used to assess employee exposures, and provided examples of how employers can accurately characterize employee exposures using the performance option (see Exposure Assessment discussion in the Summary and Explanation (Section XV) of the preamble).

At the suggestion of many commenters, OSHA has eliminated regulated area/access control plan requirements in construction. Employers in construction now have more flexibility in determining the best way to control exposures through a written exposure control plan.

In the final rule, OSHA has agreed with many commenters to eliminate the requirements for protective clothing, and thus has reduced costs to small businesses.

OSHA requested comment on the use of wet methods as a substitute for dry sweeping in the NPRM. After carefully reviewing the comments received on this issue, the Agency revised the provision to prohibit dry sweeping only where such activity could contribute to employee exposure to respirable crystalline silica. Moreover, the standard contains an exception to the prohibition on dry sweeping in such circumstances if wet sweeping, HEPA-filtered vacuuming, or other methods that minimize the likelihood of exposure are not feasible (see Housekeeping in Section XV of the preamble).

In the NPRM, OSHA requested comment on the prohibition of employee rotation to achieve compliance when exposure levels exceed the PEL. After carefully reviewing the comments received on this issue, OSHA removed the prohibition on employee rotation from the rule (see Methods of Compliance in Section XV of the preamble).

OSHA examined the issue of a 30-day exemption in the NPRM. After carefully reviewing the comments received on this issue, the Agency decided not to include a 30-day exemption from the requirement to implement engineering and work practice controls. However, OSHA clarified that where engineering controls are not feasible, such as for certain maintenance and repair activities, the use of respirators is permitted (see Methods of Compliance and Respiratory Protection in Section XV of the preamble).

OSHA adopted these alternatives to reduce costs and regulatory burdens consistent with the requirements of the OSH Act and court interpretations of the Act. For health standards issued under section 6(b)(5) of the OSH Act, OSHA is required to promulgate a standard that reduces significant risk to the extent that it is technologically and economically feasible to do so. See Section II of the Preamble to the final rule, Pertinent Legal Authority, for a full discussion of OSHA legal requirements.

OSHA has conducted an extensive review of the literature on adverse health effects associated with exposure to respirable crystalline silica. The Agency has also developed estimates of the risk of silica-related diseases assuming exposure over a working lifetime at the proposed PEL and action level, as well as at OSHA's preceding PELs. These analyses are summarized in the preamble in Section V, Health Effects and Quantitative Risk Analysis. The available evidence indicates that employees exposed to respirable crystalline silica well below the preceding PELs are still at increased risk of lung cancer mortality and silicosis mortality and morbidity. Occupational exposures to respirable crystalline silica also may result in the development of kidney and autoimmune diseases and in death from other nonmalignant respiratory diseases, including chronic obstructive pulmonary disease (COPD).

As discussed in Section VI, Significance of Risk, in the preamble, OSHA determined that worker exposure to respirable crystalline silica constitutes a significant risk and that the final standard will substantially reduce this risk. Further, there is significant risk well below the new PEL of 50 $\mu g/m^3$, but OSHA has determined that achieving a PEL of 25 $\mu g/m^3$ is not technologically feasible.

Section 6(b) of the OSH Act requires OSHA to determine that its standards are technologically and economically feasible. OSHA's examination of the technological and economic feasibility of the final rule is presented in this FEA and FRFA. OSHA has concluded that the new PEL of 50 μg/m^3 is technologically feasible for all affected sectors in general industry and maritime and that Table 1 is technologically feasible for construction.

For those few operations where the new PEL is not technologically feasible, even when workers use recommended engineering and work practice controls, employers can supplement controls with respirators to achieve exposure levels at or below the new PEL.

OSHA developed quantitative estimates of the compliance costs of the final rule for each of the affected industry sectors in Chapter V of this FEA. The estimated compliance costs were compared with industry revenues and profits to provide a screening analysis of the economic feasibility of complying with the revised standard and an evaluation of the potential economic impacts in Chapter VI of this FEA. Industries with unusually high costs as a percentage of revenues or profits were further analyzed for possible economic feasibility issues. After performing these analyses, OSHA has concluded that compliance with the requirements of the final rule will be economically feasible in every affected industry sector.

OSHA has also provided analyses of the costs and benefits of alternative PELs, though it should be pointed out these are for informational purposes only. Benefit cost analysis cannot be used as a decision criteria for OSHA health standards under the OSH Act. OSHA has examined two regulatory alternatives (named Regulatory Alternatives #1 and #2) that would have modified the PEL for the final rule. Under Regulatory Alternative #1, the PEL would have been 100 μg/m^3 for all affected industry sectors, and the action level would have been 50 μg/m^3 (thereby keeping the action level at one-half of the PEL). For the construction sector under Regulatory Alternative #1, Table 1 requirements for respirator use would have been eliminated for all workers performing Table 1 tasks. Under this alternative, only abrasive blasters and underground construction workers would have been required to wear respiratory protection, and only workers wearing respirators in these operations would have been subject to the medical surveillance provision. Under Regulatory Alternative #2, the PEL would have been 25 μg/m^3 for all affected industry sectors, while the action level would have remained at 25 μg/m^3 (because of difficulties in accurately measuring exposure levels below 25 μg/m^3). For the construction sector under Regulatory Alternative #2, Table 1 requirements would have been modified to include respiratory protection for all workers covered under Table 1, and all these covered workers would have been subject to the medical surveillance provision.

Table IX-4 presents, for informational purposes, the estimated costs, benefits, and net benefits of the final rule under Regulatory Alternatives #1 and #2, using alternative discount rates of 3 and 7 percent. The tables also present the incremental costs, the incremental benefits, and the incremental net benefits of going from a PEL of 100 μg/m^3 to the new PEL of 50 μg/m^3 and then of going from the new PEL of 50 μg/m^3 to a PEL of 25 μg/m^3 for general industry and maritime, as well as the effects in construction of the corresponding changes to Table 1 under Regulatory Alternatives #1 and #2. Table IX-4 breaks out costs by provision and benefits by type of disease and by morbidity/mortality.

Because OSHA determined that a PEL of 25 μg/m^3 would not be feasible (that is, engineering and work practices would not be sufficient to reduce and maintain silica exposures to a PEL of 25 μg/m^3 or below in most operations most of the time in the affected industry sectors in general industry and maritime), the Agency did not attempt to identify engineering controls or their costs for this alternative PEL. Instead, for purposes of estimating the costs of going from a PEL of 50 μg/m^3 to a PEL of 25 μg/m^3, OSHA assumed that all workers exposed between 50 μg/m^3 and 25 μg/m^3 would have to wear respirators to achieve compliance with a PEL of 25 μg/m^3. OSHA then estimated the associated additional costs for respirators, exposure assessments, medical surveillance, and regulated areas (the latter three for ancillary requirements specified in the final rule). For the construction sector under Regulatory Alternative #2, as previously indicated, Table 1 requirements would be modified to include respiratory protection for all covered workers, and all covered workers would be subject to the medical surveillance provision.

As shown in Tables IX-4, going from the final rule to Regulatory Alternative #2 would prevent, annually, an additional 295 silica-related fatalities and an additional 122 cases of silicosis. These estimates support OSHA's finding that there is significant risk remaining at the new PEL of 50 μg/m^3. However, the Agency has determined that it cannot select Regulatory Alternative #2 because a PEL of 25 μg/m^3 is not technologically feasible and this alternative would require extensive use of respirators for those using Table 1 under the construction standard (see the Technological Feasibility Summary in the preamble for a further discussion of the feasibility of a PEL of 25 μg/m^3).

Table IX-4: Annualized Costs, Benefits and Incremental Benefits of OSHA's Regulatory Alternatives

Millions ($2012)

	Regulatory Alternative #2						Final Rule						Regulatory Alternative #1		
	25 $\mu g/m^3$			Incremental Costs Between 50 and 25 $\mu g/m^3$			50 $\mu g/m^3$			Incremental Costs Between 100 and 50 $\mu g/m^3$			100 $\mu g/m^3$		
Discount Rate		3%	7%		3%	7%		3%	7%		3%	7%		3%	7%

RECOMMENDATIONS FROM THE SBAR PANEL AND OSHA'S RESPONSES

Table IX-5 lists all of the SBAR Panel recommendations and OSHA's responses to these recommendations.

Table IX-5: SBAR Panel Recommendations and OSHA Responses

SBAR Panel Recommendation	**OSHA Response**
The Panel recommended that OSHA give consideration to the alternative of improved enforcement of and expanded outreach for the existing rule rather than a new rule. In addition, the Panel recommended that OSHA carefully study the effects of existing compliance and outreach efforts, such as the Special Emphasis Program on silica, with a view to better delineating the effects of such efforts. This examination should include (1) a year-by-year analysis of the extent of noncompliance discovered in OSHA compliance inspections, and (2) the kinds of efforts OSHA made to improve enforcement and outreach.	As discussed in Chapter II of this FEA, Need for Regulation (and summarized in Section II of the preamble), OSHA has reviewed existing enforcement and outreach programs, as well as other legal and administrative remedies, and believes that a standard is the most effective means to protect workers from exposure to silica. The rulemaking record indicates that workers did not receive adequate protection from silica hazards under OSHA's previous standards. A review of OSHA's compliance assistance and enforcement efforts and their effects on preceding PELs for respirable crystalline silica are discussed in Section III of the preamble, Events Leading to the Final Standards.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(General Industry) The Panel recommended that OSHA revise its economic and regulatory flexibility analyses as appropriate to reflect the SERs' comments on underestimation of costs, and that the Agency compare OSHA's revised estimates to alternative estimates provided and methodologies suggested by the SERs. For those SER estimates and methodological suggestions that OSHA does not adopt, the Panel recommends that OSHA explain its reasons for preferring an alternative estimate and solicit comment on the issue.	OSHA reviewed its cost estimates in response to the comments received from the SERs and evaluated the alternative estimates and methodologies suggested by the SERs. In some cases (such as for exposure monitoring, medical surveillance, and training) OSHA revised its cost estimates in response to SER comments. However, OSHA has not made all cost changes suggested by the SERs. OSHA has retained (or simply updated) those cost estimates that it determined reflect sound methodology and reliable data. OSHA requested comments on the Agency's estimated costs and on the assumptions applied in the preliminary cost analysis. OSHA's final analysis of costs is presented in Chapter V of this FEA and reflects the final Agency response to comments from SERs and other small entities who participated in the rulemaking.
The Panel recommended that prior to publishing a proposed standard, OSHA should carefully consider the ability of each potentially affected industry to meet any proposed PEL for silica, and that OSHA should recognize, and incorporate in its cost estimates, specific issues or hindrances that different industries may have in implementing effective controls.	This FEA reflects OSHA's judgment on technological feasibility and includes responses to specific issues raised by the Panel, SERs, and other small entities who participated in the rulemaking. OSHA solicited comment on the accuracy and reasonableness of its preliminary judgments and included this topic in the NPRM. OSHA's final analysis of technological feasibility presented in Chapter IV of the FEA includes the final Agency response to comments from SERs and the other small entities who participated in the rulemaking.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
The Panel recommended that OSHA carefully review the basis for its estimated exposure monitoring costs, consider the concerns raised by the SERs, and ensure that its estimates are revised, as appropriate, to fully reflect the costs likely to be incurred by potentially affected establishments.	Table 1 in the final construction standard is designed to relieve establishments in construction from requirements for exposure assessment for identified tasks. For the final rule, OSHA clarified that Table 1 provides an alternative method of compliance, not just a partial safe-harbor as in the NPRM. OSHA also further expanded the tasks covered by Table 1 in recognition of the exposure control challenges facing many construction employers, including small entities. As a result, OSHA estimates that monitoring costs in construction will be minimal. For general industry, OSHA developed cost estimates in this FEA for exposure monitoring as a function of the size of the establishment. OSHA's cost estimates now reflect the fact that smaller entities will tend to experience larger unit costs. In the PEA and in this FEA, OSHA estimated higher exposure monitoring costs for small entities because an industrial hygienist could not take as many samples a day in a small establishment as in a large one. For the FEA, in response to public comment, OSHA raised the unit fee for industrial hygiene technician and revised other unit estimates (primarily as a result of converting to 2012 dollars). See Chapter V of this FEA for details of OSHA's unit costs for exposure monitoring in general industry and maritime.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
The Panel recommended that OSHA carefully review the basis for its estimated health screening compliance costs, consider the concerns raised by the SERs, and ensure that its estimates are revised, as appropriate, to fully reflect the costs likely to be incurred by potentially affected establishments.	OSHA's cost estimates for health screening are a function of the size of the establishment. OSHA's cost estimates now reflect the fact that smaller entities will tend to experience larger unit costs. In the PEA, OSHA estimated higher medical surveillance costs (than was estimated in the Preliminary Initial Regulatory Flexibility Analysis (PIRFA)) for small entities because smaller establishments would be more likely to send the workers off-site for medical testing. OSHA has carried forward that methodology for this FEA. In addition, for the PEA and this FEA, OSHA significantly increased the total costs of exposure sampling and x-rays in medical surveillance by assuming no existing compliance with those provisions in the proposed and final rule (as compared to an average of 32.6 percent and 34.8 percent existing compliance, respectively, in the PIRFA). A full discussion of OSHA's consideration of medical surveillance costs is included in Chapter V of this FEA and in the preamble.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) The Panel recommended that OSHA carefully review the basis for its estimated hygiene compliance costs, consider the concerns raised by the SERs, and ensure that its estimates are revised, as appropriate, to fully reflect the costs likely to be incurred by potentially affected establishments.	OSHA removed the specific hygiene provisions presented in the PIRFA from the proposed and final rules, which has resulted in the elimination of compliance costs for change rooms, shower facilities, lunch rooms, and hygiene-specific housekeeping requirements. In the NPRM, OSHA requested comment on the requirements for use of protective clothing. After carefully reviewing the comments received on this issue, the Agency removed the requirement for protective clothing from the rule (see Regulated Areas in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(General Industry) While some SERs currently provide both protective clothing and hygiene facilities, others provide neither. Those SERs that do not currently provide either felt that these provisions were both highly expensive and unnecessary. Some SERs stated that these provisions were pointless because silica is not a take-home hazard or a dermal hazard. Others suggested that such provisions only be required when the PEL is exceeded. The Panel recommended that OSHA carefully consider the need for these provisions, and solicit comment on the need for these provisions, and how they might be limited.	OSHA removed the specific hygiene provisions presented in the PIRFA from the proposed and final rules, which has resulted in the elimination of compliance costs for change rooms, shower facilities, lunch rooms, and hygiene-specific housekeeping requirements. In the NPRM, OSHA requested comment on the requirements for use of protective clothing. After carefully reviewing the comments received on this issue, the Agency removed the requirement for protective clothing from the rule (see Regulated Areas in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
The Panel recommended that OSHA carefully review the issue of dry sweeping in the analysis, consider the concerns raised by the SERs, and ensure that its estimates are revised, as appropriate, to fully reflect the costs likely to be incurred by potentially affected establishments.	In the NPRM, OSHA requested comment on the use of wet methods as a substitute for dry sweeping. After carefully reviewing the comments received on this issue, the Agency revised the provision to prohibit dry sweeping where such activity could contribute to employee exposure to respirable crystalline silica, but provided an exception for situations in which wet sweeping, HEPA-filtered vacuuming or other methods that minimize the likelihood of exposure are not feasible (see Housekeeping in Section XV of the preamble). As a result, OSHA has mitigated the potential burden the prohibition on dry sweeping might have imposed on affected employers.
(General Industry) Some SERs were concerned that the prohibition on dry sweeping was not feasible or cost effective in their industries. The Panel recommended that OSHA consider this issue and solicit comment on the costs and necessity of such a prohibition.	In the NPRM, OSHA requested comment on the prohibition on dry sweeping. After carefully reviewing the comments received on this issue, the Agency revised the provision to prohibit dry sweeping where such activity could contribute to employee exposure to respirable crystalline silica, unless wet sweeping, HEPA-filtered vacuuming or other methods that minimize the likelihood of exposure are not feasible (see Housekeeping in Section XV of the preamble). As a result, OSHA has mitigated the potential burden the prohibition on dry sweeping might have imposed on affected employers.

The Panel recommended that OSHA carefully review the basis for its training costs, consider the concerns raised by the SERs, and ensure that its estimates are revised, as appropriate, to fully reflect the costs likely to be incurred by potentially affected establishments.	One participant in the silica SBAR process objected to ERG's analytical assumption (used in the PIRFA) that training is needed only for those workers exposed above the action level and suggested that training might be necessary for all at-risk workers. For the proposed rule, the scope of this requirement was revised so that the provision would apply to all workers with any potential occupational exposure to respirable crystalline silica; OSHA estimated training costs in the PEA accordingly. The final rule requires training for each covered employee. However, the rule does not apply in general industry and maritime where the employer has objective data demonstrating that employee exposure to respirable crystalline silica will remain below 25 μg/m^3 as an 8-hour time-weighted average under any foreseeable conditions and does not apply in construction where employee exposure will remain below 25 μg/m^3 as an 8-hour time-weighted average under any foreseeable conditions. For the PEA and this FEA, for employers where the rule applies, OSHA estimated higher training costs for small entities because of smaller-sized training classes and significantly increased training costs by assuming zero current compliance for all of the affected establishments (compared to an average of 56 percent existing compliance for all establishments in the PIRFA).
(Construction) SERs raised cost issues similar to	The cost estimates in this FEA reflect OSHA's best judgment and take the much

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
those in general industry, but were particularly concerned about the impact in construction, given the high turnover rates in the industry. The Panel recommended that OSHA carefully review the basis for its estimated compliance costs, consider the concerns raised by the SERs, and ensure that its estimates are revised, as appropriate, to fully reflect the costs likely to be incurred by potentially affected establishments.	higher labor turnover rates in construction into account when calculating costs. For this analysis of the final rule, OSHA used the most recent BLS turnover rate of 70 percent for construction (versus a turnover rate of 25 percent for general industry). OSHA believes that the estimates in this FEA capture the effect of high turnover rates in construction, and in Chapter III, Profile of Affected Industries the Agency addresses the comments received on this issue in response to the NPRM.

(Construction) The Panel recommended that OSHA (1) carefully review the basis for its estimated labor costs, and issues related to the use of FTEs in the analysis, (2) consider the concerns raised by the SERs, and (3) ensure that its estimates are revised, as appropriate, to fully reflect the costs likely to be incurred by potentially affected establishments.	OSHA used the exposure profiles to estimate the number of full-time-equivalent (FTE) workers in construction who are exposed above the PEL. This would be the exposure profile if all exposed workers worked full-time only at the specified silica-generating tasks. In OSHA's preliminary analysis, the actual number of workers exposed above the PEL was estimated to be from two to five times the number of FTE workers, depending on the activity. For this FEA, OSHA developed a more nuanced approach to estimating the number of affected workers. OSHA first divided the construction sector into four subsectors in order to account for likely differences among them with respect to the frequency with which such silica-related tasks are performed. OSHA calculated that there are an estimated 387,710 FTE workers affected by the rule. In Chapter V, Costs of Compliance, OSHA converts these FTEs to 2.02 million affected construction workers disaggregated by occupation, thus resulting in an average ratio of over 5 workers per FTE. The estimate of the total number of at-risk workers takes into account the fact that most workers, regardless of construction occupation, spend some time working on jobs where no silica contamination is present. For the control cost analysis, however, it matters only how many worker-days there are in which exposures are above the PEL. These are the worker-days in which controls are required. The control costs (as opposed to the program costs) are independent of the number of at-risk workers associated with these worker-days. OSHA emphasizes that the use of FTEs does not "discount" its estimates of aggregate control costs.
(Construction) Some SERs requested that OSHA	In the NPRM, OSHA requested comment on the issue of a 30-day exemption.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
apply a 30-day exclusion for implementing engineering and work practice controls, as was reflected in the draft standard for general industry and maritime. The Panel recommended that OSHA consider this change and request comment on the appropriateness of exempting operations that are conducted fewer than 30 days per year from the hierarchy requirement.	After carefully reviewing the comments received on this issue, the Agency decided, with respect to general industry, maritime, and construction, that permitting employers to use respirators instead of feasible engineering and work practice controls for exposures occurring for 30 days or less per year would not best effectuate the purpose of the rule. OSHA also determined that it is reasonably necessary and appropriate to require the use of all feasible engineering and work practice controls in the construction industry, even for tasks of short duration, in order to protect employees from exposures to respirable crystalline silica. However, OSHA clarified in the final rules for construction, general industry, and maritime, that where engineering controls are not feasible to reduce exposures to or below the PEL, such as for certain maintenance and repair activities, respirators may be used instead (see Methods of Compliance and Respiratory Protection in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) The Panel recommended that OSHA consider and seek comment on the need to prohibit employee rotation as a means of complying with the PEL and the likelihood that employees would be exposed to other serious hazards if the Agency were to retain this provision.	In the NPRM, OSHA requested comment on the prohibition of employee rotation to achieve compliance when exposure levels exceed the PEL. After carefully reviewing the comments received on this issue, OSHA removed the prohibition on employee rotation from the rule (see Methods of Compliance in Section XV of the preamble).
(Construction) Some SERs questioned the scientific and legal basis for the draft prohibitions on the use of compressed air, brushing, and dry sweeping of silica-containing debris. Others raised feasibility concerns such as in instances where water or electric power was unavailable or where use of wet methods could damage construction materials. The Panel recommended that OSHA carefully consider the need for and feasibility of these prohibitions given these concerns, and that OSHA seek comment on the appropriateness of such prohibitions.	OSHA requested comment on the prohibitions against the use of compressed air, brushing, and dry sweeping of silica-containing debris in the NPRM. After carefully reviewing the comments received on this issue, the Agency revised the rule to (1) prohibit dry sweeping where such activity could contribute to employee exposure to respirable crystalline silica, unless wet sweeping, HEPA-filtered vacuuming or other methods that minimize the likelihood of exposure are not feasible and (2) prohibit the use of compressed air where such an activity could contribute to employee exposures to respirable crystalline silica, unless it is used in conjunction with a ventilation system that effectively captures the dust cloud or no alternative method is feasible (see Housekeeping in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) The Panel recommended that OSHA carefully consider whether regulated area provisions should be included in the draft proposed standard, and, if so, where and how regulated areas are to be established. OSHA should also clarify in the preamble and in its compliance assistance materials how compliance is expected to be achieved in the various circumstances raised by the SERs.	After carefully reviewing the comments received on the requirement for regulated areas in construction, OSHA removed the requirement from the construction standard and instead requires a written exposure control plan (see Regulated Areas and Written Exposure Control Plan in Section XV of the preamble).
(Construction) The Panel recommended that OSHA clarify how the regulated area requirements would apply to multi-employer worksites in the draft standard or preamble, and solicit comments on site control issues.	In the NPRM, OSHA requested comment on the applicability of the regulated area requirements to multi-employer worksites in construction. After carefully reviewing the comments received on this issue, OSHA removed the requirement for regulated areas from the construction standard and instead, requires a written exposure control plan that provides for a competent person to restrict access to work areas when necessary (see Regulated Areas and Written Exposure Control Plan in Section XV of the preamble). In addition, OSHA has added costs to account for additional controls for sole proprietors (self-employed workers) whose activities on a multi-employer site could expose others to silica. OSHA also amended the written exposure control plan provisions to clarify the employer's responsibility to account for silica exposures caused by sole proprietors and others when it develops its exposure control plan.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) Many SERs were concerned with the extent to which they felt the draft proposed standard would require the use of respirators in construction activities. The Panel recommended that OSHA carefully consider its respiratory protection requirements, the respiratory protection requirements in Table 1, and the PEL in light of this concern.	In the NPRM, OSHA requested comment on the use of respirators in construction activities. After carefully reviewing the comments received on this issue and the exposure data in the record (described in Chapter IV of this FEA), OSHA identified those situations where respiratory protection is necessary and made significant revisions to the respiratory protection requirements specified in Table 1 based on those findings. The result is that respiratory protection is not required for most of the tasks covered by Table 1 (see Specified Exposure Control Methods in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) The Panel recommended that OSHA carefully address the issues of reliability of exposure measurement for silica and laboratory requirements. The Panel also recommended that OSHA seek approaches to a construction standard that can mitigate the need for extensive exposure monitoring to the extent possible.	In the NPRM and PEA, OSHA raised the issue of reliability of exposure measurement and laboratory requirements for silica, and in Chapter IV of this FEA the Agency addresses comments on the issue. In the NPRM, the Agency also requested comment on the requirement for exposure assessment in the construction standard. After carefully reviewing the comments received on this issue, OSHA is not requiring employers to conduct exposure assessments for employees engaged in a task identified in Table 1, where the specified engineering controls, work practices, and respiratory protection are fully and properly implemented (see Specified Exposure Control Methods in Section XV of the preamble). Where construction employers are required to conduct exposure assessments, the Agency revised the rule to provide employers with greater flexibility for meeting this requirement using the performance option (see Exposure Assessment in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) As in general industry, many SERs were concerned about all of these [protective clothing requirement] provisions because, they contended, silica is not recognized as either a take-home or dermal hazard. Further, many said that these provisions would be unusually expensive in the context of construction work. Other SERs pointed out that protective clothing could lead to heat stress problems in some circumstances. The Panel recommended that OSHA carefully re-examine the need for these provisions in the construction industry and solicit comment on this issue.	In the NPRM, OSHA requested comment on the requirements for use of protective clothing. After carefully reviewing the comments received on this issue, the Agency removed the requirement for protective clothing from the rule (see Regulated Areas in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) The Panel recommended that OSHA explicitly examine the issue of availability of specialists called for by these [medical surveillance] provisions, and re-examine the costs and feasibility of such requirements based on their findings with respect to availability, as needed.	In the NPRM, OSHA requested comment on the availability of B Readers and pulmonary specialists to enable employers to achieve compliance with the medical surveillance provisions. After carefully reviewing the comments received on this issue, the Agency retained the requirement for B Readers given the ample evidence of sufficient numbers of B Readers and the value of B Reader interpretation according to ILO methods. The Agency also retained the requirement for examination by a specialist based on X-ray evidence of silicosis or if otherwise deemed appropriate by the physician or other licensed health care professional (PLHCP). OSHA expanded the definition of specialist to include occupational medicine specialists, in addition to pulmonary disease specialists. The record indicates a substantial number of pulmonary disease specialists are available in the U.S., and the addition of occupational medicine specialists should increase the number of qualifying specialists by about 20 percent (see Medical Surveillance in Section XV of the preamble). OSHA also requested comment on the costs for medical examinations and re-examined its estimates, as discussed in more detail in Section XV Medical Surveillance.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(General Industry) The Panel recommended that OSHA explicitly examine and report on the availability of specialists called for by these [medical surveillance] provisions, and re-examine the costs and feasibility of such requirements based on their findings with respect to availability, as needed.	In the NPRM, OSHA requested comment on the availability of B Readers and pulmonary specialists. After carefully reviewing the comments received on this issue, the Agency retained the requirement for B Readers given the ample evidence of sufficient numbers of B Readers and the value of B Reader interpretation according to ILO methods. The Agency also retained the requirement for examination by a specialist based on X-ray evidence of silicosis or if otherwise deemed appropriate by the PLHCP. OSHA expanded the definition of specialist to include occupational medicine specialists, in addition to pulmonary disease specialists. The record indicates a substantial number of pulmonary disease specialists are available in the U.S., and the addition of occupational medicine specialists should increase the number of qualifying specialists by about 20 percent (see <u>Medical Surveillance</u> in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) The Panel recommended that OSHA carefully consider the need for pre-placement physicals in construction, the possibility of delayed initial screening (so only employees who had been on the job a certain number of days would be required to have initial screening), and solicit comment on this issue.	OSHA does not require pre-placement physicals in the rule. In the NPRM, OSHA requested comment on the timing for initial examinations. After carefully reviewing the comments received on this issue, the Agency continued to only require medical surveillance in the construction standard for employees required to use a respirator for 30 or more days a year, and with respect to that group of employees, OSHA retained the requirement for employers to provide initial examinations within 30 days after initial assignment. Giving employers a 30-day period to offer medical surveillance offers them flexibility in accomplishing the screening (see Medical Surveillance in Section XV of the preamble). OSHA has also clarified that employees do not need a second "initial" screening when they switch employers but are still within the valid time period (3 years) for their initial screening.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) Like the general industry SERs, construction SERs raised the issue that they would prefer a warning label with wording similar to that used in asbestos and lead. The Panel recommended that OSHA consider this suggestion and solicit comment on it.	In the NPRM, OSHA requested comment on the requirements for warning labels. After carefully reviewing the comments received on this issue, the Agency has not included new requirements or specifications for warning labels in this standard. Warning labels are specified by OSHA's hazard communication standard (HCS) (29 CFR 1926.59;29 CFR 1910.1200). OSHA has structured the hazard communication requirements in the silica rule to be as consistent as possible with HCS to avoid a duplicative administrative burden on employers who must comply with both HCS and this rule (see Communication of Respirable Crystalline Silica Hazards to Employees in Section XV of the preamble).
(Construction) Some SERs questioned whether hazard communication requirements made sense on a construction site where there are tons of silica-containing dirt, bricks, and concrete. The Panel recommended OSHA consider how to address this issue in the context of hazard communication.	In the NPRM, OSHA requested comment on the applicability of hazard communication requirements to construction. After carefully reviewing the comments received on this issue, the Agency retained the requirements for hazard communication in the construction standard (see Communication of Respirable Crystalline Silica Hazards to Employees in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) The Panel recommended that OSHA carefully review the recordkeeping requirements with respect to both their utility and burden.	In the NPRM, OSHA requested comment on the recordkeeping requirements. After carefully reviewing the comments received on this issue, the Agency retained the recordkeeping requirements in the rule (see Recordkeeping in Section XV of the preamble). OSHA has also reviewed the recordkeeping requirements as required by the Paperwork Reduction Act. Detailed analysis of the recordkeeping requirements can be found in OSHA's information collection request submitted to OMB.
The Panel recommended that OSHA, to the extent permitted by the availability of economic data, update economic data to better reflect recent changes in the economic status of the affected industries consistent with its statutory mandate.	OSHA has prepared this FEA using the most current economic data available, including data introduced into the record by SERs and other small entities who participated in the rulemaking. The profits data now encompasses a time period that includes 2008 and reflects the economic effects of the great recession.

SERs in construction, and some in general industry, felt the estimate of affected small entities and employees did not give adequate consideration to workers who would be subject to exposure at a site but were not directly employed by firms engaged in silica-associated work, such as employees of other subcontractors at a construction site, visitors to a plant, etc. The Panel recommended that OSHA carefully examine this issue, considering both the possible costs associated with such workers, and ways of clarifying what workers are covered by the standard.	The OSH Act authorizes OSHA to protect employees. OSHA does not have authority to regulate sole proprietors without employees (self-employed workers). Therefore it would not be appropriate to include them in the estimates of entities regulated by the rule. Nevertheless, the final cost analysis for construction accounts for costs related to the presence of self-employed workers on or near multi-employer work sites. OSHA also adjusted the written exposure control plan requirements in construction to account for exposures to an employer's employees caused by the activities of another entity. To address concerns about the number of entities who might be impacted by the rule as the result of tasks that produce low levels of silica exposure and do not comprise a significant portion of their employees' work days, OSHA adjusted the scope of both the general industry and construction standards. The rule does not apply in general industry and maritime where the employer has objective data demonstrating that employee exposure to respirable crystalline silica will remain below 25 μg/m^3 as an 8-hour time-weighted average under any foreseeable conditions, and does not apply in construction where employee exposure will remain below 25 μg/m^3 as an 8-hour time-weighted average under any foreseeable conditions (see Scope in Section XV of the preamble).
The Panel recommended that OSHA clarify in any	The contents of OSHA's final rule have no direct bearing on whether silica waste

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
rulemaking action how its action is or is not related to designating silica-containing materials as hazardous wastes.	is classified as hazardous for EPA purposes. The relationship between the final rule and EPA requirements is discussed in Chapter X, Environmental Impacts, in this FEA and in Section XIV, Environmental Impacts, of the preamble.
Some SERs also noted the issue that the use of wet methods in some areas may violate EPA rules with respect to suspended solids in runoff unless provision is made for recycling or settling the suspended solids out of the water. The Panel recommended that OSHA investigate this issue, add appropriate costs if necessary, and solicit comment on this issue.	In the PEA, a preliminary analysis of wet methods for dust controls indicated that in most cases the amount of slurry discharged is not sufficient to cause a run off to storm drains. OSHA solicited comment on this topic in the NPRM. The comments received corroborated OSHA's preliminary finding. OSHA's final analysis of environmental impacts in Chapter X of this FEA contains the Agency's response to comments on this issue.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
The Panel recommended that OSHA (1) carefully consider and solicit comment on the alternative of improved outreach and support for the existing standard; (2) examine what has and has not been accomplished by existing outreach and enforcement efforts; and (3) examine and fully discuss the need for a new standard and if such a standard can accomplish more than improved outreach and enforcement.	OSHA analyzed past outreach and compliance initiatives and their effects on compliance with current PELs in Section III, Events Leading to the Final Standard, of the preamble. An explanation of OSHA's choice of the new PEL is provided in several places, including in this FRFA in the section preceding this one.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) The Panel recommended, if there is to be a standard for construction, that OSHA: (1) seek ways to greatly simplify the standard and restrict the number of persons in respirators; (2) consider the alternative of a standard oriented to engineering controls and work practices in construction; and (3) analyze and solicit comment on ways to simplify the standard.	In the NPRM, OSHA requested comment on the approach for construction in the NPRM. After carefully reviewing the comments received on this issue, the Agency significantly revised the structure of the construction rule to focus on the tasks known to generate high exposures to respirable crystalline silica. Where employers fully and properly implement the specified engineering controls, work practices, and respiratory protection for each employee engaged in a task identified in Table 1, the employer is not also required to conduct exposure assessments to determine compliance with the PEL. The Agency also revised the notes and specifications in Table 1 to clarify what is required for employers to fully and properly implement the specified engineering controls, work practices, and respiratory protection for tasks in Table 1 (see Specified Exposure Control Methods in Section XV of the preamble). The clear and specific guidance in Table 1, along with the opportunity Table 1 provides for employers to avoid exposure monitoring costs will make compliance easier and less expensive. After carefully reviewing the comments received on respiratory protection requirements for the construction standard and the exposure data in the record (described in Chapter IV of this FEA), OSHA identified those situations where respiratory protection is necessary and made significant revisions to the respiratory protection requirements specified in Table 1 based on those findings. The result is that respiratory protection is not required for most of the tasks covered by Table 1 (see Specified Exposure Control Methods in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
The Panel recommended that, if there is to be a standard, OSHA consider and solicit comment on maintaining the existing PEL. The Panel also recommends that OSHA examine each of the ancillary provisions on a provision-by-provision basis in light of the comments of the SERs on the costs and lack of need for some of these provisions.	In the NPRM, OSHA requested comment on the PEL and ancillary requirements. After carefully reviewing the comments received on this issue, OSHA retained the proposed PEL because it is necessary for any new rule to meet the legal requirement to reduce significant risk to the extent feasible. Because the new PEL is a fixed value, OSHA also believes that it is easier to understand when compared to the preceding PELs, which differed between Construction and General Industry (see Permissible Exposure Limit in Section XV of the preamble). OSHA has reexamined the costs of the ancillary provisions in light of further comments (see Chapter V of this FEA) and addresses the need for the ancillary provisions in their respective sections in Section XV Summary and Explanation of the preamble.
(General Industry) The Panel recommended that OSHA carefully examine the technological and economic feasibility of the draft proposed standard in light of these SER comments.	This FEA reflects OSHA's judgments on the technological and economic feasibility of the final standard and includes responses to specific issues raised by the Panel and other rulemaking participants. In the NPRM, OSHA solicited comment on the accuracy and reasonableness of the Agency's preliminary judgments; this final analysis reflects the Agency's review of and response to all issues raised by SERs and other small entities who participated in the rulemaking.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(General Industry) The Panel recommended that OSHA carefully consider whether regulated area provisions should be included in the draft proposed standard, and, if so, where and how regulated areas are to be established. OSHA should also clarify in the preamble and in its compliance assistance materials how compliance is expected to be achieved in the various circumstances raised by the SERs.	After carefully reviewing the comments received on the requirement for regulated areas in general industry and maritime, OSHA retained the requirement to establish regulated areas where exposures are or are reasonably expected to be above the PEL and removed the access control plan option from the standard. The provision requires employers to demarcate the regulated area, post signs with specified language at all entrances, limit access to the area, and provide appropriate respiratory protection to any employee or designated representative entering the area (see Regulated Areas and Written Exposure Control Plan in Section XV of the preamble).
(General Industry) The Panel recommended that OSHA carefully examine the issues associated with reliability of monitoring and laboratory standards in light of the SER comments, and solicit comment on these issues.	In the NPRM, OSHA requested comment on the specified sampling and analytical methods. After carefully reviewing the comments received on this issue, the Agency retained the sampling and analytical methods requirements (see Appendices in Section XV of the preamble and Chapter IV of this FEA).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(General Industry) Some SERs preferred the more performance-oriented Option 2 provision included in the draft exposure assessment requirements, stating that fixed-frequency exposure monitoring can be unnecessary and wasteful. However, other SERs expressed concern over whether such a performance-oriented approach would be consistently interpreted by enforcement officers. The Panel recommended that OSHA continue to consider Option 2 but, should OSHA decide to include it in a proposed rule, clarify what would constitute compliance with the provision. Some SERs were also concerned about the wording of the exposure assessment provision	In the NPRM, OSHA requested comment on the exposure assessment requirements for general industry and maritime. After carefully reviewing the comments received on this issue, the Agency significantly revised the requirements for initial exposure assessment and periodic exposure assessment in order to provide employers with the greater flexibility they had requested. The standard allows the employer to use either the performance option or the scheduled monitoring option for exposure assessments. OSHA also clarified that the performance option provides employers with flexibility in the methods used to assess employee exposures and provided examples of how employers can accurately characterize employee exposures using the performance option (see Exposure Assessment in the Summary and Explanation Section of the preamble, Section XV).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(General Industry) Some SERs were also concerned about the wording of the exposure assessment provision of the draft proposed standard. These SERs felt that the wording could be taken to mean that an employer needed to perform initial assessments annually. The Panel recommended that OSHA clarify this issue.	In the final rule, OSHA has clarified the regulatory text to ensure it does not suggest that employers must repeat initial assessments annually. OSHA has also provided employers with greater flexibility to use either the performance option or the scheduled monitoring option to meet their ongoing exposure assessment obligations (see Exposure Assessment in Section XV of the preamble).
(General Industry) The SER comments included several suggestions regarding the nature and wording of the health screening requirements. (See, e.g., OSHA, 2003, Document ID 0937, pp. 25-28.) The Panel recommended that OSHA consider revising the standard in light of these comments, as appropriate.	OSHA has considered these comments and revised the standard where appropriate. Revisions included naming this section of the rule medical surveillance; removing the symptom trigger for medical exams; removing the requirement for the medical and work history to be administered by a health care provider and adding smoking history as a requirement of histories; redefining the size of allowable X-ray films and limiting X-ray readings to only B Readers; defining who can offer medical exams as physicians or other licensed health care providers (PLHCPs); and decreasing the frequency for periodic examinations (see Medical Surveillance in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(General Industry) Though the provision for hazard communication simply repeats such provisions already in existence, some SERs urged OSHA to use this opportunity to change the requirement so that warning labels would only be required of substances that were more than 1% (rather than the current 0.1%) by weight of silica. The Panel recommended that OSHA consider this suggestion and solicit comment on it.	In the NPRM, OSHA requested comment on the requirement for warning labels. After carefully reviewing the comments received on this issue, the Agency has not included new requirements or specifications for warning labels in this standard. OSHA has structured the hazard communication requirements in the silica rule to be as consistent as possible with HCS to promote the harmonization of the classification and labelling of chemicals and avoid duplicative administrative burden on employers who must comply with both the HCS and this rule (see Communication of Respirable Crystalline Silica Hazards to Employees in Section XV of the preamble).
(General Industry) The Panel recommended that OSHA carefully review the recordkeeping requirements with respect to both their utility and burden.	In the NPRM, OSHA requested comment on the recordkeeping requirements. After carefully reviewing the comments received on this issue, the Agency retained the recordkeeping requirements in the rule (see Recordkeeping in Section XV of the preamble). OSHA has also reviewed the recordkeeping requirements as required by the Paperwork Reduction Act. Detailed analysis of the recordkeeping requirements can be found in OSHA's information collection request submitted to OMB.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) The Panel recommended that OSHA continue to evaluate the appropriateness of and consider modifications to scope Option 2 [the standard would apply whenever employees perform a list of activities that involve the application of certain forces to concrete, brick, block, mortar, rock, soil or other material containing crystalline silica, and to abrasive blasting operations where there is potential for exposure to crystalline silica] that can more readily serve to limit the scope of the standard.	OSHA retained Scope Option 1 [the rule would apply wherever there is occupational exposure to airborne respirable crystalline silica in construction workplaces], but revised the provision to exempt situations in which employee exposure will remain below 25 μg/m^3 as an 8-hour time-weighted average under any foreseeable conditions. (see Scope in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) Many SERs found the requirements for a competent person hard to understand. Many SERs took the competent person requirement as requiring a person with a high level of skills, such as the ability to conduct monitoring. Other SERs said this requirement would require training a high percentage of their employees as competent persons because they typically had many very small crews at many sites. In general, the SERs thought this requirement as written would be difficult to comply with and costly. The Panel recommended that OSHA seek ways to clarify OSHA's intent with respect to this requirement and more clearly delineate the responsibilities of competent persons.	OSHA clarified the role and responsibilities of the competent person in the construction standard. In paragraph (b) of the construction standard for respirable crystalline silica, OSHA defines competent person as an individual who is capable of identifying existing and foreseeable respirable crystalline silica hazards in the workplace and who has authorization to take prompt corrective measures to eliminate or minimize them. The definition also specifies that the competent person have the knowledge and ability necessary to fulfill the responsibilities set forth in paragraph (g). In paragraph (g)(4) of the construction standard, the employer is required to designate a competent person to make frequent and regular inspections of job sites, materials, and equipment to implement the written exposure control plan. None of these provisions require the competent person to have the ability to conduct air monitoring (see <u>Definitions</u> and <u>Written Exposure Control Plan</u> in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) Many SERs did not understand that Table 1 was offered as an alternative to exposure assessment and demonstration that the PEL is being met. Some SERs, however, understood the approach and felt that it had merit. These SERs raised several issues concerning the use of Table 1, including: • The Table should be expanded to include all construction activities covered by the standard, or the scope of the standard should be reduced to only those activities covered by Table 1; • The control measures endorsed in Table 1 need to be better established, as necessary; and • Table 1 should require less use of, and possibly no use of, respirators. The Panel recommended that OSHA carefully consider these suggestions, expand Table 1, and make other modifications, as appropriate.	In the NPRM, OSHA requested comment on the approach for construction. After carefully reviewing the comments received on this issue, the Agency significantly revised the structure of the construction rule to focus on the tasks known to generate high exposures to respirable crystalline silica. Where employers fully and properly implement the specified engineering controls, work practices, and respiratory protection for each employee engaged in a task identified in Table 1, the employer is not required to also conduct exposure assessments to determine compliance with the PEL. The Agency also revised the notes and specifications in Table 1 to clarify what is required for employers to fully and properly implement the engineering controls, work practices, and respiratory protection for tasks in Table 1 (see Specified Exposure Control Methods in Section XV of the preamble). The clear and specific guidance in Table 1, along with the opportunity Table 1 provides for employers to avoid monitoring costs, will make compliance easier and less expensive. After carefully reviewing the comments received on respiratory protection requirements for the construction standard and the exposure data in the record (described in Chapter IV of this FEA), OSHA identified those situations where respiratory protection is necessary and made significant revisions to the respiratory protection requirements specified in Table 1 based on those findings. The result is that respiratory protection is not required for most of the tasks covered by Table 1 (see Specified Exposure Control Methods in Section XV of the preamble).

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
The Panel recommends that OSHA thoroughly review the economic impacts of compliance with a proposed silica standard and develop more detailed feasibility analyses where appropriate.	OSHA significantly expanded its economic impact and economic feasibility analyses in Chapter VI of the PEA. As part of that impact analysis, OSHA added data on normal year-to-year variations in prices and profit rates in affected industries to provide a context for evaluating potential price and profit impacts of the proposed rule. Sections were also added to estimate the potential international trade impacts and macroeconomic impacts of the proposed rule. OSHA invited comment in the PEA on the issues of the economic impacts and the economic feasibility of the proposed rule. Chapter VI in this FEA discusses comments on economic impacts, OSHA's response to those comments, and the Agency's final analysis of economic impacts and regulatory flexibility.
(Construction) The panel recommends that OSHA re-examine its cost estimates for respirators to make sure that the full cost of putting employees in respirators is considered.	For the PEA, OSHA re-examined and updated its cost estimates for each type of respirator. Unit respirator costs included the cost of the respirator itself and the annualized cost of respirator use, to include accessories (e.g., filters), training, fit testing, and cleaning. In addition, OSHA added a cost for employers to establish a respirator program. For this FEA, all costs have been updated to 2012 dollars. OSHA solicited comment on this issue in the PEA; in this FEA, OSHA's final estimate of costs for respiratory protection (see Chapter V) conveys the Agency's response to public comment.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(Construction) Some SERs indicated that the unit costs were underestimated for monitoring, similar to the general industry issues raised previously. In addition, special issues for construction were raised (i.e., unpredictability of exposures), suggesting the rule would be costly, if not impossible to comply with. The Panel recommends that OSHA carefully review the basis for its estimated compliance costs, consider the concerns raised by the SERs, and ensure that its estimates are revised, as appropriate, to fully reflect the costs likely to be incurred by potentially affected establishments.	To reflect the fact that an industrial hygienist could not typically take as many samples a day in a small establishment as in a large one, OSHA developed cost estimates for exposure monitoring as a function of the size of the establishment. OSHA's cost estimates therefore now reflect the fact that smaller entities will tend to experience larger unit costs for exposure monitoring. To address concerns about unpredictability of exposure in construction, as well as to provide more specific guidance to employers, OSHA designed Table 1 in the final standard to allow establishments in construction the option, for many common tasks, to implement engineering controls, work practices, and respiratory protection without the need for exposure assessment. OSHA has carefully reviewed the basis for its exposure monitoring cost estimates and considered the concerns raised by the SERs. OSHA solicited comments on this issue in the PEA, and in Chapter V of this FEA the final analysis of costs for exposure monitoring reflects the Agency's response to public comment.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
(General Industry) The Panel recommends that OSHA use the best scientific evidence and methods available to determine the significance of risks and magnitude of benefits for occupational exposure to silica. The Panel further recommends that OSHA evaluate existing state silicosis surveillance data to determine whether there are industry-specific differences in silicosis risks, and whether or how the draft standard should be revised to reflect such differences.	OSHA has conducted a comprehensive review of the scientific evidence from toxicological and epidemiological studies on adverse health effects and baseline estimates of the risks of developing silica-related diseases associated with occupational exposure to respirable crystalline silica. This review is summarized in Section V of the preamble, Health Effects and Quantitative Risk Assessment. The significance of these risks is examined in Section VI, Significance of Risk. The benefits associated with the final rule are summarized in Chapter VII of this FEA. Although OSHA's final analysis indicates that a variety of factors may affect the toxicological potency of crystalline silica found in different work environments, OSHA has not identified information that would allow the Agency to calculate how these influences may affect disease risk to workers in any particular workplace setting.

Table IX-5: SBAR Panel Recommendations and OSHA Responses (continued)	
SBAR Panel Recommendation	**OSHA Response**
The SERs, however, also had many specific issues concerning what OSHA should do if it chooses to go forward with a proposed rule. In order to reflect these specific issues, the Panel has made many recommendations concerning issues to be considered if the Agency goes forward with a rule. The Panel also recommends that OSHA take great care in reviewing and considering all comments made by the SERs.	OSHA has carefully considered the Panel recommendations, and the Agency's responses are listed in this table. In addition, specific issues raised in comments by individual SERs are addressed throughout the preamble.

Chapter X: Environmental Impacts

INTRODUCTION

OSHA has reviewed the final rule according to the National Environmental Policy Act (NEPA) of 1969 (42 U.S.C. 4321 *et seq*.), the regulations of the Council on Environmental Quality (40 CFR part 1500 *et seq.*), and the Department of Labor's NEPA procedures (29 CFR part 11). The Agency has determined that the final rule will have no significant impact on air, water, or soil quality; plant or animal life; the use of land; or other aspects of the external environment. Therefore, OSHA concludes that the final standard will have no significant environmental impacts. This conclusion reaffirms the conclusions set forth in the Preliminary Economic Analysis (PEA).

To reach this conclusion, OSHA examined comments received about the potential environmental impacts posed by the final rule. Comments addressed two main issues: (1) potential water runoff from construction tasks; and (2) costs associated with federal, state, and local environmental permits employers could be required to obtain as a result of the final rule. There were no specific comments regarding soil quality, plant or animal life, or land use. This section first lays out OSHA's preliminary conclusions regarding environmental impacts and then shows why the best available evidence in the rulemaking record reaffirms those conclusions.

SBREFA AND CONCLUSIONS CONTAINED IN THE PEA

Pursuant to the recommendations from the Small Business Advocacy Review Panel, the Agency investigated potential environmental impacts and articulated its findings in the PEA. As noted in the SBREFA report (OSHA-H006A-2006-0800-0025, p. 77), the Panel requested that OSHA clarify how its silica rulemaking was related to designating silica-containing materials as hazardous wastes. In the PEA, OSHA explained that it did not believe silica wastes are classified as hazardous wastes for purposes of the Environmental Protection Agency (EPA) (Document ID 1720, p. IX-68). And the contents of OSHA's final rule on silica have no direct bearing on whether silica waste is classified as hazardous for EPA purposes.

In addition, some Small Entity Representatives (SERs) raised the possibility that the use of wet methods to limit silica exposures in some areas could violate EPA rules with respect to suspended solids in runoff unless provisions are made for recycling or settling the suspended solids out of the water. The SBAR Panel recommended that OSHA investigate this issue, add appropriate costs if necessary, and solicit comment. In response, the Agency identified six construction tasks where wet methods were utilized and found negligible costs related to controlling excess water because the amount of water used to control silica dust was minimal and typically did not produce runoff. OSHA's estimate of the potential environmental impact of each of these six equipment types was summarized in the PEA as follows:

- Stationary masonry saws: Most stationary saws come equipped with a water basin that typically holds several gallons of water and a pump for recycling water for wet cutting. The water is recirculated and, thus, not continually discharged. When emptied, the amount of water is not sufficient to produce a runoff.

- Hand-held masonry saws: Large quantities of water typically are not required in order to control dust. With these saws, water is supplied from a small capacity water tank. Any slurry residue after cutting could be dealt with by sweeping or vacuuming.

- Walk-behind and other large concrete saws: Larger concrete saws are equipped with a tank to supply water to the blade while cutting. These saws leave a slurry residue, but do not require so much water as to create a runoff.

- Walk-behind concrete grinders and millers: Some tools are equipped with a water-feed system. In these, a water line from a tank, a garden hose, or other water supply leads to the grinding head and delivers water to spray or flood the cutting tool and/or the work surface. When an automatic water feed is not available, a helper can apply water directly to the cutting surface. While such wet methods might generate enough water to create a runoff, these grinding and milling activities are typically done during the finishing stages of structure construction (e.g., parking garages) and are often performed inside the structure. Thus, direct discharges to storm drains or surface waters are unlikely.

- Asphalt millers for pavement resurfacing: A typical asphalt milling machine has a built-in reservoir from which water is applied to the cutting drum. The amount of water used, however, is insufficient to produce a runoff.

- Impact drillers/pavement breakers: Water for dust suppression can be applied manually or by using a semi-automated water-feed device. In the simplest method for suppressing dust, a dedicated helper directs a constant spray of mist at the impact point while another worker operates the jackhammer. The helper can use a hose with a garden-style spray nozzle to maintain a steady and carefully directed mist at the impact point where material is broken and crushed. Jackhammers retrofitted with a focused water mist aimed at the tip of the blade offer a dramatic decrease in silica exposure. Although water-fed jackhammers are not

> commercially available, it is neither expensive nor difficult to retrofit equipment. Studies suggest that a water flow rate of 1/8 to 1/4 gallon per minute is best for silica dust control. At this rate, about 7.5 to 15 gallons of water per hour would be applied to (i.e., sprayed on) the work area. It is unclear whether this quantity of water applied to a moveable work area at a constant rate would produce a runoff. If the work were in sufficient proximity to a storm drain or surface water, the contractor might need to use a simple barrier to prevent the water from entering the drain, or otherwise filter it. Because the volume of water is relatively small, the costs for such barriers are likely insubstantial and would typically overlap with the contractor's existing obligations for a site-control plan to prevent unwanted runoff from other causes.

In the PEA, OSHA found that employers typically have pre-existing obligations to limit runoff of solid waste, such as from rainfall, into storm drains. The Agency preliminarily concluded that: (1) the use of wet methods for certain construction tasks would not cause significant environmental problems from water runoff; and (2) employers should be able to comply with non-OSHA environmental regulations because runoff from wet methods can be easily controlled. As explained below, in light of the best available evidence contained in the record, OSHA reaffirms its preliminary conclusions.

Potential Water Runoff from Construction Tasks

While the Agency did not receive any comments directly addressing the PEA's discussion of environmental impacts, it did receive several comments on the water runoff issue. Most of the concerns expressed related to construction work, although a few comments came from entities in general industry. The construction and general industry commenters that addressed the issue of water runoff from the use of wet methods to comply with the final PEL included James Hardie Building Products, Inc.; the Unified Abrasives Manufacturers' Association; American Road & Transportation Builders Association; the General Contractors Association of New York; the Masonry & Concrete Saw Manufacturers Institute; and the Fertilizer Institute. None of the commenters to raise this issue provided any evidence to establish that runoff created by wet methods would actually create a problem (Document ID 2322, Attachment A, p. 174; 2243, p. 2; 2245, p. 4; 2314, p. 2; 2316, Attachment 1, pp. 2-3; 2101, pp. 6-7 and 11-12). For example, one commenter, the Construction Industry Safety Coalition, advanced a theoretical argument that wet methods would either: (a) require "tremendous" amounts of water; or (b) fail to effectively control silica. It stated:

> For employers using wet methods, even attempting to meet this "no visible dust" standard will require a tremendous amount of water - many studies discussed in the technological feasibility analysis certainly support this

> notion. Such large amounts of water run counter to OSHA's contractor's assessment that "minimal" water should be used to avoid environmental contamination issues. The Agency contends that construction employers can mitigate any environmental concerns by utilizing as little water as possible to prevent accumulations from occurring or potentially damaging residential or commercial buildings. Even if utilizing only a little water will effectively reduce exposures to below the proposed PEL, the CISC has significant concerns that it will prevent *all* visible dust from being emitted (Document ID 2320, Attachment 1, pp. 9-10).

In light of the discussion set forth in Chapter VI of this FEA, Technological Feasibility, and evidence in the record, OSHA's preliminary findings regarding water runoff are affirmed. The Agency concludes that the comments it received expressing concerns about the runoff issue are unsubstantiated and theoretical and do not provide a sufficient justification for OSHA to alter its preliminary conclusions. As discussed in the Technological Feasibility section, OSHA finds that appropriate wet methods will typically require only limited application of water, possibly as little as a mist. In such conditions, the water will evaporate before collecting into a body of water. Where a greater water flow is necessary to suppress airborne silica, the runoff, rather than forming a free-flowing stream, will typically consolidate into slurry. In addition, because employers want to keep nearby structures and materials dry, they will typically use as little water as necessary.

OSHA finds support for these findings in the hearing testimony compilation assembled by the Building and Construction Trades Department. That evidence demonstrates the practical reality that water runoff from construction tasks is insignificant (Document ID 4223, pp. 28-30). Indeed, Deven Johnson, of the Operative Plasterers' and Cement Masons' International Association, stated that in her years of experience in using wet methods to control relatively dusty situations involving demolition, she had never had a problem with runoff-related issues. She indicated that runoff tends to create a slurry, which is easily vacuumed up (Document ID 3581, pp. 1695-1696). Gary Fore, a consultant and former Vice President for the American National Asphalt Pavement Association, likewise said that runoff was never a problem. He confirmed the PEA's preliminary conclusion for asphalt milling operations. While there may be a substantial amount of water used in the course of a day, it is applied as an aerosol. Further, although the pavement surface may be temporarily moist, it does not produce runoff from the construction site (Document ID 3583, p. 2209). Finally, Donald Hulk, Safety Director for Manafort, a construction contractor, testified that contrary to hypothetical assertions about potential runoff issues, his company did not find managing potential runoff from wet methods to be a problem. His reasoning confirmed the PEA's finding that the amount of water required for typical silica-containing dust suppression will not create substantial runoff. Moreover, he testified that in the case of demolition related to roadway construction, excess water is typically absorbed into demolition debris or evaporates—which is aided by the fact that most construction activity occurs during the warmer parts of the year (Document ID 3583, Tr. 2384-2385).

Certain industries voiced water runoff concerns specific to their workplaces. For example, the fertilizer industry stated its apprehension about OSHA's "preference" for wet methods to control silica exposure and indicated that such methods would be potentially problematic from an environmental standpoint at its facilities (Document ID 2101, pp. 6-7 and11-12). OSHA finds the fertilizer industry's concern misplaced because the final standard does not require the use of wet methods in general industry. Additionally, as discussed in Chapter III, the Agency estimates that exposures to respirable crystalline silica in the fertilizer industry are sufficiently low that most fertilizer-related manufacturing industries will not be affected by the final standard; the mixing-only fertilizer industry, NAICS 325314, was the only one judged to be affected.

The coal-fired electric industry also raised the issue of water runoff in its industry. The Edison Electric Institute and Alabama Power Company indicated a potential for conflict between an EPA rulemaking regarding ash ponds at the site of coal-fired electric utilities and this rulemaking (Document ID 2357, pp. 28-29; 2185, Attachment 1, p. 11). OSHA considered this concern, but has concluded that this will not be a problem in practice. The commenters never explained how the wet methods that might be required in Table 1 for construction activities (e.g., cutting concrete for transmission and distribution) would result in water flowing into fly ash ponds. In any event, the Agency has found that the proper use of wet methods will not result in significant runoff issues for any of the industries covered by the standard.[1]

Air Quality/Permit Concerns

Regulations that will reduce the atmospheric concentration of respirable crystalline silica in the air within industrial and other facilities and workplaces have the potential to affect, either positively or negatively, the amount of respirable crystalline silica emitted by these sources into the ambient (external) environment. In most cases, the change will be small. As discussed in Chapter 5 most ventilation is needed to reach the preceding PEL rather than the new PEL. The extent to which the reduction in the PEL – and, hence, occupational exposures – under the OSHA standard will impact air quality depends on how employers handle the increased volume of respirable crystalline silica captured by the relevant control technologies. Taking into account the measures employers are already using to comply with the existing silica PEL, and the fact that the baghouses

[1] Alabama Power also referred to problems with environmental permits, but did not specify to which environmental permits they were referring. Permit issues are addressed later in this section.

employers are already using capture at least 99 percent of silica emissions (Document ID 3641, p. VII-19), OSHA concludes that the final rule will not have a significant impact on air quality

A number of commenters raised concerns that the final rule would create an onerous and cost-increasing administrative burden because it would necessitate obtaining EPA environmental permits, notably with regard to air quality regulations and related permits and process approvals at the state and local level. The concern was not an adverse environmental impact, per se, but rather the burden of complying with existing environmental rules in the context of the new OSHA standard (See, e.g., Document ID 2291, Attachment 1, p. 12; 2379, Appendix 1, p. 14; 2380, Attachment 2, p. 19; 2317, pp. 2-3). OSHA's response to these cost concerns is addressed in Chapter V in the section on general industry engineering control costs.

A prime concern voiced by the commenters was having to comply with OSHA compliance deadlines while simultaneously meeting deadlines under applicable air quality permitting regulations.

For example, the Asphalt Roofing Manufacturers Association (ARMA) raised the issue of EPA permits related to changes in ventilation systems.

> …the proposal appears to completely disregard environmental permitting requirements, which will present a significant time demand in almost every case because the standard will require increased dust collection, and releases to outside air will trigger air pollution limitations and permitting requirements for both State and or Federal agencies. Recent experience of ARMA members relating to implementation of the new National Ambient Air Quality Standards (NAAQS) for particulate matter (PM2.5) reveals that, even in the case of minor facility modifications which emit particulate matter, authorization to construct or modify a control device can take more than a year to obtain. Even longer permitting times will be experienced in cases requiring complex modeling of nearby sources, or State or Federal approval of modeling methods and protocol inputs. These factors could further delay the issuance of permits by an additional twelve months, assuming the facility is able to develop a passing model. If the model does not pass, further modeling and review by permitting agencies, or additional emissions abatement, may be required to obtain the permits, extending still further this step in the process (Document ID 2291, Attachment 1, p. 12).

As the Agency explains in the Summary & Explanation section of the preamble dealing with paragraph (j), dates, the final rule's effective and enforcement dates have been tailored to allow a sufficient period of time for employers to meet requirements for approval by other regulatory agencies. (A discussion of various state permitting times can be found in "Examples of State Environmental Agency Permit Turnaround Times," ERG, 2015). The Agency believes providing longer compliance deadlines should address the primary concerns expressed by commenters regarding the time necessary to obtain any required environmental permit approvals. Ultimately, as discussed in the Summary and Explanation, cases that are unusually problematic can be addressed through OSHA's enforcement discretion if the employer can show that it has made good faith efforts to implement engineering controls, but has been unable to implement such controls due to the time needed for environmental permitting.

Some industries raised permit concerns unique to their operations. The Association of American Railroads and American Short Line and Regional Railroad Association stated that it foresaw a need for a permit under the Clean Water Act if a ballast was sprayed with a chemical, which, through run off or by another means, reached a body of water (Document ID 2366, p. 7).

OSHA considers the railroad industry's concern about the threat of significant water contamination from chemical dust suppressant speculative because of the limited amount of water potentially used. Consequently, the Agency does not foresee a significant environmental impact. Additionally, no current OSHA standard governs the use of chemical dust suppressants. While some state or local governments may require a permit, it is not clear this would pose a new issue for the railroads, as OSHA believes it is likely that they already have to deal with such issues in the context of runoff from deicing chemicals, as well as oil and metal particles from normal operations. OSHA notes, however, that the analysis in the railroad section of Chapter IV of this FEA, Technological Feasibility, discusses chemical suppressants merely as a possibility for reducing exposures, but it is not ultimately identified as necessary to enable employers in the industry to meet the PEL of 50 $\mu g/m^3$. Accordingly, the FEA's cost analysis for the railroad industry does not include chemical suppressants, but assumes the industry will use wet methods to reduce exposures, and estimates the costs accordingly. To the extent chemical dust suppressants are more cost-effective than water, the FEA has overestimated the cost to the industry. And to the extent suppressants pose an environmental air quality permitting issue, OSHA notes that suppressants are not required under the final rule and is not including relevant permitting costs in its analysis.

The Shipbuilders Council of America (SCA) stated that if the final silica rule altered blasting technologies and/or facility equipment, the data currently used for shipyard permits in certain states (e.g. state air and water permits) would be invalid, necessitating permit and plan updates and creating additional costs for the industry (Document ID 2255, p. 2). The final rule does not specify engineering control changes in this area; nor does the Agency believe the lower PEL will require a change in engineering controls for abrasive blasting, relative to current standards. As laid out in Chapter V in this FEA, employers complying with the hierarchy of controls under the existing silica PEL and ventilation standards will already be using engineering controls to limit exposures. OSHA has found that the only additional feasible engineering controls employers in shipyards can implement to reduce exposures is the use of HEPA vacuums (in lieu of dry sweeping). Implementation of this control will reduce potential environmental problems because the use of HEPA vacuums raises less dust than dry sweeping.

Positive Environmental Effects

Based on its review of the record, OSHA concludes that the final rule will potentially have a positive environmental impact. At least one industry commenter, in the context of the hydraulic fracturing industry, suggested that its technology, the adoption of which would presumably be hastened by the promulgation and enforcement of the final rule, would reduce potential environmental impacts (Document ID 3589, Tr. 4140). In a similar vein, as discussed in both Chapters IV and V of this FEA, the final standard actually helps construction employers' reduce fugitive and co-generated dust, aiding in their compliance with environmental standards related to the dust. (The issue of controlling fugitive dust overlaps with the issue of existing employer obligations to minimize the runoff of solid waste into public water, discussed previously in this chapter, as well as the general expectation that employers clean up their work sites after their work is completed, as discussed in Chapter V).

CONCLUSION

As a result of this review, OSHA has reaffirmed its conclusions in the PEA, that the silica final rule will have no significant impact on air, water, or soil quality; plant or animal life; the use of land; or aspects of the external environment. It finds that the final standard is in compliance with NEPA and will have no significant environmental impact.
